T lymphocytes require a foreign antigen to be presented on a cell surface in association with a self-transplantation antigen before they can recognize it effectively. This phenomenon is known as major histocompatibility complex (MHC) restriction[1]. It is not clear how an incalculably large number of foreign proteins form unique complexes with a very limited number of MHC molecules. We studied the recognition properties of T cells specific for a peptide derived from bacteriophage λ cI protein. Analogues of this peptide, as well as peptides derived from other unrelated antigens which can be presented in the context of the same MHC molecule, can competitively inhibit activation of these T cells by the cI peptide. Furthermore, these unrelated antigens can stimulate cI-specific T cells if certain specific amino-acid residues are replaced. Here we suggest a model in which all antigens give rise to peptides that can bind to the same site on the MHC molecule. T-cell recognition of this site (which is presumed to be polymorphic) with or without antigen bound can explain self-selection in the thymus and MHC restriction.

We immunized BALB/c mice with the 102 amino-acid N-terminal domain of bacteriophage λ cI protein (cI) and produced cI-specific, class II-restricted T-cell hybridomas More than 75% of specific hybridomas could be stimulated by a peptide comprised of residues 12-26 (P12-26) in the context of 1-A^d Independently isolated T cells could be divided into at least three groups on the basis of their reactivity to truncated analogues of P12-26 (Fig 1) Following Rock and Benacerraf[2] and others[3], who showed competition for presentation between related antigens, we examined whether inactive truncated analogues could inhibit activation of T cells stimulated with the parent peptide or active truncated analogues In the case of the hybridoma 7B7 3, P12-24 can inhibit activation by P15-26, but not in the case of hybridoma 9H35 (see Fig 2*a*) Failure to obtain competition has also been noted in other systems[1,4], suggesting that competition depends on the T cell involved It may well be that the active peptide and the analogues compete for binding to the same site on I-A (ref 5) but the T cell enhances the avidity of the active peptide for I-A so that competition cannot be seen This hypothesis agrees with recent findings from several laboratories[6,7] To test the hypothesis that other antigens which can be presented in the context of 1-A^d inhibit cI peptide stimulation, we screened 14 overlapping peptides derived from

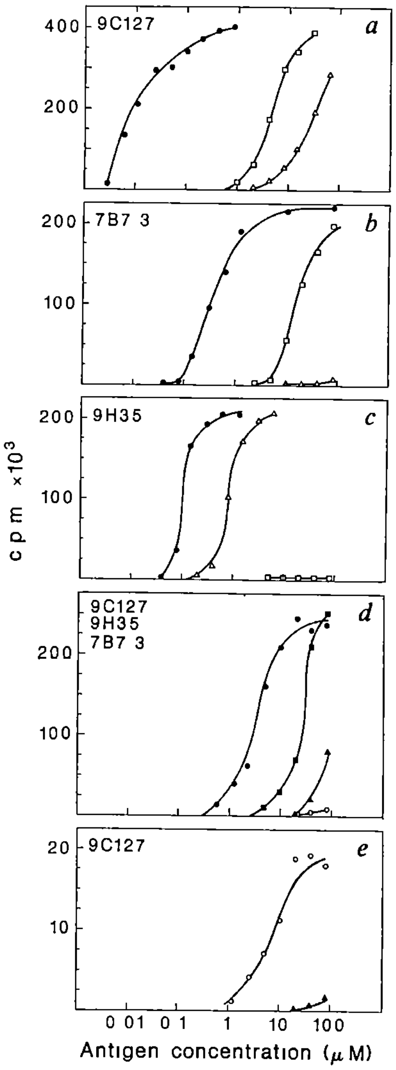

Fig. 1 *a–c*, Response of cI-specific T-cell hybridomas to various peptides derived from bacteriophage cI protein. Activity was measured with P12-26 (residues 12-26) (●), P15-26 (residues 15-26 (□) and P12-24 (residues 12-24) (△) as measured by IL-2 production. *a*, Hybridoma 9C127, *b*, hybridoma 7Bn,3, *c*, hybridoma 9H35. Values are the arithmetic mean of triplicate samples. *d*, *e* The stimulation of cI-specific T cells by analogues of peptides derived from *S aureus* nuclease and chicken ovalbumin. *d*, Hybridomas 9C127 (●), 9H35 (▲) and 7B7 3 (■) were incubated in the presence of [Lys 73, Ile 75] Nase I (see Fig 3) at the concentration indicated and activation was measured by IL-2 release as described below. The activity in the presence of Nase I (see Fig 3) for all the T-cell hybridomas is also shown (○). *e*, Hybridoma 9C127 was incubated in the presence of [Lys 331, Ile 333, Lys 336] Ova I (○) (see Fig 3) and Ova I (▲) (see Fig 3), as described above.

Methods. The T-cell hybridomas were derived from BALB/c mice immunized with bacteriophage λ repressor cI protein N-terminal fragment (residues 1-102), as described[4]. Those T cells reacting to a synthetic peptide (residues 12-26) were selected. The complete sequence of λ repressor cI protein is reported by Sauer and Anderegg[13]. All peptides used in this letter were made by the solid phase method of Merrifield[14] using an automated Applied Biosystems 430A peptide synthesizer. The peptides were desalted on a G-25 column (2.5×90 cm) equilibrated with 4 M glacial acetic acid and then lyophilized twice after resuspension in distilled water. 5×10^4 A20 antigen presenting cells were incubated in 200 µl in 96-well Costar plates with 5×10^4 hybridoma T cells at the indicated concentration of peptide. After 24 h of culture, supernatant (50 µl) was harvested and assayed for IL-2 concentration by the following incorporation of ^{3}H-thymidine into the IL-2 dependent CTL-L cell line (10^4 cells per well). Twenty-four hours after culture of T-cell supernatant in the presence of CTL-L cells, 1 µCi of ^{3}H-thymidine was added per well. Six hours later the cells were harvested by an automated cell harvester (Skatron Inc.) and thymidine incorporation was measured by scintillation counting.

the antigen *Staphylococcus aureus* nuclease (Nase)[8]. One peptide (residues 61-80) was a potent inhibitor of all three cI-specific T cells tested (Fig 2*b*). Note that the stimulating analogue showing the lowest apparent avidity was used for each T cell respectively (see Fig 2, legend) to allow observation of inhibition.

If the inhibition observed with the Nase peptide is biologically relevant, that is, if its ability to bind to a specific site on the I-A molecule is related to its ability to be presented, then Nase peptide P61-80 should also be the target peptide for Nase reactivity in the H-2^d mouse. This is indeed the case[8]. As a control, the Nase peptide P81-100 is the target peptide for activation in the context of I-E^k and does not act as an inhibitor in this system[8]. Examination of the sequence of residues of 61-80 revealed that residues 66-78 (Nase I) were remarkably similar to the cI peptide P12-24 (Fig 3). There are only two residues (positions 73 and 75) that differ significantly, all other changes are conservative. If Nase I binds to exactly the same site as P12-24 and if the structures of the bound peptides are the same, we reasoned that replacement of the residues at positions 73 and 75 of Nase I with the residues found in the equivalent positions on P12-24 might produce a peptide able to stimulate the cI-specific T cells. This is indeed the case (Fig 1*d*). Both peptides are equally active for the T cell 9C127, but the T cell 9H35 requires ~100-fold higher concentration of the Nase analogue. Surprisingly, the peptide [Lys 73, Ile 75] Nase I stimulates the T cell 7B7 3, whereas the cI derived peptide (the immunogen analogue) P12-24 does not. The unmodified Nase peptide does not stimulate any cI-specific T cells.

This suggested to us that all peptides restricted by I-A^d might bind to exactly the same site on I-A and act as inhibitors of cI-specific T cell activation. The peptide derived from ovalbumin, residues 324-336 (Ova I) is I-A^d restricted, and its behaviour has been well characterized[4,9]. As shown in Fig 2*c*, this peptide inhibits all cI-specific T cells tested. However, this peptide has little obvious similarity to P12-24 (Fig 3). We have shown independently[10] that P12-26 competes with Ova P323-339 for binding to the I-A molecule. We assume that Ova I is capable of forming a structure very similar to P12-24 either in solution or, more likely, once bound to the I-A molecule. If we assume that both peptides bind to the same site on I-A and that the structural requirements for T-cell activation are the same for all antigens, then we should be able to make Ova I activate cI-specific T cells by replacing a few critical residues on the Ova I peptide. Watts *et al.*[9] have shown that the histidine residue (boxed in Fig 3) is a critical 'epitope' for Ova-specific T-cell activation. Using this residue to align Ova I with P12-24, we made the peptide [Lys 331, Ile 333, Lys 336] Ova I (see Fig 3). This peptide can stimulate the cI-specific T-cell hybridoma 9C127 (Fig 1*e*), which has the highest affinity for 12-24. The concentration of the Ova analogue peptide required to give half-maximal stimulation of 9C127 is the same as P12-24. This probably reflects its intrinsic affinity for I-A (also as measured in the inhibition assay). The maximal level of stimulation for the 9C127 T cell is 15-20% of that seen with P12-24, this probably reflects a weak affinity of the T cell for the bound antigen. It is plausible that maximal T-cell stimulation requires

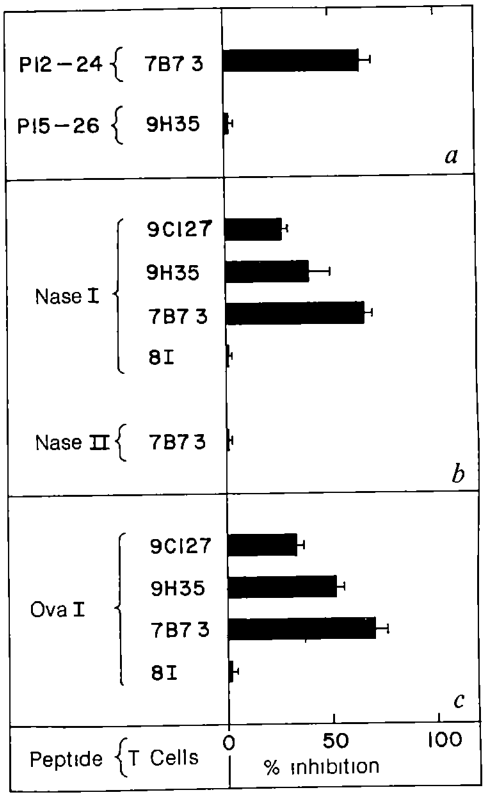

Fig. 2 Inhibition of T-cell activation by various peptides The extent of inhibition was analysed by comparing the amount of IL-2 production in the presence of a fixed concentration of inhibitor and varying the amount of stimulating peptide over a 50-fold range Inhibition was clearly competitive in that the extent of inhibition seen was greatest at high ratios of inhibitor to activator and least when the ratios were reversed For simplicity, we present here the inhibition data obtained at a concentration of stimulator which gives 50% of maximal stimulation, the inhibitor concentrations are given below *a*, The activity of T-cell hybridoma 7B7 3 was measured in the presence of P15-26 (20 μM) alone as described in the legend to Fig 1 or in the presence of both P15-26 (20 μM) and P12-24 (40 μM) The response of T-cell hybridoma 9H35 was measured in the presence of P12-24 (1 μM) alone or in combination with P15-26 (60 μM) The difference in activity seen when two peptides were included in assay cultures compared to the activity seen when stimulator peptide alone was given is presented as the per cent inhibition *b*, The activity of the T-cell hybridoma 9C127 was measured in the presence of P12-24 (20 μM) alone, as described in Fig 1 (legend) or in the presence of both P12-24 (20 μM) and a synthetic peptide (residues 61-80) derived from the protein *S aureus* nuclease (Nase I) (60 μM) The response of the hybridoma 9H35 was measured in the presence of P12-24 (1 μM) alone or in combination with Nase I (60 μM) The response of the hybridoma 7B7 3 was measured in the presence of P15-26 (20 μM) alone or in combination with Nase I (60 μM) or Nase II (residues 81-100) (100 μM) The activity of T-cell hybridoma 8I was measured in the presence of P15-26 (0 25 μM) alone or in combination with Nase I (60 μM) T-cell hybridoma 8I was derived from immune A/J mice and recognized P15-26 in the context of I-E^k Accordingly the cell line TA3 was used for antigen presentation *c*, The same conditions as *b*, except Ova I (25 μM) was used as an inhibitor

Fig. 3 The wild-type sequence of bacteriophage λ repressor protein residues 12-24 (P12-24), is shown Nase I represents residues 66-78 from *S aureus* nuclease and Ova I represents residues 324-336 from chicken ovalbumin The residues in boxes indicate the locations where modifications to the parent peptides were made All peptides and their analogues were synthesized and purified as described in Fig 1 The peptide [Lys 73, Ile 75] Nase I has the amino-acid sequence of Nase I, except that the residues at positions 73 and 75 were replaced by the residues present at the boxed positions of P12-24 The peptide [Lys 331, Ile 333, Lys 336] Ova I has the amino-acid sequence of Ova I, except that the residues at positions 331, 333 and 336 were replaced by the residues at the boxed positions of P12-24

more than the two identical amino-acid contacts provided by the analogue

These results suggest that the class II transplantation antigen is a simple receptor containing a single binding site for peptides able to form similar general structures once bound The function of the transplantation antigen would be to position the antigen for T-cell binding uniquely It has been postulated that all T-cell antigens are peptides capable of forming amphipathic α helices[11], it is not likely that the peptide P12-26 described here will do so However, it is attractive to consider that a structure like an α helix or β sheet is the common structure that immunogenic peptides form either in solution, or, more likely, when bound to the transplantation antigen Given recent results[12], it is also reasonable to propose that similar models can be constructed for class I-restricted antigen presentation The 'docking' of the T-cell receptor onto the transplantation antigen which allows it to interact with the antigen uniquely requires an intrinsic affinity of the T-cell receptor for the area of the protein surrounding the peptide binding site This area is the same for all antigens presented on a given transplantation antigen molecule, and is presumably the site learned as 'self' in the thymus It follows that the binding site and its local area is the polymorphic region of the I-A molecule which imparts unique qualities to both the peptide binding site itself (controlling which amino-acid sequences bind best to the site) and the self recognition site(s) We envisage that the transplantation antigen has one peptide binding site The properties of the site (α helical-binding) would be imposed by the general structure of the transplantation antigen (class I or class II)

This model provides a framework for the construction of synthetic immune agonists and antagonists Further physical and chemical data are required to test these proposals

Identification of a common class of high affinity receptors for both types of porcine interleukin-1 on connective tissue cells

T. A. Bird & J. Saklatvala

Strangeways Research Laboratory, Worts Causeway,
Cambridge CB1 4RN, UK

Interleukin-1 (IL-1) is the name given to the polypeptides produced by activated mononuclear phagocytes which were originally defined as lymphocyte activating factors (LAF)[1]. Administration of IL-1 *in vivo* causes fever[2] and synthesis of acute phase proteins[3]. *In vitro* they have been shown to cause cartilage and bone resorption[4-7], and to stimulate fibroblasts and chondrocytes to make prostaglandins and latent collagenase[4,8]. IL-1 has therefore been proposed to be an important inflammatory mediator[9] and may be involved in the destruction of cartilage and bone that is a feature of rheumatoid arthritis and other inflammatory diseases of joints. We therefore looked for IL-1 receptors on connective tissue cells which might be targets for therapeutic intervention. Here we report the iodination, to high specific activity and with retention of full biological potency, of the two types of natural porcine IL-1. These ligands have been used to demonstrate high affinity dissociation constant ($\sim 10^{-10}$ M) specific binding sites on pig chondrocytes and synovial fibroblasts, human dermal fibroblasts and murine osteoblasts (3,000–5,000 sites per cell). Most interestingly, the two different Il-1 proteins show a similar affinity for a common class of receptors.

Two types of IL-1 have been isolated from culture supernatants of porcine mononuclear leucocytes stimulated with Concanavalin A. These are immunologically different proteins that have identical relative molecular masses (M_rs) of 21,000 (21K) on SDS polyacrylamide gel electrophoresis (PAGE) and have been characterized elsewhere[5]. One is acidic, having an isoelectric point (pI) of 5 (IL-1/5) and the other basic (pI of 8). These proteins are probably the porcine counterparts of the human IL-1α (which has a pI of 5) and the human IL-1β (which has a pI of 7 (ref. 10)) since an antiserum to porcine IL-1/5 cross reacts with human IL-1α and the N-terminal amino-acid sequence of porcine IL-1/8 shows 35% homology with that of human IL-1β (J.S., unpublished observations).

Attempts to label the different types of porcine IL-1 by direct oxidative methods proved unsuccessful, resulting in loss of biological activity. However, we were able to produce ^{125}I-labelled preparations of IL-1 which were fully active in a cartilage-resorption assay (Fig. 1*b*) using di-^{125}I-Bolton and Hunter reagent. The labelled proteins migrated as single bands upon SDS-PAGE, in positions expected for the native 21K proteins (Fig. 1*a*). The specific activity in each case was 470–580 Ci mmol^{-1}. ^{125}I-IL-1 could be stored at −20 °C for at least 6 weeks without loss of binding affinity. We initially studied the interaction of ^{125}I-IL-1/8 and ^{125}I-IL-1/5 with monolayers of pig synovial fibroblasts. Figure 2*a* shows the time course for specific (displaceable) binding of ^{125}I-IL-1/8 (2.4×10^{-10} M) to pig synovial fibroblasts at various temperatures. The rate of binding increased with increasing temperature, equilibrium was only attained after 6 h of incubation at 19 °C. To examine whether some ^{125}I-IL-1/8 was internalized at 37 °C parallel cultures were briefly exposed to an acidic glycine buffer[12] to remove surface-bound ligand. 85% of the radioactivity could be removed from monolayers incubated at 4 °C or 19 °C in this way but, as shown in Fig. 2*a*, a large proportion of the radioactivity bound at 37 °C rapidly became resistant to this treatment and was presumably internalized. The amount of acid-labile radioactivity bound at 37 °C reached a steady state within one hour, the fact that a

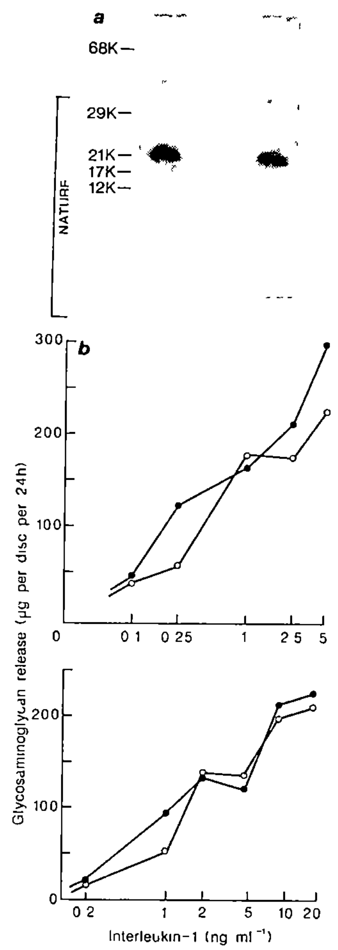

Fig. 1 *a*, Autoradiographs of ^{125}I-IL-1/8 (lane 1) and ^{125}I-IL-1/5 (lane 2) electrophoresed on 12.5% SDS-polyacrylamide slab gels in an ammediol buffer system[16] with reduction. The M_rs of Coomassie brilliant blue-stained standard proteins run in parallel are indicated in kilodaltons, *b*, comparison of ^{125}I-IL-1/5 (●, upper panel) and ^{125}I-IL-1/8 (●, lower panel) with the corresponding native interleukin 1 (○) in a cartilage resorption assay. Vertical axis, glycosaminoglycan release (µg per disc per 24 h), horizontal axis, concentration of IL-1 (ng ml^{-1}).

Methods. Purified IL-1s (2–4 µg estimated from A_{280}, assuming absorbance of a 1 mg ml^{-1} solution in a 1 cm lightpath to be unity) were iodinated by the method of Bolton and Hunter[17]. The interleukins, freeze-dried from aqueous solution, were dissolved in 20 µl 0.1 M borate buffer (pH 8.5) and added to 1 mCi *N*-succinimidyl 3-(4 hydroxy-3,5-[^{125}I] di-iodophenyl) propionate freshly dried from a solution in benzene. After agitation of the mixture on ice for 30 min the reaction was quenched by addition of 50 µl 1 M glycine in borate buffer. Iodinated proteins were separated from byproducts by gel filtration on Sephadex G-25 which was equilibrated and eluted with 0.05 M sodium phosphate buffer (pH 7.5) containing 0.25% (w/v) gelatin. Because ^{125}I-glycine and free ^{125}I-Bolton and Hunter reagent were quantitatively eluted from the column, residual radioactivity in the gel slurry was counted to estimate retained ^{125}I-IL-1. Recovery of labelled protein was typically 75%. After correcting for recovery, aliquots of labelled IL-1 were tested against unlabelled material for their ability to stimulate cartilage resorption[4]. Disks (2 mm) of bovine nasal cartilage were maintained in 96-well microtitre plates in 150 µl of Dulbecco's modified Eagles Medium (DMEM) containing 5% (v/v) bovine serum and test samples for 24 h at 37 °C in CO_2/air (1:19). Chondroitin sulphate released into the medium was measured using the metachromic dye dimethyl methylene blue. Each point represents the mean of four disks. Release of chondroitin sulphate in the absence of interleukin 1 was less than 30 µg per disk. Note that the different dose/response relationships in Fig. 1*b* arise from the fact that different batches of cartilage were used for each assay. When the two types of IL-1 are tested on the same batch of cartilage, they have the same specific bioactivity[5].

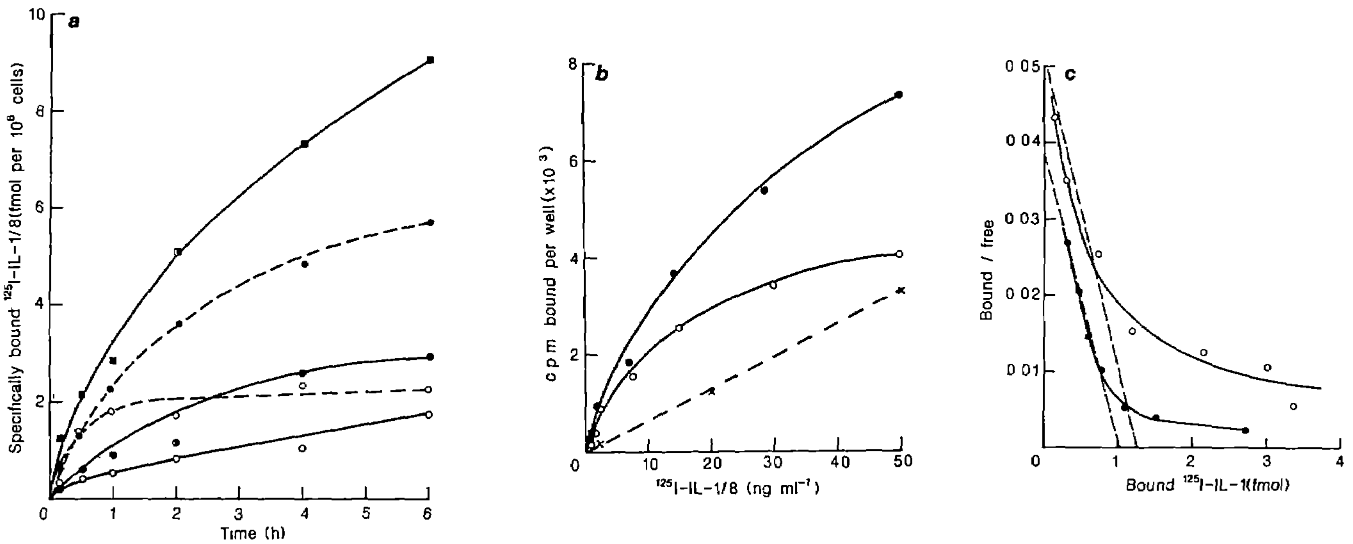

Fig 2 *a*, Time course of ^{125}I-IL-1/8 binding to porcine synovial fibroblasts (PSF) at various temperatures, and internalization of ligand at 37 °C ■—■, binding at 37 °C, ●—●, binding at 19 °C, ○—○, binding at 4 °C, ○---○, acid-labile radioactivity, ●---●, residual, SDS soluble radioactivity, *b*, saturable binding of ^{125}I-IL-1/8 to PSF incubated for 4 h at 19 °C, ●, total binding, ○, specific binding, ×, nonspecific binding *c*, Scatchard analysis of ^{125}I-IL-1/5 (●) and ^{125}I-IL-1/8 (○) to PSF at 19 °C

Methods. *a*, *Monolayers of PSF, isolated from metacarpophalangeal joints of freshly-killed young pigs by enzymatic dissagregation*[18] were maintained in DMEM plus 10% (v/v) heat-inactivated fetal calf serum until required Newly confluent monolayers ($1\ 2\times10^5$ cells) in 4 cm^2 plastic wells were washed twice with Hank's balanced salts solution supplemented with 0 1% BSA and 20 mM HEPES *p*H 7 4 (binding buffer), then incubated on a rotatory platform (70 cycles min^{-1}) *for the indicated times at* 4 °C, 19 °C or 37 °C with 400 µl per well binding buffer containing $2\ 4\times10^{-10}$ M ^{125}I-IL-1/8 Monolayers were then rinsed with 3 changes of ice cold binding buffer (1 ml), solubilized with 0 5 ml 1% SDS and counted in a gamma counter In some cases, monolayers incubated with ^{125}I-IL-1 at 37 °C were rinsed with binding buffer and kept on ice for 15 min in 1 ml of 50 mm glycine/150 mM NaCl *pH* 3 0 *before solubilization in* 1% SDS The acid-labile radioactivity and residual, SDS soluble radioactivity were counted separately Each point is the mean of three determinations from which nonspecific binding (measured in the presence of 5×10^{-8} M partially purified IL-1) has been subtracted Conditions in *b* and *c* were the same with varying ^{125}I-IL-1/8 *concentrations at* 19 °C *for* 4 h Each *point is calculated from the average values of four determinations Straight lines were fitted,* where appropriate, by the method of least squares

pool of surface-bound ligand was maintained despite the appearance of radioactivity in an intracellular compartment suggests receptor recycling such as that described for the LDL receptor[13] For subsequent studies, cells were incubated with labelled IL-1 at 19 °C for 4 hours Figure 2*b* shows that binding of ^{125}I-IL-1/8 to pig synovial fibroblasts at 19 °C was saturable, with half maximal binding occurring at 4×10^{-10} M (9 ng ml^{-1}), nonspecific binding was 10–30% of total binding Similar data were obtained using ^{125}I-IL-1/5 Scatchard analysis of binding to pig synovial fibroblasts (Fig 2*c*) gave curvilinear plots resolving into a high affinity component and, usually, a much lower affinity component Straight lines could be fitted to points lying on the first part of the plots to yield, by extrapolation, capacities of approximately 5,400 and 4,500 sites per cell for ^{125}I-IL-1/8 and ^{125}I-IL-1/5 respectively, with equilibrium dissociation constants (K_D of $1\ 5\times10^{-10}$ and $1\ 7\times10^{-10}$ M) High affinity binding was reproducible over a number of experiments using different batches of cells and different preparations of ^{125}I-IL-1, but the contribution of low affinity binding was less consistent Given the sensitivity of Scatchard analysis to various sources of error at high levels of bound ligand[14], this component may be artefactual and result from imprecise measurement of non-specific binding Similar experiments were performed using human dermal fibroblasts and porcine articular chondrocytes In each case linear Scatchard plots were obtained, human fibroblasts bind 4,800 sites per cell with a K_D of $6\ 8\times10^{-11}$ M, porcine chondrocytes bind 7,000 sites per cell with a K_D of $2\ 5\times10^{-11}$ M Reversibility of binding was assessed after preincubation of pig synovial fibroblasts with 10 ng per ml ^{125}I-IL-1/8 (with or without excess unlabelled IL-1) The cells were washed and incubated at 19 °C in 2 5 ml per well of binding buffer When the preincubation was performed at 19 °C, 33% of specifically bound ligand was released over 6 hours The dissociation curve followed a first order model with $K_{-1}=2\times10^5$ s^{-1} and $t=$ 637 min The dissociable radioactivity was TCA-precipitable (not shown) 55% of the radioactivity bound at 37 °C became dissociated over 6 hours of which 40% was TCA-precipitable, indicating that some degradation had occurred

We wished to test whether both types of ^{125}I-IL-1 interacted with the same receptor sites, Fig 3*a* shows the results of experi-

UMR 106	Osteogenic sarcoma	Rat	543±59	ND
M-3	Melanoma Cloudman	Mouse	<100	<100

Chondrocytes were isolated by sequential enzyme digestion[19] of pig metacarpal head cartilage and used in primary culture Pig synovial fibroblasts, prepared as described in Fig 1 (legend), were used between passages three and nine Human gingival fibroblasts, a gift from S J Atkinson, were subcultured through six passages before use Human foreskin fibroblasts (Flow 7000) were used between passages 17 and 21 Neonatal mouse calvarial osteoblasts, prepared by a sequential digestion procedure[20] were obtained *from Dr J Heath and used in primary culture The UMR-106 cell line* was obtained from Professor T Chambers, all other established lines were from Flow Laboratories All cells were maintained in DMEM supplemented with 10% (v/v) heat-inactivated FCS, and were subcultured, where appropriate, using trypsin-EDTA Confluent monolayers, in 4 cm^2 wells, were incubated for 4 h at 19 °C with ^{125}I-IL-1/8 ($3\ 57\times10^{-10}$ M) or ^{125}I-IL-1/5 ($2\ 38\times10^{-10}$ M) Specifically bound radioactivity was measured as described for Fig 2 Cells in additional wells were counted in a haemocytometer after trypsin-EDTA treatment Results are the mean ± s e m of four determinations, ND, not determined

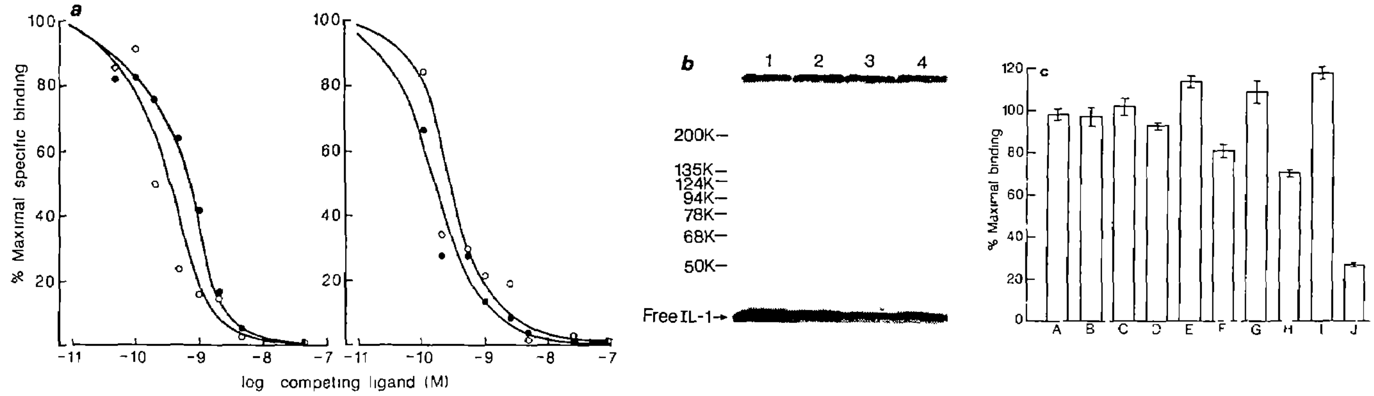

Fig 3 *a*, Competition of IL-1/5 (○) and IL-1/8 (●) with left panel, ^{125}I-IL-1/5, right panel, ^{125}I-IL-1/8 for binding to porcine synovial fibroblasts Vertical axis, per cent maximal specific binding, horizontal axis, $\log_{10}$ concentration of competing ligand *b*, Covalent crosslinking of ^{125}I-IL-1/8 to intact monolayers *c*, Specificity of the IL-1 receptor, the percentage of maximum ^{125}I-IL-1 binding observed in the presence of various other unlabelled polypeptide hormones and growth factors is shown

Methods Experimental conditions in *a* were as for Fig 2*b* with the addition of the indicated concentrations of unlabelled IL-1, labelled IL-1 was added at $1\ 2\times10^{-10}$ M Results are expressed as specific binding relative to binding in the absence of competing ligand and are the means of triplicate determinations *b*, Monolayers of 3T3 fibroblasts (clone A41, Flow Laboratories) in 25 cm^2 flasks were incubated for 4 h at 19 °C with 5 ml binding buffer supplemented with $9\ 5\times10^{-10}$ M ^{125}I-IL-1/8 and unlabelled IL-1/5 or IL-1/8 as indicated below Unbound radioactivity was removed by washing the monolayers with three changes of ice-cold protein-free binding buffer The flasks each received 5 ml of this buffer followed by 200 μl ethylene glycol bis (succinimidyl succinate) (Pierce) freshly dissolved in dimethyl sulphoxide, final crosslinker concentration was 0 5 mM After standing the flasks on ice for 45 min, the crosslinker was removed and replaced with 5 ml of a quenching solution (10 mM TrisHCl *p*H 7 5, 1 mM EDTA) The cells were scraped into this buffer, pelleted by centrifugation and dissolved in 300 μl of 1% SDS containing the protease inhibitors PMSF (10 mM) EDTA (2 mM) and *N*-ethylmaleimide (10 mM) Samples containing equal amounts of radioactivity were adjusted to 125 mM Tris HCl *p*H 6 8, 2% SDS, 5% 2-mercaptoethanol, boiled for 5 min and electrophoresed on SDS-polyacrylamide (5% stacking gel, 7 5% resolving gel)[21] The gel was dried under vacuum and exposed to X-ray film for 7 days at −80 °C Track, 1, no competing ligand, track 2, porcine IL-1/8 (1 μg ml^{-1}), track 3, porcine IL-1/5 (1 μg ml^{-1}), track 4, recombinant murine IL-1 (1 μg ml^{-1}) The positions and M_rs (in kilodaltons) of α2-macroglobulin, chick skin collagen, phosphorylase a, transferrin, serum albumin and goat IgG are given *c*, Porcine synovial fibroblasts were incubated with $2\ 4\times10^{-10}$ M ^{125}I-IL-1/5 and various unlabelled polypeptide hormones and growth factors A, synthetic human angiotensin II (2 μg ml^{-1}), B, human vasopressin (2 μg ml^{-1}), C, bovine parathyroid hormone (2 μg ml^{-1}), D, salmon calcitonin (2 μg ml^{-1}), E, mouse submaxillary gland epidermal growth factor (2 μg ml^{-1}), F, human platelet-derived growth factor (1 μg ml^{-1}), G, bovine insulin (3 μg ml^{-1}), H, mouse submaxillary gland 2 5 S nerve growth factor (90% pure, containing some renin-like activity 2 μg ml^{-1}), I, recombinant human tumour necrosis factor (2 μg ml^{-1}), J, porcine Il-1/5 (1 μg ml^{-1}) Values are expressed as the means ±s e m of radioactivity bound in triplicate determinations relative to an assay without added competitor Samples A, B, and G were from Sigma, E and F were from Bethesda Research Laboratories, C and D were obtained from Dr J K Health, Cambridge, H was a gift from Dr R Lindsay, Sandoz Institute for Medical Research, London, and sample I was provided by Dr M Palladino of Genentech, San Fransisco

ments in which unlabelled IL-1 (both types) was used to displace labelled IL-1 ($1\ 2\times10^{-10}$ M) from pig synovial fibroblasts It is clear that the two different molecules bind to a common class of receptor sites with an approximately equal affinity Very similar results were obtained using human dermal fibroblasts and porcine articular chondrocytes (not shown) Additional evidence that both types of IL-1 interact with a common site on fibroblasts is provided by crosslinking studies on pig synovial fibroblasts and murine 3T3 fibroblasts Similar results are obtained with both cell types but because the efficiency of crosslinking on 3T3 is greater, only these results are shown (Fig 3*b*) When ^{125}I-IL-1/8 was bound to fibroblasts in the presence of a homobifunctional crosslinker, faint high molecular weight complexes (95K and 190K) could be seen after SDS-PAGE and autoradiography The patterns were similar when samples were analysed under reducing and non-reducing conditions Inclusion in the incubation medium of a high concentration of either unlabelled porcine IL-1 or murine recombinant IL-1 prevented the formation of these complexes indicating that they are involved in the specific binding of IL-1 of either type

We examined the specificity of the IL-1 receptor further by including a series of polypeptide growth factors and hormones in the binding assay (Fig 3*c*) Of the ten factors tested, only IL-1 was able to compete effectively for binding of ^{125}IL-IL-1/5 to pig synovial fibroblasts We have screened other cells for IL-1 binding (see Table 1), receptor expression varies from a high level in chondrocytes and osteoblasts which respond strongly to IL-1 by producing collagenase and prostaglandin (unpublished results), to cells without measurable binding (HeLa and HT1080 which do not produce PGE$_2$ in response to IL-1 and may be relatively insensitive Our findings for fibroblasts are quantitatively similar to those recently reported[15] for binding of human ^{125}I-IL-1 (*p*I7) which was 95% inactivated by Bolton-Hunter labelling fibroblasts to human and mouse fibroblasts, and they substantiate an initial report[22] of cross competition for binding of recombinant human IL-1 on murine T cells The present report indicates the suitability of the different types of porcine IL-1 as probes for receptors, as they can be radiolabelled preserving full activity, and provides the first evidence that the two forms show similar affinity for a common receptor on relevant target cells

We thank Dr M Palladino for the sample of recombinant TNF, Dr P Lomedico for the gift of recombinant murine IL-1 and the Arthritis and Rheumatism Council for their generous support

The cell surface receptors for interleukin-1α and interleukin-1β are identical

Steven K. Dower, Shirley R. Kronheim, Thomas P. Hopp, Michael Cantrell, Michael Deeley, Steven Gillis, Christopher S. Henney & David L. Urdal

Immunex Corporation, 51 University Street, Seattle,
Washington 98101, USA

Interleukin-1 (IL-1) is a factor that can induce proliferation of murine T lymphocytes[1,2] and can elicit a variety of other biological responses. These include bone resorption[3], fibroblast proliferation[4], acute phase protein release from hepatocytes[5], cartilage breakdown[6] and fever[7]. This spectrum of activities is consistent with a role for IL-1 as a mediator of inflammation. Recently, sequence data have shown that there are at least two members of the IL-1 family; these distantly related proteins have been termed IL-1α and IL-1β[8–11]. We have found previously that both murine T cells and fibroblasts possess a relative molecular mass (M_r) ~80,000 (80K) plasma membrane receptor for human IL-1β[12,13]. We show here that the receptor for IL-1α on both murine and human cells is identical to that for IL-1β. This result raises the issue of what separation, if any, there might be between the biological activities of IL-1α and IL-1β.

Both IL-1α and IL-1β are encoded by complementary DNAs for proteins of ~30K[8–11], whereas the active forms found in macrophage culture supernatants are ~17K[3,14–16] The start positions within the precursors for murine IL-1 and human IL-1β (nIL-1β) have been established by N-terminal protein sequence analysis[8 10] Recombinant human IL-1α (rIL-1α) and IL-1β (rIL-1β) were produced in *Escherichia coli* from truncated cDNA clones encoding polypeptides identical to the secreted forms, and subsequently purified to homogeneity (S R K, unpublished) nIL-1β was purified from culture supernatants and labelled with di-iodo (^{125}I) Bolton-Hunter reagent as described previously[12,15] rIL-1β was labelled with Bolton-Hunter reagent, and rIL-1α was labelled with sodium (^{125}I) iodide using a modified chloramine-T method[17] For all three lymphokine preparations, radioiodination yielded specific activities in the range 1×10^{15} to 5×10^{15} c p m mmol^{-1} (0 4-2 atoms I per molecule protein) and SDS-polyacrylamide gel electrophoresis (PAGE) revealed a single labelled polypeptide of 17 5K (Fig 1), consistent with previously reported[3,10,14–16] values for IL-1

All these labelled preparations were >98% TCA precipitable, thus the ^{125}I was covalently bound to protein Comparison of biological activities on murine T lymphoma cells[18] between labelled and unlabelled IL-1 showed that rIL-1β, like nIL-1β[12], suffered some loss of activity on labelling, but rIL-1α retained 100% biological activity (1×10^{12} U mg^{-1}) after labelling and >95% could be bound by IL-1 receptor bearing cells

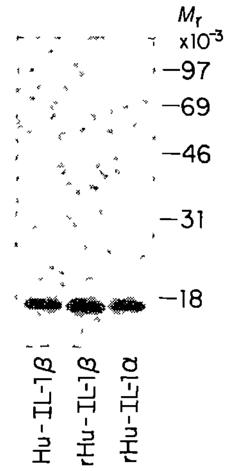

Fig 1 SDS-PAGE analysis of radiolabelled IL-1 preparations ^{125}I-IL-1 preparations were boiled for three minutes in sample buffer and analysed on a 10-20% polyacrylamide gradient slab gel as described elsewhere[12] Track 1, human IL-1β, track 2, recombinant human IL-1β, track 3, recombinant human IL-1α
Methods. IL-1 preparations to be used for radiolabelling were checked for purity and approximate protein concentration by SDS-PAGE and silver staining, the exact concentration was later determined by amino-acid analysis on an LKB 4150 amino-acid analyser and comparison with the predicted composition from the cDNA sequence[8] nIL-1β was labelled using di-iodo (^{125}I) Bolton-Hunter reagent (NEN) as described previously[12] Briefly 1 μg (0 06 nmoles) of nIL-1β in 50 μl of borate (0 02 M) buffered saline (0 15 M) was added to 10 μl of sodium borate (0 1 M) buffered saline (0 75 M) *p*H 8 5, the IL-1 was reacted with 1 mCi Bolton-Hunter reagent according to the manufacturer's instructions for 12 h at 8 °C Subsequently 30 μl of 2% gelatin and 5 μl of 1 M glycine ethyl ester were added and the protein separated from unreacted Bolton-Hunter reagent on a 1 ml bed volume Biogel P6 (Biorad) column Routinely ~5% of the Bolton-Hunter reagent was incorporated into protein Recombinant IL-1β was labelled with di-iodo Bolton-Hunter reagent by essentially the same protocol, except that 10 μg (0 57 nmol) of protein in 10 μl of phosphate (0 015 M) buffered saline (0 15 M) *p*H 7 2 were mixed with 10 μl of sodium borate (0 1 M) buffered saline (0 15 M) *p*H 8 5 and reacted with 1 mCi (0 23 nmoles) of Bolton-Hunter reagent Routinely 50-60% incorporation of label was observed Recombinant IL-1α was labelled with Na(^{125}I) using chloramine-T Briefly 10 μg of rIL-1α (0 57 nmol) in 10 μl of phosphate buffered saline were added to 2 5 mCi (1 0 nmol) of sodium iodide in 25 μl of 0 05 M sodium phosphate *p*H 7 0, reaction was initiated by addition of 30 μl of 1 4×10^{-4} M chloramine-T (4 2 nmol, Sigma) After 30 min on ice the reaction mixture was fractionated by gel filtration as described above Routinely 40-50% of ^{125}I was incorporated into protein Precipitation of the ^{125}I-IL-1 preparations in 1% gelatin carrier using 10% trichloroacetic acid, or rechromatography on gel filtration columns both showed that >98% of the ^{125}I label was protein bound after P6 purification

Table I summarizes the binding of ^{125}I-nIL-1β, ^{125}I-rIL-1β and ^{125}I-rIL-1α to LBRM-33-1A5 murine T lymphoma cells, human dermal fibroblasts, BALB-c/3T3 cells and ARH77, a human B lymphoblastoid cell line The number of sites on the LBRM-33-1A5 cells (Table 1) was at the high end of the range for 25 experiments, in which we observed considerable fluctuation in the number of receptors detected (290-3,430 sites per cell) The data in Table 1 show that all three types of ^{125}I-IL-1 detected a single class of high affinity sites on the cells Similar experiments with primary human dermal fibroblasts and murine 3T3 fibroblasts also showed that both IL-1α and IL-1β detected a single class of cell surface binding sites, the numbers of receptors detected by the two ligands were the same within experimental error (Table 1) In ARH77 cells, nIL-1β and rIL-1β bound to similar numbers of high affinity binding sites with identical affinities (Table 1) We could not obtain interpretable

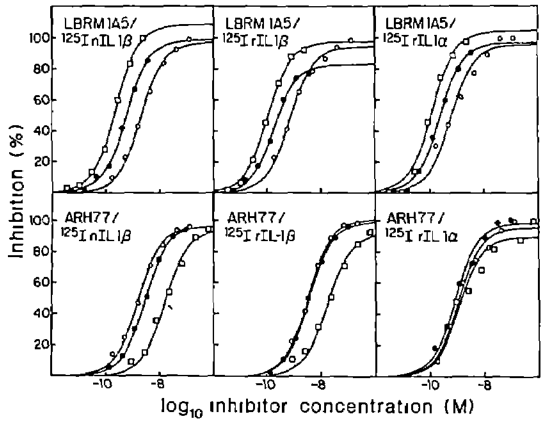

Fig. 2 Cross competition between rIL-1α, rIL-1β and nIL-1β on LBRM-33-1A5 and ARH77 cells Unlabelled competitor ●, nIL-1β, ○, rIL-1β, □, rIL-1α LBRM-33-1A5 cells ($3\ 1\times10^{7}$ per ml) or ARH77 cells ($2\ 1\times10^{7}$ per ml) were incubated with a fixed concentration of each type of ^{125}I-IL-1 and various concentrations of unlabelled IL-1 (as indicated in the figure) in 150 µl of RPMI 1640 with 1% BSA, 0 1% sodium azide and 20 mM HEPES *p*H 7 4 for 2 h at 8 °C on a rocker platform in round bottomed 96 well microtitre plates Concentrations of ^{125}I-IL-1 used were with LBRM-33-1A5 cells—nIL-1β, $3\ 9\times10^{-10}$ M, rIL-1β, $1\ 9\times10^{-9}$ M and rIL-1α, $9\ 2\times10^{-10}$ M, with ARH77 cells—nIL-1β, 9×10^{-10} M, rIL-1β, $1\ 9\times10^{-9}$ M and rIL-1α, $4\ 6\times10^{-9}$ M At the end of the assay, cells and bound radiolabel were separated from unbound label by centrifuging 60 µl aliquots of the reaction mixtures through 200 µl of phthalate oils in 400 µl polyethylene centrifuge tubes and excising the tips with a razor blade[17] Maximal binding was measured with the ^{125}I ligands alone, background binding was measured with ^{125}I-IL-1 and 6×10^{-7} M unlabelled homologous IL-1 All data have been corrected for nonspecific binding by subtraction The cells were greater than 90% viable by trypan blue exclusion at the end of the assay The continuous curves passing through the data were calculated from the best fit parameter values in Table 1 using a simple competitive inhibition model[19]

Table 1 Binding parameters for the interaction of rIL-1α, rIL-1β and nIL-1β with murine and human cells

Cell	Ligand	K_A (M^{-1})×10^{-9}	K_I (M^{-1})×10^{-9}	Receptors per cell (×10^{3})
LBRM-33-1A5	nIL-1β	1 4±0 1	4 0±1 8	2 8±0 1
LBRM-33-1A5	rIL-1β	0 3±0 02	1 8±0 3	3 2±0 2
LBRM-33-1A5	rIL-1α	4 6±0 7	11 3±2 1	3 43±0 02
ARH77	nIL-1β	0 44±0 06	0 7±0 4	11 3±0 3
ARH77	rIL-1β	0 5±0 1	1 5±0 6	11±1
ARH77	rIL-1α	ND	0 4±0 1	ND
Human dermal fibroblasts	nIL-1β	1 8±0 1	3 4±0 6	2 4±0 1
Human dermal fibroblasts	rIL-1α	1 6±0 1	4 1±0 4	2 8±0 1
BALB-c/3T3 fibroblasts	nIL-1β	2 1±0 6	2 3±1 1	4 8±0 5
BALB-c/3T3 fibroblasts	rIL-1α	3 0±0 5	2 3±1 1	5 5±2 0

LBRM-33-1A5 murine T lymphoma cells[2] and ARH77 human B lymphoma cells were grown in 175 cm^{2} tissue culture flasks in RPMI 1640 containing 10% fetal calf serum (Hyclone) Human dermal fibroblasts were obtained from the American Type Tissue Culture Collection (CRL 1229, passage 5) and propagated in monolayer cultures in DMEM 10% fetal calf serum, cells were tested for IL-1 binding at passage 10-12 BALB-c/3T3 cells were obtained from the American Type Tissue Culture Collection and propagated in DMEM with 10% calf serum (Hyclone) Fibroblasts were harvested for binding assays by treatment with PBS containing EDTA (0 5 mM) to avoid proteolysis of receptor Equilibrium binding data were analysed using a simple bimolecular binding model[12] The values for nonspecific binding were determined by fitting a straight line passing through the origin to data obtained from binding of ^{125}I-ligand to the cells in the presence of 100-fold molar excess of unlabelled IL-1 of the same type These values were subtracted from the data before analysis for determination of K_A and receptors per cell values Inhibition data were analysed with an equation describing competition between two ligands for one class of sites[19] All data analysis was done using RS/1, a commercially available scientific programming package running on a VAX 11/750 under the VMS operating system (BBN Software Products) Error values are standard errors of the mean generated from the nonlinear least-squares fitting program

saturation binding data from these cells for ^{125}I-labelled rIL-1α because the affinity of this ligand for the cells is low (see Fig 2)

To test directly whether IL-1α and IL-1β bind to the same receptor we conducted inhibition experiments (Fig 2) in which the binding of each radiolabelled IL-1 preparation to cells was inhibited by unlabelled IL-1 from the same stock solution and from the other two unlabelled IL-1 preparations For each ^{125}I-labelled IL-1 preparation on either LBRM-33-1A5 or ARH77 cells, complete inhibition of radiolabelled ligand binding was achieved with all three unlabelled IL-1 preparations Thus no receptors on either cell type bound IL-1α or IL-1β exclusively The data in Fig 2 were analysed quantitatively by a nonlinear least-squares fitting of an equation describing competition between labelled and unlabelled hormone for a single class of sites[12,19] The parameter values from this analysis are given in Table 1

The dose-response curves in Fig 2 provide further support for the view that both cell types have a single class of IL-1 receptors that bind all three IL-1 preparations If there existed a subset of receptors that bound one type of IL-1 preferentially, competition between the labelled and unlabelled forms of this type of IL-1 would show a shift to lower concentration of inhibitor than when the unlabelled form competed against labelled heterologous IL-1 This is not observed Finally, for all 18 data sets in Fig 3 the curves pass close to most of the data points A model incorporating only one type of cell surface receptor site thus provides a satisfactory description of the data in all cases

The results of similar experiments with human and murine fibroblasts are summarized in Table 1 Both for 3T3 cells and for human dermal fibroblasts, cross competition experiments revealed that IL-1α and IL-1β bind to identical receptor populations (data not shown) Interestingly, the pattern of relative reactivity differed from one cell line to another, IL-1α bound more avidly than IL-1β to murine T cells but less avidly to human B cells, both forms bound equally well to fibroblasts, irrespective of the species of origin The data suggest that the receptors on different cell lineages, although similar, may not be identical Overall, however, our data are consistent with the view that there are only limited differences in receptor binding activities of IL-1α and IL-1β, and almost no difference in receptor binding between nIL-1β and rIL-1β

The observation that the two forms of IL-1 bind to the same receptor on a variety of cells explains their shared biological activities It is striking that this should occur despite the limited sequence homology between the molecules This may indicate that the tertiary structures are less divergent than the primary sequences, particularly in the active site region This feature of the IL-1 system, that IL-1α and IL-1β bind to the same receptor protein, is also found for the TNF system[20] and the A chain and B chain dimers of PDGF[21] These three hormone-receptor systems appear to have at least partially overlapping roles in controlling connective tissue metabolism and inflammatory responses It is therefore tempting to speculate that the existence of two hormones with a common receptor in all three cases is a consequence of some as yet undiscovered feature of the regulation of responses to disease and injury

Presence of Ti (WT31) negative T lymphocytes in normal blood and thymus

Lewis L. Lanier* & Arthur Weiss†

* Becton Dickinson Monoclonal Center, Inc, Mountain View, California 94043, USA
† Department of Medicine, Howard Hughes Medical Institute, University of California, San Francisco, California 94143, USA

The antigen receptor expressed on most T lymphocytes is a disulphide-linked heterodimer (Ti) that is composed of α-chain and β-chain subunits[1-6]. On the surface of human T lymphocytes, Ti is non-covalently associated with three invariant proteins, designated CD3-γ, -δ, and -ε[7]. It has been suggested that Ti is obligatory for CD3 expression[8,9]. But a T leukaemia cell line[10], IL-2 (interleukin 2) dependent T-cell clones established from fetal blood[11] and IL-2 dependent cell lines established from immunodeficiency patients with bare lymphocyte syndrome and ectodermal dysplasia syndrome[12] have recently been shown to express CD3, but not Ti[13] (detected due to monoclonal antibody WT31). These lymphocytes may express the product of the T-cell antigen receptor γ (TCR-γ) gene, rather than the α/β heterodimer, in association with CD3[10,12]. Preliminary studies suggested that T cells expressing CD3 but lacking Ti are present in low frequency in normal lymphoid tissues[10,12]. Here we show that in normal blood and thymus CD3$^+$, WT31$^-$ T cells express neither CD4 nor CD8. The low frequency (<0.2–0 9% of total thymocytes) of CD3$^+$, WT31$^-$ cells in the thymus suggests that this population does not represent a major stage of thymic development and may be a distinct lineage of T cells

Peripheral blood lymphocytes (PBL) were stained by direct two-colour immunofluorescence with fluorescein isothiocyanate (FITC) conjugated anti-Ti (WT31) and biotin conjugated anti-CD3 (Leu 4), followed by phycoerythrin (PE) conjugated streptavidin and analysed by flow cytometry Although most CD3$^+$ T cells co-expressed Ti (WT31), a small, distinct subset of CD3$^+$ T cells did not Based on analysis of >30 normal adult blood donors, ~3% of T lymphocytes were CD3$^+$, WT31$^-$ (range <0 5%-10%), whereas the remainder were CD3$^+$, WT31$^+$ CD3 is expressed on all peripheral blood T cells, but these cells can be divided into subpopulations on the basis of expression of other surface antigens For example, the CD4 and CD8 antigens are mutually exclusive markers for the two major subpopulations of mature T cells This phenotypic heterogeneity has some functional correlation, CD4-bearing cells recognize antigen in association with class II major histocompatibility (MHC) antigens and generally function as helper cells, whereas the CD8 bearing cells recognize antigen in association with class I MHC antigens and generally function as cytotoxic T cells Thus it was of interest to determine whether CD3$^+$, WT31$^-$ cells could be detected in one of these major subpopulations, as this would have implications for cells bearing this unusual CD3 receptor complex. Three-colour immunofluorescence was performed to determine whether CD3$^+$, WT31$^-$ T lymphocytes in blood co-express the CD4 or CD8 antigens Surprisingly, they express neither CD4 nor CD8 (Fig 1) By setting an electronic gate on CD3$^+$ lymphocytes (stained with allophycocyanin (APC)-conjugated streptavidin/biotin-conjugated anti-CD3), it was possible to examine directly CD3$^+$ T cells co-stained with FITC-conjugated anti-Ti (WT31) and a mixture of PE-conjugated anti-CD4 plus PE-conjugated anti-CD8 (Fig 1, right panel) Note that (1) all CD3$^+$, WT31$^-$ T lymphocytes lacked CD4 and CD8, and (2) all detectable CD3$^+$, WT31$^+$ T cells expressed either CD4 or CD8 Identical results were obtained from several independent donors

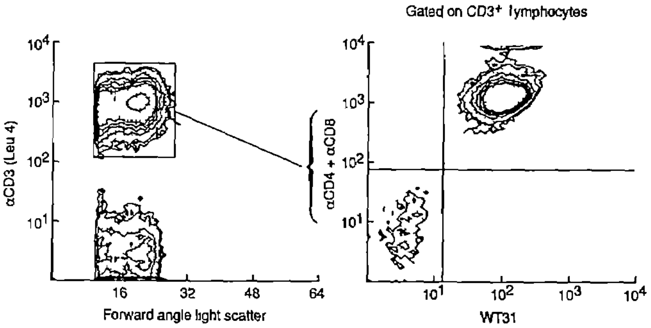

Fig 1 Presence of CD3$^+$, WT31$^-$ T lymphocytes in peripheral blood Mononuclear cells were isolated from peripheral blood using Ficoll/Hypaque Adherent cells were removed using plastic tissue culture flasks PBL were stained with FITC-conjugated WT31, biotin-conjugated anti-CD3 (Leu 4) and a mixture of PE-conjugated anti-CD4 (Leu 3) and anti-CD8 (Leu 2) APC-conjugated streptavidin was used as the second reagent Fluorochrome-conjugated, isotype-matched monoclonal antibodies that do not react with human cells were used to control for nonspecific immunofluorescence Samples were analysed by multi-parameter flow cytometry using a dual laser FACS 440 system with an argon ion laser (488 nm, 100 mW) and a helium neon laser (633 nm, 33 mW) (Becton Dickinson Immunocytometry Systems) Immunofluorescence, flow cytometry and data analysis were performed as described[14,15] Based on the immunoglobulin control sample, contour plots were divided into quadrants to identify unstained cells (lower left), cells stained with both fluorochromes (upper right), and cells stained only with a single fluorochrome (upper left and lower right) In the control sample >99% of lymphocytes were unstained (lower left quadrant, not shown) Left, forward angle light scatter (linear scale, proportional to cell size for lymphoid cells) versus APC anti-CD3 fluorescence Insert, An 'electronic' gate on CD3$^+$ T lymphocytes The correlation of the WT31, CD4 and CD8 antigens on CD3$^+$T lymphocytes is displayed (right panel) In this individual 8% of total lymphocytes were CD3$^+$WT31$^-$ and all lacked CD4 and/or CD8 expression

Further experiments were conducted to determine whether this unique subset of CD3$^+$, WT31$^-$ T cells expressed other T-cell-associated differentiation antigens As shown in Fig 2, >95% of CD3$^+$, WT31$^-$ T lymphocytes co-expressed CD2, CD5 and CD7, similar to expression of these antigens on CD3$^+$, WT31$^-$ T lymphocytes CD1 (a class I MHC homologous antigen limited to thymocytes), CD19 (a pan B cell associated antigen), CD14 (a monocyte associated antigen), transferrin receptors and IL-2 receptors were not expressed on CD3$^+$, WT31$^-$ T cells (not shown)

We have shown previously[10] that CD3$^+$, WT31$^-$ cells comprise <1% of total thymocytes As blood CD3$^+$, WT31$^-$ T cells are CD4$^-$8$^-$, we examined CD4$^-$8$^-$ thymocytes (6% of total thymocytes) for expression of CD3 or WT31 As shown in Fig 3 (top), essentially all thymocytes expressing CD4 and/or CD8 showed linked expression of CD3 and Ti, cells were either CD3$^+$, Ti$^+$ or CD3$^-$, Ti$^-$ The 'diagonal' in the bivariate contour plot indicates a direct quantitative relationship between CD3 and Ti Further analysis by three-colour immunofluorescence

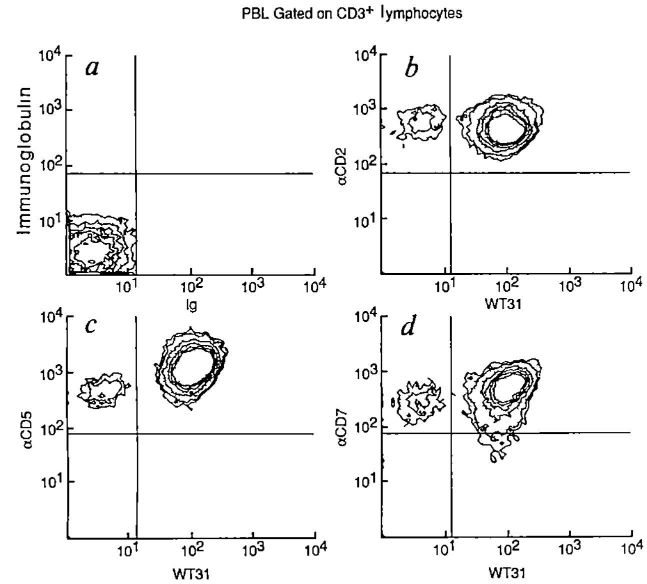

Fig. 2 Expression of T-cell differentiation antigens on CD3$^+$, WT31$^-$ T lymphocytes. PBL (from the same individual as in Fig. 1) were stained with *a*, biotin-conjugated anti-CD3 (Leu 4), FITC-conjugated immunoglobulin control, and PE-conjugated immunoglobulin control, *b*, biotin anti-CD3, FITC-conjugated WT31, and PE-conjugated anti-CD2 (Leu 5) *c*, biotin-conjugated anti-CD3, FITC-conjugated WT31, and PE-conjugated anti-CD5 (Leu 1), *d*, biotin-conjugated anti-CD3, FITC-conjugated WT31, and PE-conjugated anti-CD7 (Leu 9). APC-conjugated streptavidin was used as the second step reagent. An 'electronic' gate was placed on CD3$^+$ T lymphocytes (shown in Fig. 1, left) and the correlation of WT31 with CD2 (B), CD5 (C) or CD7 (D) was directly determined. In control samples (using fluorochrome conjugated isotype-matched immunoglobulin) >99% of lymphocytes were unstained.

(staining with FITC-conjugated anti-CD8, PE-conjugated anti-CD4 and APC-conjugated anti-CD3)[14] indicated that essentially all 'single positive' CD4$^-$8$^+$ and CD4$^+$8$^-$ and about half the immature CD4$^+$8$^+$ thymocytes expressed CD3 (not shown). By contrast, a very minor subset of CD4$^-$8$^-$ thymocytes expressed CD3 but lacked Ti (WT31) (0.8% of total thymocytes, Fig. 3). In fact, all detectable CD3$^+$ lymphocytes in this population were Ti (WT31) negative. Furthermore, like peripheral blood CD3$^+$, WT31$^-$ lymphocytes, CD3$^+$4$^-$8$^-$ thymocytes expressed CD2 and CD5, but not transferrin receptors or IL-2 receptors (Fig. 4). In contrast to peripheral CD3$^+$, WT31$^-$ lymphocytes, CD1 was expressed on a fraction (~40%) of these CD3$^+$, WT31$^-$ thymocytes (Fig. 4*d*), although the amount of CD1 antigen was approximately 10% the amount present on most thymocytes (not shown). Thymocytes from five donors (age 2–6 years) were examined with similar results (mean ~0.5% CD3$^+$, WT31$^-$ thymocytes, range <0.2–0.9%).

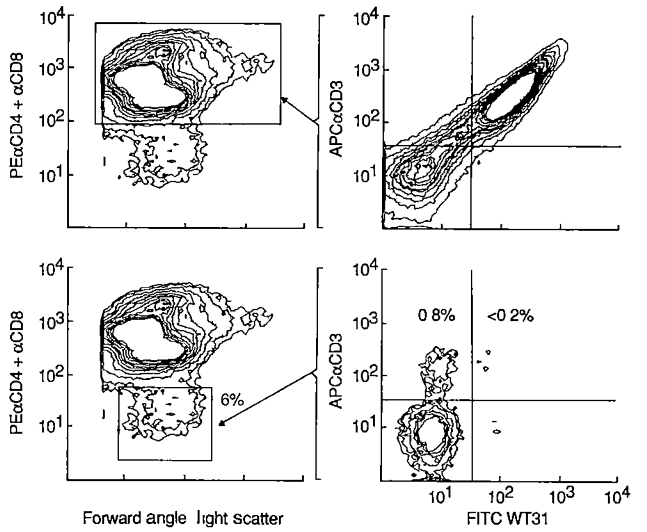

Fig. 3 Expression of CD3 and WT31 on thymocytes. Normal thymus were obtained from paediatric cardiac patients. A single cell suspension of thymocytes was prepared, using the entire thymic lobule to ensure that cortical and medullary thymocytes were accurately represented, and stained with FITC-conjugated WT31, biotin-conjugated anti-CD3 (Leu 4) and a mixture of PE-conjugated anti-CD4 (Leu 3) with anti-CD8 (Leu 2), followed by APC-conjugated streptavidin. An electronic gate was set on thymocytes expressing CD4 and/or CD8 (top) or lacking both CD4 and CD8 (bottom) and the correlation between WT31 and CD3 was determined. In this individual 6% of thymocytes were CD4$^-$8$^-$ and 0.8% were CD3$^+$4$^-$8$^-$, WT31$^-$. In samples stained with fluorochrome-conjugated, isotype-matched control Ig <0.2% of thymocytes were nonspecifically stained (not shown).

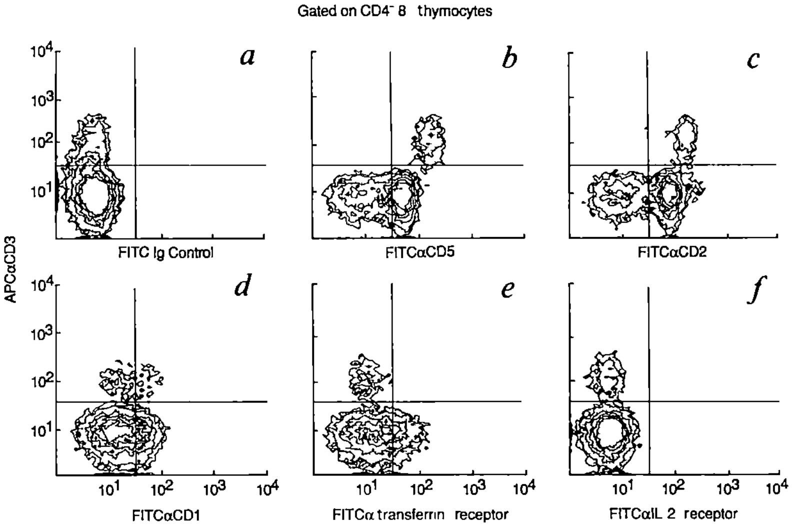
We have thus shown that CD3$^+$ T lymphocytes lacking Ti are present in normal blood and at a lower frequency in the thymus. CD3$^+$, WT31$^-$ T cells and thymocytes are only found in the small CD4$^-$8$^-$ subset. Peripheral blood CD3$^+$4$^-$8$^-$ T lymphocytes are morphologically and phenotypically mature, small resting lymphocytes[15]. IL-2 dependent cell lines of CD3$^+$4$^-$8$^-$ thymocytes[16] and normal peripheral blood T lymphocytes[16] established in culture stably express this phenotype, remain Ti

Fig. 4 Expression of T-cell differentiation antigens on CD3$^+$4$^-$8$^-$ thymocytes. Thymocytes (from the same individual as in Fig. 3) were stained with biotin-conjugated anti-CD3 (Leu 4), a mixture of PE-conjugated anti-CD4 (Leu 3) and anti-CD8 (Leu 2), and, *a*, FITC-conjugated Ig control, *b*, anti-CD5 (Leu 1), *c*, anti-CD2 (Leu 5), *d*, anti-CD1 (Leu 6), *e*, anti-transferrin receptor, *f*, anti-IL-2 receptor. APC-conjugated streptavidin was used as the second step reagent. As shown in Fig. 3 (bottom panel), an electronic gate was set on CD4$^-$8$^-$ thymocytes and the correlation between expression of CD3 and of the other differentiation antigens was determined.



(WT31) negative, and demonstrate cytotoxic function (refs 16, 17 and LLL, unpublished) Some cell lines with this phenotype[12,16] do not express mature Ti-α or Ti-β messenger RNA but express a novel heterodimer (probably composed of TCR-γ and another unidentified glycoprotein) in association with CD3 The CD3$^+$ WT31$^-$ cells we have observed *in vivo* are CD4$^-$8$^-$, but some IL-2 dependent lines with this phenotype express CD8[11,12] We do not know whether CD3$^+$8$^+$ WT31$^-$ cells are present *in vivo* in numbers we cannot detect (<0 2%) or whether CD8 arises on these cells as a consequence of culture

These observations raise questions regarding the lineage and differentiation pathway of these unique CD4$^-$8$^-$ T lymphocytes As rearrangement and transcription of TCR-γ genes apparently precedes Ti-β and Ti-α[17–21], it has been proposed that the antigen receptor on immature T cells may be composed of TCR-γ gene products before the Ti-α/β heterodimer appears However because CD3$^+$, WT31$^-$ thymocytes are a minor subpopulation of the putative immature CD4$^-$8$^-$ thymocytes, it is unlikely that CD3$^+$, WT31$^-$ T cells represent a major stage in thymic development If selection of antigen/MHC recognition is from a CD3$^+$, WT31$^-$ thymic subset, there should be more of these cells Because most thymocytes (including the abundant immature CD4$^+$8$^+$ subset) express Ti (WT31), selection may occur mainly via the CD3/Ti receptor complex Alternatively, CD3$^+$Ti$^-$ lymphocytes may be a distinct T-cell lineage and never express Ti The fact that CD3$^+$, WT31$^-$ cells in blood are identical in phenotype to the thymocyte subpopulation (except for CD1, found only on thymocytes) supports this possibility Finally, CD3$^+$, WT31$^-$ peripheral blood cells could be precursors of the CD3$^+$, WT31$^-$ thymocytes which might then be important in thymocyte development If so, a cell population equivalent to the CD3$^+$, Ti$^-$ T cells should be present in athymic mice, and might account for the T-cell-mediated functions observed in these animals[22–25] MacDonald *et al*[26] have recently described a subset of Thy1$^+$, L3T4$^-$, Ly2$^-$ cells in athymic mice and Mak[27] has recently reported that nylon wool non-adherent lymphocytes from athymic mice transcribe TCR-γ, but not Ti-α or competent Ti-β mRNA Further studies are necessary to test this hypothesis and establish the relationship between CD3$^+$, Ti$^+$ and CD3$^+$, Ti$^-$ T lymphocytes

We thank Drs Willem Tax and Patrick Kung for providing the WT31 antibody and Dr Jim Allison for discussion and review of the manuscript

Von Willebrand factor (vWF), a multifunctional haemostatic glycoprotein derived from endothelial cells and megakaryocytes, mediates platelet adhesion to injured subendothelium and binds coagulation factor VIII in the circulation. Native vWF is a disulphide-bonded homopolymer; the monomeric subunits, of apparent relative molecular mass (M_r) 220,000 (220K) are derived from an intracellular precursor estimated at 260–275K (refs 1–5). Multimer assembly is preceded by the formation of dimers, linked near their C-termini, which then assemble into filamentous polymers. The importance of the removal of the large vWF pro-polypeptide during multimer assembly, and whether this or other stages of the complex post-translational processing require components specific to endothelial cells or megakaryocytes, is unknown. Here we report an analysis of the complete sequence of pre-pro-vWF and expression of the molecule in heterologous cells. The vWF precursor is composed of several repeated subdomains. When expressed in COS and CHO cells, it is cleaved and assembled into biologically active high relative molecular mass disulphide bonded multimers. This suggests that the information for assembly of this complex molecule resides largely within its primary structure.

The nucleotide sequence of pre-pro-vWF complementary DNA (which is printed in its entirety elsewhere[48]) has a major open reading frame encoding 2,813 amino acids The initiator methionine, followed by a classical signal peptide, can be identified unambiguously because it is the only Met between an in-frame upstream stop codon and the Ala (residue 23) determined by amino-acid sequencing to be the N-terminus of the 100K pro-polypeptide[6] The signal peptidase cleavage site (defined by this N-terminal sequence) conforms well to the consensus[7] The predicted M_r of pro-vWF is 307K without the extra 15% contributed by glycosylation[8], this is considerably larger than the size of the intracellular precursor estimated from SDS-PAGE[5]

The amino-acid sequence of pre-pro-vWF shows extensive internal repetition (Fig 1) A central region of ~600 amino-acids contains three domain A repeats, which together with the short B and C repeats, were identified in partial-length clones described by others[9,10] A striking feature of the A region is its lack of cysteine residues, in contrast, the flanking regions (amino acids 34–1,242 and 1,948 to the C-terminus) are rich in cysteine, the most abundant amino acid in pre-pro-vWF, comprising 8 3% of the residues (10 4% in the regions outside domain A) These cysteine-rich regions include a further series of four repeats, which we term D1–D4, beginning just after the signal peptide (Fig 1) The second of these 350 amino-acid repeats is truncated,

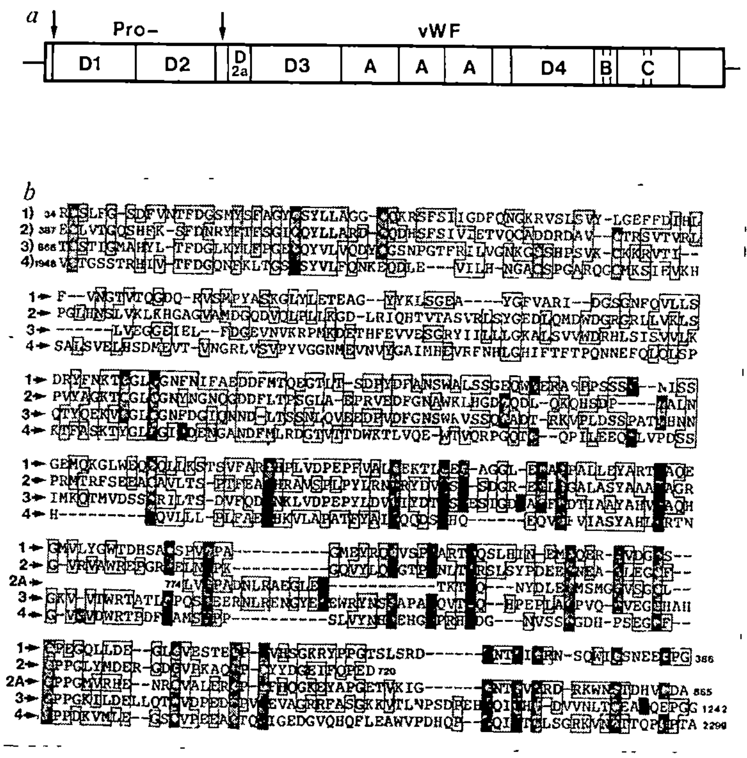

Fig. 1 Repeated elements in the primary structure of vWF *a*, Schematic of vWF cDNA D1–D4, cysteine-rich repeat blocks The A, B and C repeat domains of Sadler *et al*[9,10] are also labelled Arrows, sites at which the signal peptide and the large pro-polypeptide are cleaved from the primary translation product *b*, Alignment of the four cysteine-rich D repeat blocks Matching residues are boxed and lightly shaded, cysteine residues are darkly shaded Small numbers at the sides refer to the adjacent amino-acid residues, relative to the initiator methionine, assigned position 1 Amino acids 721–773, (between repeats 2 and 2A), and 1,243–1,947 (including the A domain repeats), have been omitted, the sequence is otherwise continuous as shown Gaps introduced to maximize homology are shown as dashes D4 appears to be the least conserved of the repeat blocks, in this alignment, the percentage of matching amino acids for each pairwise comparison is D1–D2, 34 8, D1–D3, 30 4, D2–D3, 33 6, D1–D4, 24 1, D2–D4, 25 0, D3–D4, 24 1 The sequence TCGLC, which forms the centre of a highly conserved block in the D repeat regions, also occurs in the B domain, indicating a possible relationship between these two repeated elements

Methods The amino-acid sequence shown is deduced from the sequences of the same cDNA clones used in construction of pvWF2 (Fig 2 legend) Both strands of the sequence were determined by the Sanger dideoxy method[34,35] M13 subclones for sequencing were constructed by exonuclease digestion methods[36,37] The region of residue 1,472 (see text) was sequenced in three further independent clones (pvWG8b, pvWH22, pvWH23) using an internal oligonucleotide primer[38] Repeat blocks were defined manually following identification of short repeated motifs by computer search The consensus alignment was also arrived at by hand, with reference to computer-generated pairwise alignments

and its C-terminal one-third duplicated (Fig 1, D2a) Interestingly, the site of pro-polypeptide cleavage (Fig 1, arrow) falls within this region of discontinuity of the D repeats

Based on partial cDNA sequences, Sadler and colleagues[10] proposed the existence of a fifth repeated element which they term domain E Our analysis shows that this element is, in fact, the C-terminal portion of the D repeat block, and these sequences are included in the alignment in Fig 1

Within the D repeats there is striking conservation of the positions of the abundant cysteine residues (Fig 1*b*) Because no free sulphydryl groups can be detected in native vWF[11,12] all these cysteines must participate in inter- and intra-chain disulphide bonding, an important determinant of the tertiary and quaternary structure of the protein Electron microscopy of vWF shows a central filament separating globular regions at each end of the monomer[13–15] These two structural features may correspond to the cysteine-poor A domains and the highly disulphide-bonded cysteine-rich domains, respectively The intron-exon arrangement underlying the repeated structure of vWF has not yet been defined, but the common evolutionary origin of mature vWF and the pro-polypeptide is evident from our analysis As the cleavage of pro-vWF occurs at a position where the cysteine-rich repeat sequence is interrupted by a partial duplication, it could be that after the duplications of the D repeats a later aberrant recombination introduced the new cleavage site, leading to the separation of the pro-piece from mature vWF Despite the functional similarities between vWF and fibronectin[16] and fibrinogen[17], we find no similarity in sequence between these proteins other than the consensus tetrapeptide Arg-Gly-Asp-Ser, which defines the binding site for platelet glycoprotein IIb/IIIa and is common to many adhesive glycoproteins[18–20]

Discrepancies exist between our full-length sequence and the partial sequence of Sadler *et al*[9,10] The first 13 base pairs (bp) of the clone λHvWF-1 (ref 9) differ completely from our sequence, which in this region was determined on two independent clones, pvWH33 and pvWH5 At amino-acid residue 770 (residue 7 of the mature monomer), the Sadler *et al* sequence has His rather than the Pro determined from N-terminal amino-acid sequencing[9], whereas our clones H33 and H5 both have the expected Pro At residue 1,472, our sequence contains CAC (His) rather than GAC (Asp) Of three further non-identical clones from our endothelial cDNA library, two have GAC and one CAC at this position, suggesting an amino-acid polymorphism Some other potential polymorphisms have been previously noted[10]

To study vWF biosynthesis in heterologous cells, we assembled a full-length cDNA and inserted it into the expression vector pMT2 (Fig 2 legend), in which transcription is directed by the adenovirus major late promoter In assays of transient expression, the conditioned medium of monkey kidney (COS) cells transfected with the pMT2-vWF construct contained 50–100 ng ml^{-1} of vWF antigen COS cells transfected with pMT2 alone did not produce material reacting in our inhibition enzyme-linked immunosorbent assay (ELISA)

For expression of vWF in Chinese hamster ovary (CHO) cells, we used a second expression vector, pMT2ADA-vWF (Fig 2) with a protocol of selection for cells over-expressing the enzyme

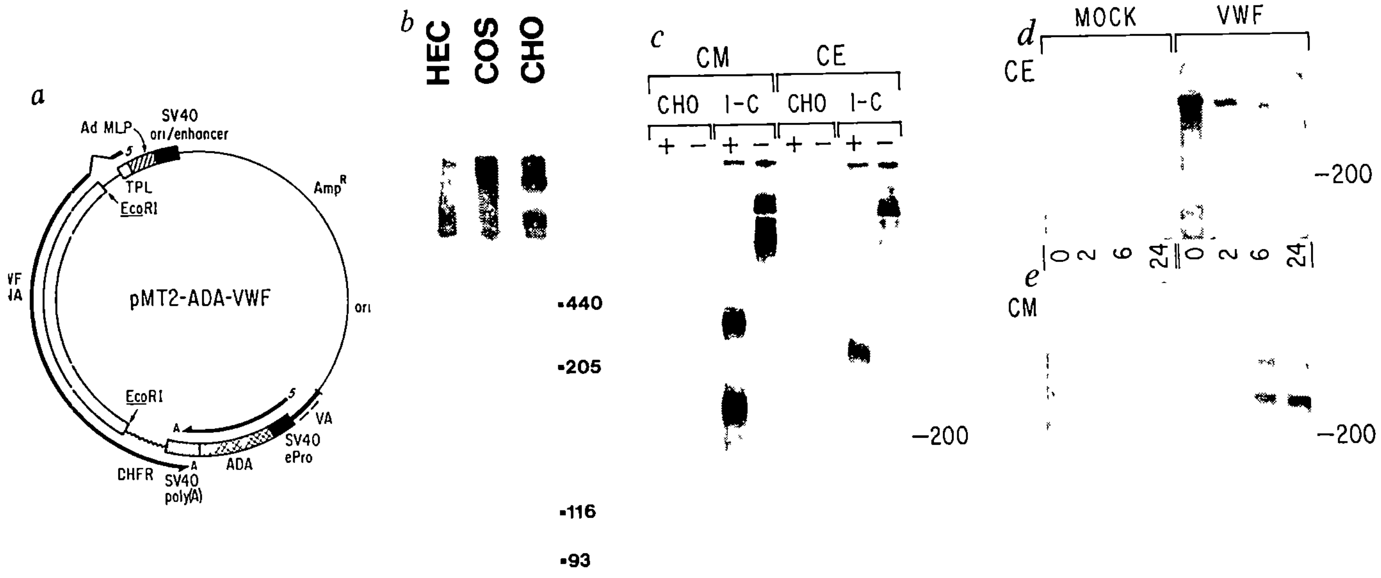

Fig 2 Expression of vWF cDNA *a*, Plasmid pMT2ADA-vWF used for expression in CHO cells It is similar to pMT2-vWF, but contains in addition a human adenosine deaminase (ADA) transcription unit AdMLP, adenovirus major late promoter, TPL, tripartite leader VA genes ePro, simian virus 40 (SV40) early promoter *b–e*, Analysis of immunoprecipitated material from cell extracts or conditioned medium of passaged human endothelial cells (HEC), COS cells or CHO cells *b*, Immunoprecipitates from conditioned medium analysed unreduced on a 4 3% gel (extended run time) *c*, Labelled immunoprecipitates from conditioned medium (CM) or cell extracts (CE) of CHO cells (untransfected) and the transfected, ADA-selected line 1−C, with (+) or without (−) reducing agent *d*, Pulse-chase of ^{35}S-labelled material from transfected or mock-transfected COS cell extracts *e*, Pulse-chased material in conditioned medium from the same experiment

Methods Segments of overlapping cDNA clones[32] were recombined as follows pvWH33 from the 5′ *Eco*RI linker to the unique *Bam*HI site, pvWE6 from the *Sac*II site to the 3 *Eco*RI linker, pvWH5 between the above *Bam*HI and *Sac*II sites The full-length cDNA in plasmid pUC13[39] was designated pvWF2 For transient expression in COS cells, the *Eco*RI fragment containing the entire coding region was transferred to the expression vector pMT2, generating pMT2-vWF pMT2 is a derivative of the mammalian cell expression vector p91023(B)[40] in which the ampicillin resistance marker has replaced the tetracycline resistance marker pMT2-vWF was grown in *Escherichia coli* DH5 (*recA*) to prevent deletion of vWF sequences The expression vector used for CHO cells was constructed by inserting a *Pvu*II/*Hin*fI fragment from pSV2 ADA (Ia)[41], containing the SV40 early promoter and human ADA coding region, into a unique *Xba*I site in pMT2 This generated a transcription unit that uses the SV40 late polyadenylation signal present in pMT2 for expression of ADA The vWF cDNA fragment was then inserted at the unique *Eco*RI cloning site to generate pMT2ADA-vWF (*a*) Protoplasts of *E coli* DH5 carrying pMT2ADA-vWF were fused to CHO cells as described[42] After 2 days, the cells were subcultured into selective medium containing 1 1 mM adenosine, 1 mM uridine, 50 μM alanosine and 0 1 μM 2′ deoxycoformycin[20] Transformants (~100) were pooled and propagated sequentially in 0 5 and 1 0 μM 2′ deoxycoformycin to select for amplification of the ADA and vWF cDNAs One such line obtained was designated 1−C For assay of vWF, these cells were rinsed and incubated for 24 hours in serum-free medium COS cells were transfected with pMT2-vWF or with pMT2 by the DEAE-dextran technique, with chloroquine treatment[43–45] Forty-eight hours after transfection, cells were rinsed and fed serum-free medium for 24 h Culture medium was then collected vWF antigen was measured by an inhibition ELISA, using affinity-purified rabbit anti-vWF antiserum, purified vWF antigen and biotinylated second antibody (goat anti-rabbit IgG) with colour development by avidin–peroxidase complex COS cells were labelled with ^{35}S-cysteine (0 5 mCi ml^{-1}, NEN) for 15 min, 60 h after transfection They were then fed with serum-free medium containing cysteine, and incubated at 37 °C for the times indicated Control CHO cells and the 2′ deoxycoformycin-resistant CHO cells were labelled for 3 h with ^{35}S-methionine (0 5 mCi ml^{-1}), followed by addition of an equal amount of label for a further 3 h CM and CE were prepared for immunoprecipitation as described[46] Immunoprecipitation was carried out with a 1 40 dilution of affinity purified rabbit anti-vWF antibody for 8–12 h at room temperature, followed by either Staphylococcal protein A or goat anti-rabbit IgG immobilized on Sepharose beads After 2 h incubation the beads were washed and taken up in SDS-gel loading buffer with or without 1 mM dithiothreitol, heated to 100 °C and run on 6% (*d–e*) or 4 3% (*b–c*) polyacrylamide gels using the Laemmli buffers[47], followed by drying and autoradiography

adenosine deaminase to amplify the plasmid sequences[21] The cell line obtained (1−C) secretes 4 μg ml^{-1} vWF antigen per 10^6 cells per 24 h as measured by ELISA, a level approaching that of normal plasma (5–10 μg ml^{-1})

Functional vWF multimers are normally assembled only in endothelial cells and megakaryocytes via a complex series of processing steps[3–5] The vWF pro-polypeptide cleavage site, preceded by the basic amino acids Lys-Arg, is similar to the cleavage sites of many prohormones (see, for example, refs 22–27) Although COS cells can correctly process at least one such site[28], the requirements for precursor cleavage have not been defined, and correct removal of the large vWF pro-polypeptide could not be confidently expected Furthermore, the assembly of vWF monomers into disulphide-bonded dimers and subsequently into linear arrays of high M_r multimers might require enzymes or organelles restricted to the specialized cell types that normally secrete vWF

To investigate the post-translational processing of recombinant vWF, we labelled cells with ^{35}S Cys or Met and immunoprecipitated vWF from medium and cell extracts We analysed unreduced immunoprecipitates on 4 3% polyacrylamide gels A series of high M_r bands is seen in medium from passaged human endothelial cells (HEC) and from transfected COS and CHO cells (Fig 2*b*), although the lack of resolution in this region of the gel precludes detailed comparison of the multimer structure On reduction and denaturation, the immunoprecipitated material from the medium (CM) of transfected CHO cells (Fig 2*c*) or COS cells (not shown) runs as the expected two bands of M_r 260K and 220K Control immunoprecipitates from untransfected CHO cells are negative (Fig 2*c*, lanes 1, 2) Cell lysates (CE) contain predominantly the precursor species (Fig 2*c*, lane 7), which appears slightly smaller than the precursor seen in conditioned medium, in accord with previous observations on endothelial cells[5] In pulse-chase experiments on transfected COS cells (Fig 2*d*, *e*, cell extract and conditioned medium, respectively), labelled vWF, predominantly in the processed form, is present in the cell medium from 6 h, while the labelled precursor disappears from the cell extracts over a similar time period

These studies indicate that cells expressing recombinant vWF not only remove the vWF pro-polypeptide but can assemble high M_r disulphide-bonded multimers from the cleaved product To assess the functional properties of recombinant vWF, we examined its interactions with platelet glycoprotein Ib and with collagen Binding of native vWF multimers to these two macromolecules results in attachment of platelets to vascular

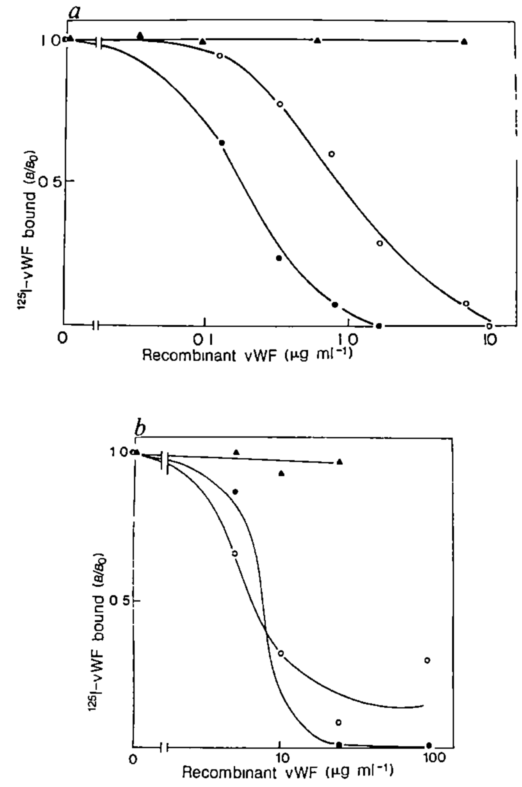

Fig 3 Biological activity of recombinant vWF The ability of culture media derived from COS cells transfected with pMT2 or pMT2-vWF to compete with purified native vWF for binding to platelet glycoprotein Ib (GpIb) or to collagen coated monolayers is shown *a*, Competition for binding to collagen-coated monolayers (closed circles) is compared with competition by purified plasma vWF (open circles) *b*, Competition for binding to GpIb using ristocetin to induce binding to freshly prepared washed platelets (closed circles) or formalin-fixed platelets (open circles) The control supernatants did not compete in either experiment (triangles)

Methods vWF multimers were purified from normal human plasma and iodinated by the Iodobead technique[29] To raise the concentration of recombinant vWF from COS cells sufficiently to carry out the radioligand assays, 50-100 ml conditioned medium was dialysed against 50% Ficoll for 6 to 8 h, and the 10 fold-concentrated samples were reassayed with the inhibition ELISA For analysis of GPIb binding, platelets were washed free of plasma and used immediately or treated with 1% paraformaldehyde and stored at 4 °C for several weeks Binding of ^{125}I-vWF was induced by the addition of 1 5 mg ml^{-1} final concentration of ristocetin, as previously described[29] For the collagen binding assays, a 1 mg ml^{-1} solution of acid-soluble types I and III collagen at *p*H 3 0 was added to the wells of an Immulon microtitre plate Unbound collagen was aspirated after 1 h, and the wells washed with a series of buffered solutions to raise the *p*H to 7 4 Labelled vWF and competing ligand were added to the wells, and after 1 h at room temperature unbound material was removed by aspiration and several washes with 150 mM NaCl, 10 mM Tris, *p*H 7 6 The wells were then detached from the plate and bound radioactivity determined In previous studies binding was found to be specific, saturable and reversible, and to require vWF multimers and native collagen[30]

subendothelium We used concentrated COS cell supernatants as competing ligand against purified, ^{125}I-labelled human plasma vWF multimers under conditions in which native vWF binds specifically and saturably (Fig 3, refs 29, 30) The concentration of recombinant vWF displacing 50% of native vWF from collagen (IC$_{50}$) is 0 2 μg ml^{-1}, fivefold lower than the IC$_{50}$ obtained using purified human vWF For GP Ib binding, the IC$_{50}$ for recombinant vWF (Fig 3*b*) and plasma vWF (not shown) are equivalent (5-7 μg ml^{-1}) Control medium from cells transfected with the vector pMT2 does not compete (Fig 3*a*, *b*, solid triangles) Multimeric recombinant vWF thus exhibits similar activity to native vWF in two relevant bioassays

The availability of vWF cDNA clones[31-33] permits new experimental approaches to the complex biosynthesis of this protein Here, we show that recombinant vWF is processed and secreted in high M_r form by two heterologous cell types The multimer conformation is sufficiently like that of native vWF that the recombinant material competes effectively for binding to platelets and collagen, In fact, recombinant vWF competes more effectively than vWF derived from human plasma for binding to collagen, possibly because some of the highest M_r and most active multimers are lost during purification of plasma vWF, whereas recombinant vWF was not fractionated or chromatographed before analysis This suggests that assembly of vWF multimers is directed largely by the sequence of the primary translation product rather than by endothelial- or megakaryocyte-specific machinery More detailed analysis of the structure of recombinant vWF multimers is in progress

Our analysis reveals similarities between the mature vWF subunit and the large vWF pro-polypeptide These two related glycoproteins are both secreted after cleavage[6], but possible functions of the pro-polypeptide in the circulation, or in linkage of the N-termini of dimers during multimer assembly, remain undefined Site-directed mutagenesis and expression of the cDNA in cultured cells can now be used to identify features of pro-vWF that are important for its processing and biological activity

This work was partly supported by NIH grants to R I H and S H O We thank Patricia Murtha and Monique Davies for technical help, and Dr Robert Wise for comments and discussion S H O is an Investigator of the Howard Hughes Medical Institute

The diurnal variation in the activity of ribulose-1,5-bisphosphate carboxylase (RuBPCase), the major CO_2-fixing enzyme in plants, has been shown to result from the influx and efflux of Mg^{2+} ions into and out of the chloroplast stroma. A recent re-examination of the phenomenon indicates that the inactivation of the enzyme, rather than being due to the efflux of Mg^{2+}, is correlated in some plant species with an increase in the concentration of an organic phosphate ester in the chloroplast in the dark[1-3]. We have purified this potent inhibitor from dark-treated potato (*Solanum tuberosum*) leaves, and established that its structure is 2-carboxy-D-arabinitol-1-phosphate, a molecule that closely resembles an intermediate in the carboxylase reaction of RuBPCase.

The method used to isolate the inhibitor from dark-treated plant material exploited its affinity for the active enzyme The carboxylase was extracted and purified in buffer containing CO_2 (HCO_3^-) and Mg^{2+} so that the inhibitor remained bound The specific carboxylase activity of the enzyme at the first stages of purification was only 40% that of the enzyme purified from leaves during the day This activity could be more than doubled by treatment with sulphate to release the inhibitor from the enzyme[1] Full details of the purification procedure are given in the legend to Table 1 Figure 1 shows the inhibition of purified wheat RuBPCase as a function of the total phosphate content of the purified inhibitor at various dilutions Maximum inhibition was seen at inhibitor concentrations stoichiometric with those of the enzyme's active site

There are a number of phosphate esters synthesized in the chloroplast[4] (for example, 6-phosphogluconate) that may act as potent inhibitors of the carboxylase The purified inhibitor was compared to such compounds by thin layer chromatography on cellulose powder and in several solvent systems The R_f values of the natural inhibitor and its dephosphorylated product indicated that it was unlike any of the phosphorylated sugars or sugar alcohols usually found in plants

Table 1 Inhibitor purification from dark-harvested potato leaves

Fraction	Weight of dry residue (mg)	Total phosphorus (μg atom)
Extract in 80% methanol	1,500	11 9
Sephadex G-10 column	92	10 6
Polar fraction from C_{18} Sep-Pak	16	7 6
QAE-A25 column	1 7	6 1

To obtain enough material for detailed analysis, 1 kg of potato leaves were collected early in the morning and the soluble proteins extracted at *p*H 8 0 in a buffer containing 20 mM $MgCl_2$ and 20 mM $NaHCO_3$ RuBPCase with the inhibitor bound was isolated from the plant debris as a precipitate using polyethylene glycol The precipitate was redissolved in a minimum volume of the activation buffer, 0 1 M bicine *p*H 8 0 containing 20 mM $MgCl_2$ and 20 mM $NaHCO_3$ Further purification was achieved by chromatography on an S400 (Pharmacia) gel filtration column The inhibitor was released from the enzyme by addition of methanol to give a final concentration of 80% v/v Precipitated protein, 1 3 g, was removed by centrifugation and re-extracted with further additions of 80% methanol The combined extracts were concentrated and desalted into a volatile buffer (10 mM NH_4HCO_3) using a Sephadex G-10 column and those fractions exhibiting the strongest inhibition of wheat RuBPCase were evaporated to dryness This step removed $MgCl_2$ introduced with the buffer used in extraction and purification of the potato enzyme The residue was dissolved in distilled water, adjusted to *p*H 4 0 with formic acid, and further purified by passage through a C_{18} Sep-Pak column (Waters) The final treatment was consecutive ion-exchange chromatography using anionic and cationic columns[9] The resulting compound, dried to constant weight, was suitable for spectrophotometric analysis

A sample containing 2 5 μmol of the inhibitor (based on total phosphate) was dissolved in 0 4 ml of D_2O (*p*D ~ 3 0) and the solution was examined by proton NMR spectroscopy using a Bruker 500 MHz instrument The spectrum consists of a number of multiplets arising from only six protons associated with four C centres Selective irradiation spin decoupling experiments indicate that three of these centres are adjacent to one another Consideration of the spin coupling constants and the chemical shifts for these protons suggests a structure of $HOCH_2$-CH(OH)-CH(OH)- The remaining multiplets correspond to a pair of methylene protons that are not coupled to the other protons in the molecule and have chemical shifts and additional splittings ($J_{^{31}P-^{1}H} = 5$ Hz) characteristic of a $-CH_2OPO_3^{2-}$ group[5] Thus the inhibitor has the general structure CH_2(OH)-CH(OH)-CH(OH)-X-$CH_2OPO_3^{2-}$ The NMR spectrum is *p*H dependent, consistent with the presence of a carboxylic acid group as a branch to the carbon chain, and at low *p*H cyclization to a lactone ring can occur X was therefore considered to be a quaternary carbon with a carboxylic group, that is >C(OH)-CO_2^- This suggested that the compound might be similar to the potent carboxypentitol inhibitors 2-carboxyarabinitol-1,5-bisphosphate and 2-carboxyribitol-1,5-bisphosphate (2CABP and 2CRBP, respectively) but with a single phosphate group at the 1 position

The confirmation that the natural inhibitor must be a 2-carboxy pentitol-1-phosphate was achieved by first dephos-

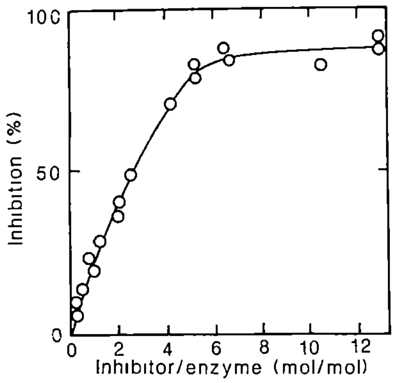

Fig 1 Inhibition of carboxylase activity of purified wheat RuBPCase[8] by the inhibitor from potato leaf The carboxylase was activated (2 mg ml^{-1}) in 0 1 M bicine, *p*H 8 2 at 40 °C for 40 min in the presence of 10 mM $NaHCO_3$ and 20 mM $MgCl_2$ Samples of this solution (20 μl) were mixed with 20 μl of a solution containing the inhibitor After at least 2 min, 20 μl of the mixture was assayed for carboxylase activity at 25 °C The inhibitor concentration is based on the phosphate content of the solutions

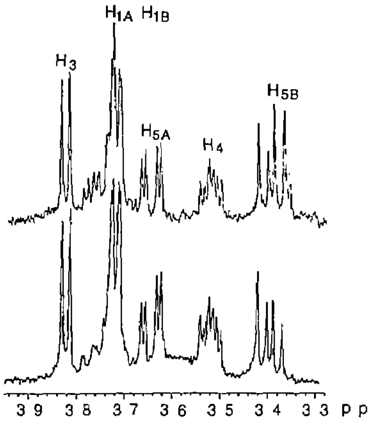

Fig. 2 The proton NMR spectrum at 500 MHz of 2-carboxyarabinitol-1-phosphate. *a*, The natural compound, isolated by dissociation from the active site of RuBPCase and then purified as outlined in the legend to Table 1. *b*, The spectrum of the monophosphate synthesized from 2-carboxyarabinitol-bisphosphate by partial hydrolysis with alkaline phosphatase (S.G. and M.A.J.P., unpublished data). The chemical shifts are given in Table 2. The *p*D of the samples was 8.0 and hence the spectra are for the open chain form.

phorylating the compound with alkaline phosphatase and then producing the trimethyl silylated derivative for examination by gas chromatography mass spectrometry. One of the major silylated products has an ion ($m/z = 613$, M-15$^+$) that is consistent with a fully trimethyl silylated derivative of carboxypentitol. A second ion ($m/z = 466$, M$^+$) was also observed corresponding to the trimethyl silylated lactone form of a carboxypentitol. The same molecular ions were produced when 2-carboxyarabinitol was synthesized from 2CABP by phosphatase treatment and silylated under the same conditions.

There are four epimers that satisfy the general structure described above. The natural compound could be 2-carboxyarabino- or 2-carboxyribo- stereoisomers (epimeric about C_2) or 2-carboxylyxitol or 2-carboxyxylitol monophosphates (epimeric about C_3). To distinguish between these possibilities, the bisphosphates were synthesized as previously described[6,7], the phosphate groups were removed and the proton spectra of the resulting acids compared to the dephosphorylated natural inhibitor. It is quite clear from the chemical shifts of the protons (Table 2) that the compound is identical to 2-carboxy-D-arabinitol, therefore, the natural phosphate ester is 2-carboxy-D-arabinitol-1-phosphate. Its proton spectrum is shown in Fig. 2 along with the spectrum of the monophosphate synthesized from 2CABP.

2-carboxyarabinitol-1-phosphate has many features enabling it to act as a potent and yet reversible inhibitor of RuBPCase. It closely resembles the 2-carboxy-3-ketoarabinitol-1,5-bisphosphate intermediate of the carboxylase reaction (see Fig. 3). However, unlike 2CABP the absence of a second phosphate group on the primary alcohol group at the five position ensures that it does not become bound irreversibly to the active site. The response of RuBPCase to effectors, particularly transition state analogues, in terms of activation and activity *in vitro* have been exhaustively studied (see ref. 4 for a review), but this is the first report of a compound with this type of structure functioning in this way in the chloroplast. The function of the transition state analogue as an inhibitor of RuBPCase *in vivo* is unknown. During normal photosynthesis, the enzyme is activated by carbamylation with CO_2 thus forming the binding site for the essential Mg^{2+} ion. The substrate, ribulose bisphosphate, binds to the active site and the close interaction with the metal initiates the catalytic process[5]. However, if the substrate binds to the active site before the reaction with CO_2 and Mg^{2+} it very effectively blocks the activation process. An inhibitor that can dissociate from the active site and yet is preferentially bound to the activated form of the enzyme, might serve to stabilize this conformation during periods of reduced light or in darkness to ensure it is primed for rapid substrate turnover when photosynthesis recommences. Certainly, the rates of appearance and disappearance of the inhibitor are consistent with such a function.

Fig. 3 The structure of the natural inhibitor 2-carboxyarabinitol-1-phosphate compared to a reaction intermediate of the carboxylase reaction of RuBPCase.

The metabolic precursor of the inhibitor has not yet been determined. The inhibitor must be a major component of dark-induced metabolism because the concentration of RuBPCase active sites in the stroma is at least 3 mM and therefore 2-carboxyarabinitol-1-phosphate must accumulate to these concentrations to cause significant inhibition. The inhibition of the enzyme at night has not been detected in all plants[3]. Until the biosynthetic enzymes that regulate the inhibitor concentration

Table 2 Chemical shifts* in p.p.m. relative to dioxane of the natural inhibitor, the dephosphorylated derivative and synthetic compounds

Compound	C-1 A	C-1 B	C-3	C-4	C-5 A	C-5 B

* Overlapping multiplets are shown as a range of p.p.m. values.

are identified, it will be unclear whether the absence of inhibition is due to rapid turnover or the lack of an available pool of precursors Alternatively, RuBPCase enzymes from different plant species may have different affinities for 2-carboxyarabinitol-1-phosphate, either intrinsically or because of competition with other endogenous phosphate esters Nevertheless, it is likely that this molecule is the natural inhibitor common to all plants that exhibit diurnal RuBPCase regulation In support of these observations, we have been informed that 2-carboxyarabinitol-1-phosphate has also been identified as the inhibitor bound to ribulose bisphosphate carboxylase in *Phaseolus vulgaris* at night[10]

We thank Roger Moffitt and the farm staff at Rothamsted for allowing unscheduled collection of leaves from potato plants and Dr N F Janes for discussion of the chemical evidence

Hepatocellularcarcinoma (HCC) that occur in woodchucks chronically infected with woodchuck hepatitis virus (WHV) were screened for activation of cellular oncogenes. Enhanced expression and allelic alterations of the c-*myc* oncogene were found in three HCC out of nine. Variations in the size of the c-*myc* transcripts, ranging from 2.0 kilobases (kb) to 5 6 kb, as well as in the level of c-*myc* gene expression, 5–50-fold higher than in adjacent liver tissues, were observed among the three HCC. Rearrangements of the c-*myc* locus were either upstream of the gene or within the first intron. Cloning and sequencing of the break-point region from one of the three tumours showed that the c-*myc* gene was truncated and joined to a unique cellular sequence of unknown function. WHV DNA was not integrated near the c-*myc* coding exons, excluding a direct role of the virus in c-*myc* activation. The novel type of rearrangement and activation of the c-*myc* gene, reported here in liver tumours of hepatitis virus infected animals, appears strikingly similar to those resulting from chromosomal translocations in human Burkitt's lymphomas, acute B- and T-cell leukaemias and mouse plasmacytomas.

Total RNA recovered from HCC and adjacent liver tissues of woodchucks chronically infected with WHV was screened for expression of cellular oncogenes by RNA dot-blot hybridization and Northern blotting Similar low levels of transcription were observed in tumours and non-tumorous liver for most oncogenes tested (*abl*, *erb-A*, *erb-B*, *ets*, *fes*, *fms*, *myb*, *mos*, *raf*, Ha-*ras*, Ki-*ras*, N-*ras*, *sis* and *src*, not shown) The level of c-*myc* transcripts was markedly increased in three of nine HCC compared with the non-tumorous parts of the same livers (Fig 1) Polyadenylated RNA from the tumorous and non-tumorous parts of the livers of woodchucks W74, W93 and W64 was analysed by Northern blotting (Fig 1) using probes representa-

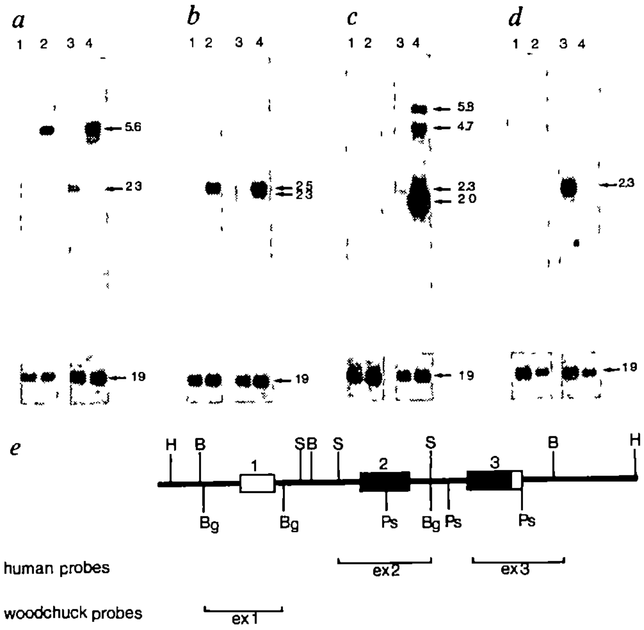

Fig 1 Northern blot analysis of c-*myc* mRNA from three woodchuck HCC and adjacent liver tissues Polyadenylated RNA from HCC (lanes 2, 4) and adjacent liver tissues (lanes 1, 3) of woodchucks (*a*, W74, *b*, W93, and *c*, W64), *d*, poly(A)$^+$ RNA from the human promyelocytic cell line HL60[24,25] (lanes 1, 3) and normal liver of woodchuck W20 (lanes 2, 4), Lanes 1 and 2 were probed with c-*myc* exon 1, lanes 3 and 4 were probed with c-*myc* exon 2 Restriction enzymes B, *Bam*HI, Bg, *Bgl*II, E, *Eco*RI, H, *Hin*dIII, Ps, *Pst*I and S, *Sac*I *e*, Restriction map of a molecularly cloned woodchuck c-*myc* gene

Methods *a*–*d*, Poly(A)$^+$ RNA was prepared as described elsewhere[21] Two identical samples of each RNA (5 μg for *a* and *d*, 10 μg for *b* and *c*) were electrophoresed in the same formaldehyde-agarose gel and blotted to nitrocellulose filters as previously described[26] The filters were prehybridized for 4 h at 42 °C in 50% formamide, 5 SSC, 50 mM NaH_2PO_4 *p*H 6 5, 1 × Denhardt's solution and 250 μg ml^{-1} sonicated, denatured salmon sperm DNA They were hybridized for 16–24 h with 10^6 c p m ml^{-1} of ^{32}P-labelled nick-translated probes (specific activity was routinely 2–5 × 10^8 c p m), after addition of 1/4 volume of 50% dextran sulphate The filters were washed twice in 0 1 SSC, 0 1% SDS at 60 °C for 30 min for hybridization with c-*myc* exon 1, or in 0 2 SSC, 0 1% SDS for hybridizations with c-*myc* exon 2, dried and exposed to Kodak XAR5 films with an intensifying screen at −70 °C for 48 h The filters were subsequently hybridized with the murine *β*-actin gene[27] to check for uniform loading (lower panels *a*–*d*) *e*, The positions of exons 1, 2 and 3 (boxes) were determined by hybridization with murine exon 1 and human exons 2 and 3 The boundaries of woodchuck *myc* exons were tentatively located by comparing conserved restriction sites in the woodchuck, human and murine c-*myc* genes, assuming similar organization of c-*myc* in the three species Only relevant restriction sites are shown Human c-*myc* exons 2 and 3 probes were a 1 5-kb *Sac*I fragment and a 1 6-kb *Cla*I fragment purified from a plasmid constructed in pKH47, a gift from Dr Stehelin The c-*myc* probe containing exon 1 was a 1 4-kb *Bgl*II fragment purified from a cloned woodchuck c-*myc* gene Hybridization signals obtained with a probe of murine c-*myc* exon 1 (a 0 4-kb *Bam*HI/*Sac*I fragment of pMc-myc 54 (ref 28)) were identical in position but very weak, indicating substantial divergence between murine and woodchuck c-*myc* exons 1, and therefore are not shown

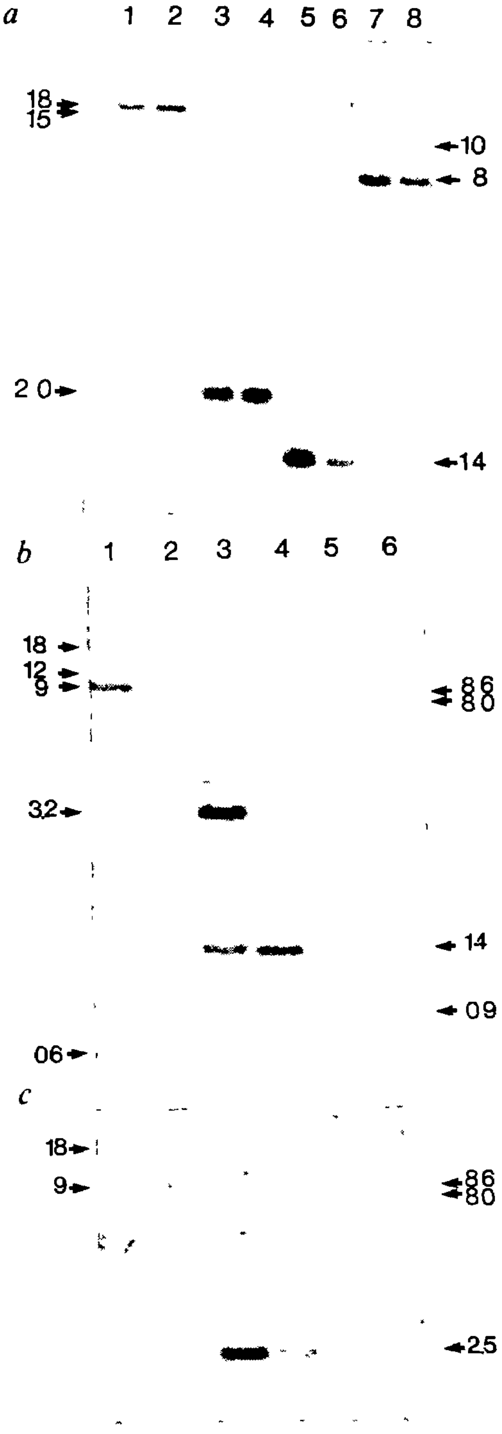

Fig 2 DNA rearrangement at the c-*myc* locus in W74 HCC and W93 HCC *a*, Hybridization of W74 HCC and W20 liver DNA with c-myc exon 1, *b*, hybridization of W93 tumour and non-tumour liver DNA with c-*myc* exon 1, *c*, subsequent hybridization of the same filter with c-*myc* exon 2 *a*, Cellular DNA (30 μg) from W74 HCC (lanes 1, 3, 5, 7) or W20 normal liver (lanes 2, 4, 6, 8) was digested with 1, 2, *Eco* RI, 3, 4, *Bam*HI, 5, 6, *Bgl*II, 7, 8, *Hin*dIII *b,c*, DNA from W93 tumour (lanes 1, 3, 5) and non-tumour (lanes 2, 4, 6 liver samples was digested with 1, 2, *Eco*RI, 3, 4, *Bgl*II, 5, 6, *Hin*dIII Southern blotting was performed as described[21] For probes and conditions of hybridization see Fig 1 legend The restriction pattern of DNA from the non-tumorous part of W74 liver was identical to that of W20 liver DNA and thus is not shown The sizes of the c-*myc*-containing fragments are given in kb DNA size markers were bacteriophage λ DNA digested with *Hin*dIII and double digested with *Eco*RI and *Hin*dIII The blots were exposed to X-ray films for 5 days The filters were reprobed with ^{32}P-labelled pBR322 DNA to ensure that all bands were *myc*-specific

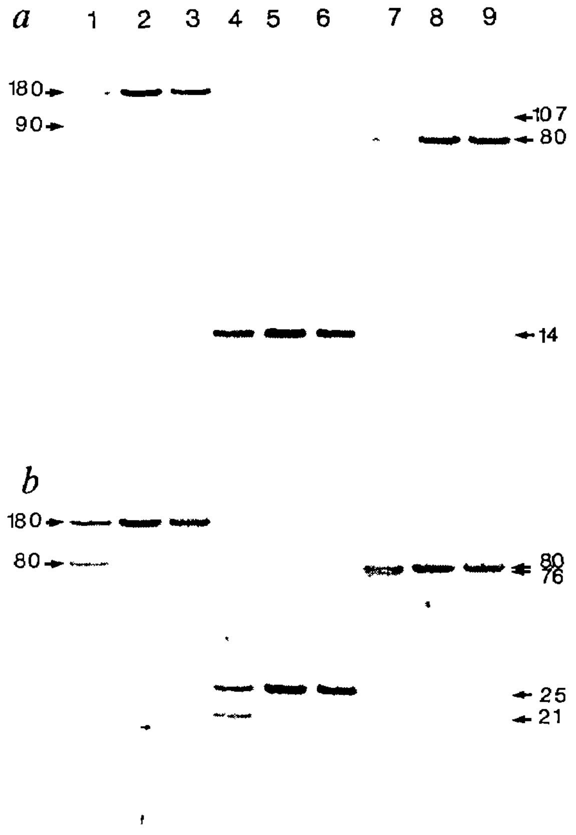

Fig. 3 DNA rearrangement at the c-*myc* locus in W64 HCC *a*, Southern blotting analysis of genomic DNA from W64 HCC (lanes 1, 4, 7), non-tumorous parts of W64 liver (lanes 2, 5, 8 and W20 normal liver (lanes 3, 6, 9) probed with *myc* exon 1 Lanes 1-3 are digestions with *Eco*R1, lanes 4-6 with *Bgl*II, and lanes 7-9 with *Hin*dIII (Figs 1 and 2 legends) *b*, The same filter was rehybridized with *myc* exon 2 Hybridization of the filter with a probe derived from pBR322 did not reveal any band Sizes in kb

tive of woodchuck c-*myc* exon 1 and human c-*myc* exons 2 and 3 The results obtained with *myc* exon 3 probe (not shown) were identical to those of *myc* exon 2 Densitometric analysis indicated that c-*myc* RNA levels were elevated at least 5-, 10- and 50-fold in W74, W93 and W64 HCC, respectively compared with the corresponding adjacent liver tissues from the same animal The level of c-*myc* transcription was below the threshold of detection in normal adult woodchuck liver The same probes revealed abundant 2 3-kb c-*myc* transcripts in the RNA of human HL60 cells (Fig 1*d*) However, hybridization of HL60 RNA with a c-*myc* exon 1 probe of woodchuck origin gave a considerably weaker signal than with the human c-*myc* exon 2 probe.

In contrast with the apparently normal 2 3-kb c-*myc* RNA found in the non-tumorous parts of the livers, the tumours produced c-*myc* transcripts of different sizes W74 HCC produced a major 5 6-kb c-*myc* RNA which annealed to all three c-*myc* exons (Fig 1*a*) The c-*myc* transcripts in W93 HCC also hybridized with all three c-*myc* exons (Fig 1*b*), they migrated as a heterogeneous population of 2 3-2 5 kb, slightly larger than normal This could reflect a shift in c-*myc* promoter usage from P2 to P1, as seen in Burkitt's lymphomas[1,2] and murine plasma cell tumours[3] W64 HCC had a major truncated 2 0-kb c-*myc* messenger RNA, and two minor mRNAs of 5 8 and 4 7 kb (Fig 1c) These RNAs annealed to human c-*myc* exons 2 and 3, but not to woodchuck c-*myc* exon 1 (Fig 1*c*), indicating that the normal transcriptional unit was disrupted in the tumour as has been reported for B-lymphoid tumours[4-7]

Fig 4 *a*, Schematic representation of the normal woodchuck c-*myc* allele Brackets, the recombination break points for the W74 HCC and W93 HCC as deduced from genomic blot studies, arrow, the precise breakpoint for W64 HCC (determined by molecular cloning and sequencing) The normal c-*myc* gene was mapped from restriction endonuclease digests of cloned DNA from W64 HCC as described (Fig 1 legend) Scale bar, 1 kb *b*, Mutant c-*myc* allele of W64 and sequence analysis of the break-point region Unshaded bar, incoming cellular sequences, small bar, probe s/bg, lower panel, enlargment of the region between *Bgl*II and *Sac*I sites The sequence of the mutant c-*myc* allele in the break-point area (W64 HCC) was aligned with the corresponding sequences of the normal c-*myc* intron 1 from woodchuck (W c-*myc*) and man (H c-*myc*) Asterisks, homologous nucleotides, arrow, breakpoint for W64 HCC *c*, Southern blotting analysis of *Hin*dIII-digested DNA from lanes 1, 4 W64 HCC, 2, 5, W64 non-tumorous part of liver, 3, 6, W20 normal liver Hybridization was performed as described (Fig 2 legend) Lanes 1-3 were probed with the 1 7 kb *Sac*I-*Bgl*II fragment located immediately upstream of the break point (small bar, Fig 4*b*), lanes 4-6 were probed with c-*myc* exon 2 Asterisks denote the tumour-specific fragment of 2 6-kb which also hybridizes with exon 2 (see Fig 3) *d*, Northern blotting analysis of total cellular RNA Lane 1, non-tumorous part and lane 2, tumorous part of W64 liver, lane 3, normal liver W101, lane 4, normal liver, W20 Hybridization to the s/bg probe was as described in Fig 1 legend

Methods Total cellular DNA from W64 HCC was partially digested with *Sau*3A 10-20-kb fragments were selected and ligated to the *Bam*HI-digested arms of the vector λ-L47 1 A library (2×10^6 phages) was screened with the human c-*myc* exons 2 and 3 (see Fig 1*e*), using the Benton and Davies *in situ* hybridization procedure[29] Eleven independent clones were obtained and analysed by restriction mapping and hybridization Five clones covered the entire normal c-*myc* gene as represented in Fig 4*a* Three clones retained c-*myc* exons 2 and 3 but contained non-*myc* sequences upstream of exon 2 The restriction map of the mutant c-*myc* allele was established from the DNA of these three clones (*b*), and is consistent with the data obtained by Southern blotting (Fig 3) The 2 3-kb *Sac*I fragment of the mutant allele, encompassing the break-point region was subcloned in a plasmid vector and further cloned into the M13 phage vector mp8, using the method of Deininger *et al*[30] The 0 7-kb *Sac*I fragment from the normal c-*myc* intron 1 was directly subcloned in M13 tg130 The sequencing reactions were performed as described by Sanger *et al*[31]

Cellular DNA from W74, W93 and W64 HCC was analysed for rearrangement or amplification of the c-*myc* locus Figure 2 compares Southern blots of genomic DNA from W74 and W93 HCC with W20 normal liver and with the non-tumorous part of W93 liver, respectively Additional c-*myc* bands were revealed in these HCC, indicating that a c-*myc* allele has been rearranged in the tumour cells The novel DNA fragments were not due to polymorphism in the length of restriction fragments, since identical normal c-*myc* bands were detected in DNA samples from the non-tumorous parts of livers W74 and W93 and from W20 (Fig 2) and 16 other woodchuck livers (not shown) Using woodchuck *myc* exon 1 as a probe, tumour-specific fragments were observed in *Eco*RI and *Hin*dIII digests of W74 HCC DNA, but not in *Bam*HI and *Bgl*II digests (Fig 2*a*) Hybridization with *myc* exons 2 and 3 revealed the same novel *Eco*RI and *Hin*dIII fragments and normal 2 5-kb and 4 1-kb *Bgl*II bands (not shown) Comparison of genomic blot analysis of W74 HCC DNA with the restriction map of a cloned normal woodchuck c-*myc* allele suggests a recombination event outside, and probably upstream of, the c-*myc* gene (Fig 4) In W93 HCC, novel 9-kb *Eco*RI and 8 6-kb *Hin*dIII fragments hybridized with *myc* exons 1 and 2 probes, and the faint 12-kb *Eco*RI and 0 9-kb *Hin*dIII fragments with *myc* exon 1 probe only (Fig 2*b*,*c*) Tumour-specific *Bgl*II bands were revealed only after hybridization with *myc* exon 1 This suggests a complex recombination event, next to the 5′ end of the c-*myc* gene

(Fig 4) Southern blot analysis of DNA isolated from different parts of W93 HCC revealed that rearrangements of the c-*myc* locus were restricted to one part of the tumour, this tumour was thus oligoclonal Enhanced expression of c-*myc* was found only in the tumour samples in which the c-*myc* gene was altered In contrast, W64 and W74 HCC appeared monoclonal after several blot experiments (results not shown)

W64 HCC also showed rearrangement at the c-*myc* locus (Fig 3) The probes for *myc* exons 1 and 2 annealed with the same normal *Eco*RI fragment, but with distinct tumour-specific bands This was also observed with *Hin*dIII digests The results obtained using a *myc* exon 3 probe (not shown) were identical to those for *myc* exon 2 Digestion with *Bgl*II revealed a novel band specific to *myc* exon 2 (Fig 3*b*) The c-*myc* DNA rearrangement in W64 HCC thus takes place within the first intron or the second exon The faint signals observed for tumour-specific fragments annealing to woodchuck *myc* exon 1 may indicate a partial loss of rearranged *myc* exon 1 We cloned the rearranged c-*myc* allele from a λ phage library of W64 HCC DNA, and located the recombination site in c-*myc* intron 1 by restriction mapping (Fig 4*b*) A 2 3-kb *Sac*I fragment, encompassing the joining region between c-*myc* and partner sequences, was subcloned and sequenced We compared this sequence with those of normal c-*myc* alleles from woodchuck (cloned from W64 HCC DNA) and man[8] Figure 4*b* (lower panel) shows that the breakpoint occurs 505 nucleotides upstream of the *Sac*I site nearest to the 5′ boundary of *myc* exon 2, which is found in both species Thus the mutant c-*myc* allele retains the cryptic promoters and initiation sites of intron 1, which are used for the transcription of truncated c-*myc* genes in human Burkitt's lymphoma[9], acute B-cell leukaemia[10], and murine plasmacytomas[5,7] In such cases, as in the woodchuck tumour, recombination *myc* exon 1 or intron 1 results in the production of novel RNA species that are shorter than the normal c-*myc* transcripts[11]

To improve our understanding of the mechanisms of c-*myc* activation in this tumour, we characterized the invading sequence next to the c-*myc* coding exons Hybridization studies of the cloned mutant c-*myc* allele from W64 HCC, using pWHV-1 as a probe[12], showed that there were no WHV sequences in the 5-kb regions flanking the 5′ and 3′ sides of the c-*myc* gene (not shown) A 1 7-kb *Sac*I-*Bgl*II fragment (denoted s/bg in Fig 4*b*) immediately next to the rearranged c-*myc* gene was used to probe Southern blots of W64 and W20 DNA, and revealed a unique 17-kb *Hin*dIII band in normal woodchuck liver DNA Another tumour-specific fragment of 7 6 kb in W64 HCC DNA annealed with both s/bg and *myc* exon 2 (Fig 4*c*) Further blot studies showed that the s/bg probe anneals to a unique sequence in the human genome (results not shown) The same probe revealed an abundant 4 6-kb transcript in W64 and normal W101 and W20 livers (Fig 4*d*) and other woodchuck livers (not shown) In W64 HCC, it also annealed to a 5 8-kb transcript migrating at the same position as the longer minor c-*myc* RNA which could therefore be a co-transcript of s/bg and c-*myc* exons 2 and 3 A computer-assisted search of the Los Alamos database failed to identify the s/bg sequence with any known cellular gene, including the immunoglobulin locus and the T-cell receptor gene

Activation of c-*myc* by different mechanisms has been implicated in a variety of haematopoietic malignancies and carcinomas[13,14] In some solid tumours, c-*myc* amplification[15,16] or rearrangement in a few cases[16] leads to an increased level of expression, but no major alteration of the c-*myc* locus has been reported in rodent liver tumours induced by chemical carcinogens[17] In B and T lymphoid tumours, c-*myc* expression is deregulated by a structural alteration of the gene, either chromosomal translocation[5,10] or insertional mutagenesis with non-acute oncogenic retroviruses[18,19] The DNA rearrangements and enhanced expression of c-*myc* in viral-associated HCC reported here seem quite similar to those found in B and T cell neoplasias It has been proposed that integration of hepatitis viruses in the cellular DNA of their natural hosts, observed almost invariably in liver tumour cells, is critical to HCC development[20] Indeed, Southern blot and cloning data revealed the presence of integrated WHV sequences in the three woodchuck HCC examined here (ref 21 and our unpublished results), but our data exclude c-*myc* activation by insertional mutagenesis in W64 HCC We have no evidence so far for viral insertion near c-*myc* in the other two tumours The recombination of a truncated c-*myc* gene with another cellular gene, described here for W64 HCC, is reminiscent of the reciprocal translocations of c-*myc* and immunoglobulin or T-cell receptor genes which occur in human Burkitt's lymphoma, B- and T-cell acute lymphoid leukaemia and mouse plasmacytoma Furthermore, it has recently been pointed out that in Burkitt's lymphoma and mouse plasmacytoma, c-*myc* alterations occur after a long pre-neoplastic period of chronic cell stimulation, provoked in some cases by Epstein-Barr or Abelson virus[22] A similar situation could result from chronic hepatitis virus infection in woodchuck and man, favouring chromosomal breaks[23] and finally leading to the development of HCC

We thank Dr S Aaronson, S Alonso, E Chang, T Curran, K Marcu, C Sherr and D Stehelin for providing *onc*-specific and actin clones, C Pichoud and C Jacquet for maintenance of woodchucks and surgical biopsies, M Hadchouel for histological examination of tumour tissue, J Robert-Lézènes for helpful discussions, J Davies for a critical reading of the manuscript and L M Da and A Cova for typing the manuscript T M is supported by the Commission of the European Community This work was supported by NIH grant CA 97300-02, the Economic European Community and the Association pour la Recherche contre le Cancer

The role of nucleotide sequences in splice site selection in eukaryotic pre-messenger RNA

L. P. Eperon, J. P. Estibeiro & I. C. Eperon

Department of Biochemistry, University of Leicester,
Leicester LE1 7RH, UK

Alternative splicing of eukaryotic messenger RNA precursors is now known to be of widespread importance in generating multiple transcripts from a single gene. This phenomenon has emphasized the problem of the way in which splice sites are selected; recent studies have discussed the role of secondary structure[1] or affinity and spatial relationships[2] in this selection. Splice site sequences vary widely, although a loose consensus has been derived for the 9 bases around the 5′ splice site and for a longer region around the 3′ splice site[3]. Mutagenesis experiments have defined the sequences essential for a potential 5′ splice site[4,5,6], but, except for some experiments with the *E1a* gene of adenovirus[5,6], these experiments have not examined 5′ splice site sequences for features responsible for site preference where alternative splicing sites exist. Such tests require a choice of site: an appropriate reference site and a constant position at which test sites are introduced. We have begun a series of experiments designed to show whether splice site sequences can be ranked in a hierarchy of preferential use. Here we show that the archetypal consensus sequence is used efficiently, and characterize the cryptic sites of β-globin: sequences alone can explain why these sites are not normally used. We also show with the *E1a* gene of adenovirus, a simple example of alternative splicing, that one of the two 5′ splice sites used by this gene is intrinsically stronger We also demonstrate that tandem repeats and secondary structure influence the choice of sites *in vivo* We discuss the mechanism of splice site selection.

To define a hierarchy of splice site efficiency, we calibrated sequences by competition against a constant reference site An assay was devised involving choice between alternative splice sites contained in short oligonucleotides and the 5′ splice site of the second intervening sequence (IVS-2) of the rabbit β-globin gene (Fig 1*a*) The splicing junction to be assessed was always 25 nucleotides upstream of the authentic site The sequences tested (Table 1) vary at the 5′ splice junction in the last three nucleotides of the exon and first six of the intron, the region defined by the consensus sequence The 'cons' oligonucleotide is composed of the most frequently-used bases at each position in the consensus[3], 'glo' is a replica of the reference site, a necessary control for the effect of position, the 'cry' oligonucleotides contain sequences corresponding to the cryptic β-globin sites which are revealed only when the 'GT' at the beginning of

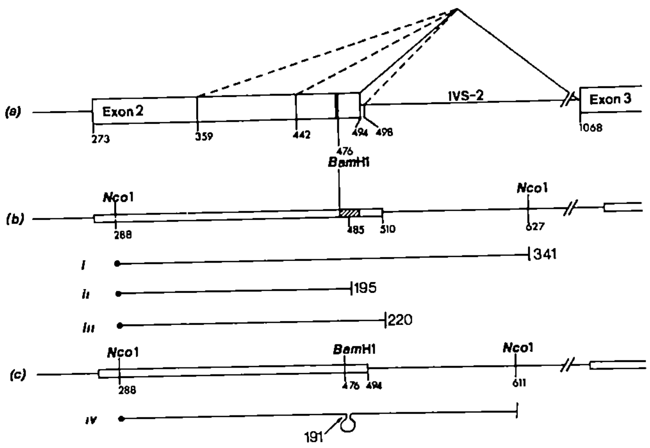

Fig. 1 *a*, Splicing of the second intervening sequence (IVS-2) of rabbit β-globin The boxes represent exons Solid lines between exons, authentic splicing pattern, dashed lines, splicing to cryptic sites when the 5′ splice site of IVS-2 is mutated *b*, explanation of the RNA mapping strategy, *c*, use of *in vitro* RNA corresponding to β-globin gene sequences *a*, The position of the *Bam*HI site into which 16-base oligonucleotide pairs (see Table 1) were cloned is shown The 'cons' and 'cry' paired oligonucleotides were first inserted into the *Bam*HI site of a *Bam*HI-*Bgl*II fragment of the β-globin gene which had been cloned into an M13 vector The *Bam*HI-*Eco*RI oligonucleotide-containing fragment was used to create the appropriate derivative of pβSV via three-way ligations The 'glo' oligonucleotides were inserted as a monomer, dimer (glo^2) and a tetramer (glo^4) directly into pβSV and the recombinants screened using the 'microprep' method This involved growing 96 small cultures in a microtitre plate and preparing the DNA by a modification of the alkaline lysis 'miniprep' method[11] The products were analysed by restriction enzyme digestion All the insertions into pβSV were sequenced using the dideoxy method[12] either directly on the double stranded plasmid or via recloning into M13 vectors *b*, An inserted oligonucleotide is shown by a shaded box, the *Bam*HI site is restored only at the 5′ end of the oligonucleotide (i), Undigested, full length probe, an *Nco*I restriction fragment, 3′ end-labelled by a two nucleotide extension at the staggered end using dCTP and [α-^{32}P]dATP and Klenow polymerase (indicated by a spot) This fragment was separated from other *Nco*I fragments on a 4% or 6% preparative sequencing gel containing 20% formamide (ii), The product after hybridization of the probe to an RNA transcript which has used the new 5′ splice site, and digestion with S$_1$ nuclease (iii), The digested probe when the reference site was used for splicing *c*, A *Pst*I-*Bgl*II fragment was cloned into pSP64, and RNA was trancribed *in vitro* from this (iv), Hybridization of a probe made from β-globin with oligonucleotide inserts to the RNA transcribed *in vitro* Digestion with S$_1$ nuclease would give a 191 nucleotide fragment The RNA made *in vitro* is a valuable size marker

Table 1 5′ Splice site efficiencies

Name	Sequence	Test site (%)	Reference site (%)	Details
glo	GATCCCAGG GTGAGTC	64	36	IVS-2 β-globin 5′ site
cons	GATCCCCAG GTAAGTC	100	0	From the optimal consensus[3]
cry1(498)	GATCCCTGA GTTTGGC	0	100	β-globin cryptics

E1a$_{1111}$	GATCCCACA GTAAGTC	63	37	
Ela$^2_{1111}$		100	0	2 correctly oriented oligonucleotides The 5′-most site is used
E1a$^{comp}_{1111}$		0	100	1 complementary sense oligonucleotide

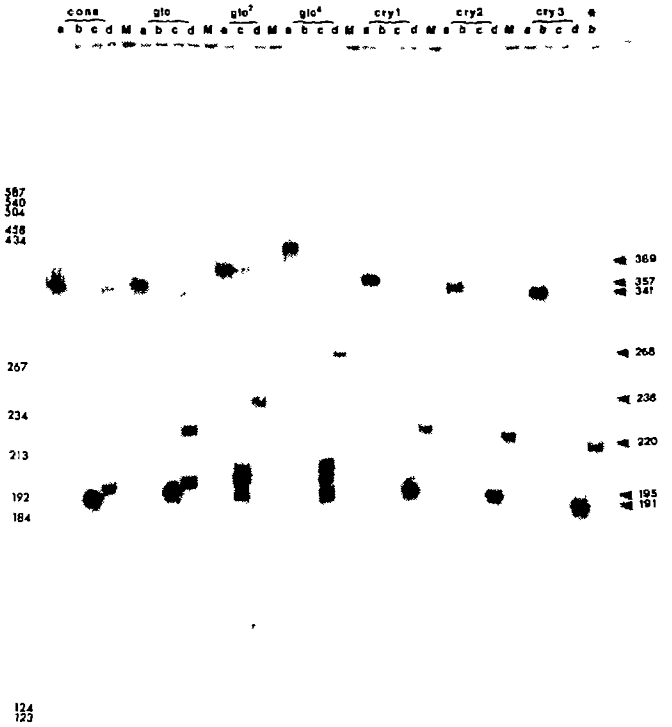

Fig 2 Determination of the splice sites chosen using S_1 nuclease, for β-globin genes containing the following test sequences the consensus (based on observed frequencies at each position[3] 43%C, 64%A, 73%G, 100%G, 100%T, 62%A, 68%A, 84%G, 63%T), β-globin IVS-2 (glo), IVS-2 dimer (glo^2), IVS-2 tetramer (glo^4) and the β-globin cryptic sites (cry 1, 2, 3) Total RNA was extracted from HeLa cells with LiCl$_2$-urea[13] 48 h after calcium phosphate transfection RNA was hybridized to the *Nco*I double-stranded probe at 49 °C for 2 h Standard conditions were used for S_1 nuclease digestions[14] Samples were separated on a sequencing gel[15] comprising 6% acrylamide, 20% formamide Size markers (M) were [^{32}P]-phosphorylated *Hae*III-cut pBR322 Their sizes are on the left hand side Numbers refer to base pairs For each construction, lane a shows the probe alone without S_1 digestion, lane b, S_1 nuclease digested probe, lane c, the relevant oligonucleotide containing probe hybridized to the *in vitro* β-globin transcript and lane d the result of hybridizing the probe to the expressed RNA followed by digestion with S_1 nuclease When the probe can form substantial secondary structure as in the case of glo^2 and glo^4 (lanes c) the pattern of S_1 nuclease digestion (multiple lengths) confirms that such structures are being formed Lane b for glo^2 (*) is at the far right hand side of the figure The autoradiographs were scanned with a laser densitometer after exposure to pre-flashed films (Kodak X-AR5) with an intensifying screen Lighter exposures than those shown were scanned, where the absorbance was proportional to the dose

IVS-2 is mutated[4], the *E1a* oligonucleotides ('E1a$_{973}$' and 'E1a$_{1111}$') are the two alternative 5′ splice sites of the adenovirus 2 *E1a* gene (at positions 973 and 1111) that are used to give two distinct mature transcripts Insertion of more than one oligonucleotide can be used to look at the effects of position and secondary structure

Oligonucleotides were cloned into the *Bam*HI site of a rabbit β-globin gene in pβ5′SV *Bgl*II[7] ('pβSV') and the products verified by sequencing The genes were introduced into HeLa cells and, after transient expression, the site of splicing was determined by S_1 mapping (Figs 1*b*, *c*) The proportion of splicing at the test site compared to the reference site was estimated by laser densitometry of autoradiographs

The results of the S_1 mapping experiments are shown in Figs 2 and 3, quantitative estimates are given in Table 1 A number of conclusions can be drawn

(1) The competitive assay for 5′ splice site sequences allows us to rank some sequences Splicing preferences can be shifted from the test site to the reference or vice versa depending on the sequence inserted at the test site The results with an oligonucleotide inserted in the complementary sense (E1a$^{\mathrm{comp}}_{1111}$) confirm that insertions of 16 nucleotides into the pre-mRNA structure do not disrupt splicing patterns This argues against a significant role for mRNA degradation induced by either the presence of extra upstream sequences when the reference splice site is used or the use of the new (test) site It is however possible that in some cases splicing to the reference site is followed by elimination of these transcripts, due to the presence of a splice signal at the test site (for example, 'cons' in Fig 2) Natural patterns of alternative splicing could be influenced likewise However, this would not impair the system's discrimination between sequences that promote splicing to the test site in the presence of the competing reference site and those that do not. However, if test site sequences have different susceptibilities to degradation, this could affect the comparisons among sequences that allow splicing to the test site (points (2), (3) and (6) below) Table 1 shows that the proportion of transcripts spliced to the reference site is inversely related to the degree of homology of a test site to the consensus sequence Thus degradation is probably insignificant or selective, in which case it would seem to reflect a further aspect of splicing activity at the test site In practice, the abundance of transcripts that have spliced to the reference site and carry natural splicing sequences at the test site suggests that splice site-specific degradation is not a major factor

A weaker reference site than that of β-globin may enable better discrimination among sites that are not used in the present arrangement

(2) The consensus sequence is used to the exclusion of the reference site, none of our other single inserts is as effective This site, which contains at each position the nucleotide found to be most abundant in natural sites[3], is so much 'stronger' than the others and small differences in sequence are so important (for example, cons and glo) that it is surprising all 5′ splice sites in genes that do not exhibit alternative splicing patterns do not conform exactly to the consensus The use of less efficient sequences would seem to imply unnecessary competition with exon sequences that by chance resemble naturally-occurring splicing signals However, such competition might facilitate the evolution of new proteins if acceptable signals arise The use of inefficient sequences might also alter the efficiency of gene expression One might expect that the time taken by splicing would be minimized to reduce degradation of nascent transcripts However, if site preference is related to the rate at which splicing occurs, then the frequent use of sub-optimal sequences suggests that there is little selective pressure for rapid splicing

(3) The consensus sequence and E1a$_{1111}$ differ only in the region that is usually within the exon, and these differences are clearly significant It has recently become common practice for 5′ splice site listings to include only the intron portion The region included in our oligonucleotides is the region for which conserved nucleotides have been detected, it would be surprising if sequences were conserved without functional importance We have not established whether sequences outside this region significantly influence splicing choices or efficiencies The exon sequences may constrain the evolution of protein sequence, or the protein sequence may dictate the splice site signals, this may not be important if sub-optimal sequences are acceptable in most genes (see point 2 above), but may influence alternative splicing patterns

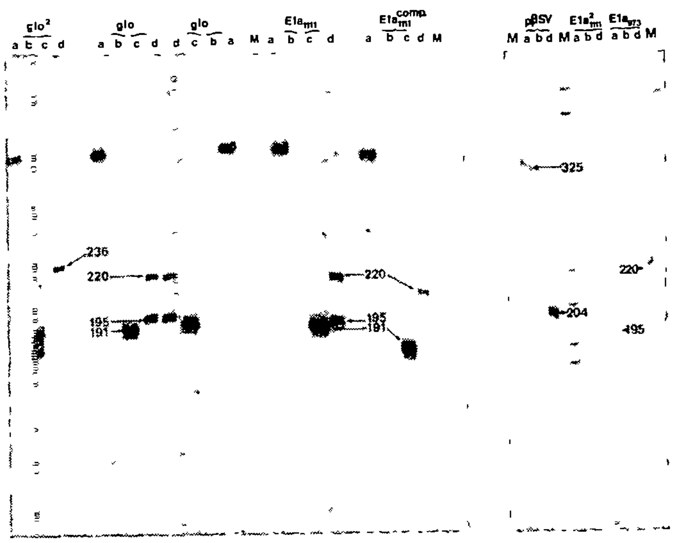

Fig 3 Determination of the splice sites chosen using S_1 nuclease, for β-globin genes containing the following test sequences rabbit β-globin IVS-2 5′ splice site (glo), adenovirus 2 *E1a* sites 973 and 1111 ($E1a_{973}$ and $E1a_{1111}$), a tandem dimer of $E1a_{1111}$ ($E1a^2_{1111}$) and a complementary insert ($E1a^{comp}_{1111}$), and no insert (p*βSV*) Lanes a, b, c, d and M are as described for Fig 2 Numbers refer to sizes in base pairs Samples were run on two 5% sequencing gels, containing 20% formamide, RNA was hybridized to the probe overnight at 49 °C and standard conditions were used for S_1 nuclease digestions[14] The two sets of lanes for glo represent independent isolates

(4) The sequences of the cryptic 5′ splice sites are not used, thus, the fact that these sites are not used in the β-globin gene (unless the normal IVS-2 5′ splice site is not available[4]) can be attributed to their sequence without invoking effects of secondary structure or position

(5) The results from constructions glo² and glo⁴ illustrate the importance of secondary structures Short inverted repeats can sequester a site and cause splicing to occur only at the reference This is a new way in which secondary structure can influence splicing, involving the site directly It has been shown[1] that an exon flanked by inverted repeats can be sequestered such that it is excised within the intron It is possible that the effect of secondary structure would be minimized if no choice was available, and we are testing this by inactivating the reference site in glo²

(6) Another factor which affects the choice of sites is that of relative position If we assume that the different flanking sequences of the two signals in the $E1a^2_{1111}$ tandem dimer have no bearing on their use, it seems that the upstream site is used preferentially and use of the reference site is drastically reduced This construction gave rise to a comparatively faint band on S_1 analysis (Fig 3), whether this is significant can be resolved only by experiments *in vitro* The significance of linear order may be influenced by the distance between two sites or by their environment, when a single β-globin sequence is inserted it is preferred to the reference β-globin site by a ratio of only 2 1

(7) The two *E1a* splice site sequences are used with very different efficiencies, even though both sites are used when intact *E1a* genes are expressed in HeLa cells Experiments in which β-globin restriction fragments were duplicated[2] showed that an upstream site is usually, but not always, used to the exclusion of a downstream site The results described in (6) emphasize the linear 5′ to 3′ order of alternative sites Thus, we anticipated that in the *E1a* gene a much more efficient sequence might be found at the downstream site in order to balance its unfavourable position This prediction was shown to be correct (Table 1, and unpublished results with sites intermediate in efficiency between glo and cryptic sites in our assay), but further experiments are required to test the importance of linear order and pre-mRNA structure

(8) The fact that splicing can be directed to the inserted oligonucleotide, away from a viable and efficient natural site, has mechanistic consequences If two 5′ splice site-binding complexes[8,9] bind simultaneously to the two sites, it is unlikely that the two sites could still be distinguished on the basis of their sequences in subsequent steps However, we have shown here that primary sequence alone is the basis of discrimination It is possible that both 5′ sites independently bind a complex and that the ratios of site usage are related to the average lifetime of bound complex We propose a model in which only one 5′ splice site complex can bind, perhaps limited by a requirement for the presence of a 3′ site complex (in agreement with some[8,10] but not all[9] *in vitro* data) The 5′ splice site complex can bind to either 5′ site, but the dissociation rates differ and the resulting pattern of usage then depends on the lifetime at each site The involvement of only one 5′ complex is rendered very likely by the proximity of our sites, experiments that increase the separation between the two 5′ splice sites will reveal whether the sequence discrimination and the model only apply to such close sites

We thank Mr J Keyte for synthesizing the oligonucleotides, and the members of the laboratory for critically reading the manuscript This work was supported by the MRC, J P E is a recipient of an SERC postgraduate training award

WHY PAY MORE FOR LESS?

CAMBRIDGE LIFE SCIENCES PRESENT THE 961 AND 962 MICROTITRE PLATE READERS.

A fresh approach by an innovative British Company.

Top quality instruments at about half the price of an average plate reader.

Benefits of the CLS 961 and 962 Models:

- Highly accurate and precise
- Interchangeable wavelengths
- Unique plate reading and transport
- Battery operated and rechargeable
- Compact, robust and portable
- Easy to use

The CLS 962 has these additional benefits:

- Auto blanking
- Sensitivity 0 - 2.999 Absorbance
- Data transmit facility with optional RS 232 output
- Optional rechargeable thermal printer

PRODUCT REVIEW

Immunoglobulin-derived drugs

Gary S. Hahn

Immunoglobulins may provide a novel source of drugs for the treatment and suppression of allergic reactions and other immunologically-mediated diseases.

RECENT research has suggested the possibility that small peptides derived from immunoglobulins (Igs) can serve as therapeutic drugs. All Igs secreted by plasma cells perform their effector and regulatory functions by a common pathway; by binding to Fc receptors (FcRs) in an isotype-specific manner. The precise FcR binding sites of Igs are unknown except for staphylococcal Protein A. Conventional dogma asserts that Ig FcR binding sites consist of large clusters of amino acids that require a specific three-dimensional configuration to bind to FcRs effectively. No small Ig-derived peptides with high affinities for FcRs have been reported to date. This historically led to the tacit assumption that small peptides from Igs would probably not be pharmacologically 'useful' since their affinity for FcRs would be too low.

Free-floaters

An alternative hypothesis, however, suggests that the Ig receptor binding sites consist of amino-acid clusters which also contain biologically active peptide segments. When released as free peptides, these small biologically active segments, or active site peptides (ASPs), have a low affinity for FcRs compared to intact Igs, and indeed may act as receptor agonists only after they are enzymatically released as free peptides (Fig. 1). According to this hypothesis, ASPs are released by proteolytic action while the Ig is bound to an FcR at the site of a developing immune response, and then act as short range immunoregulatory hormones.

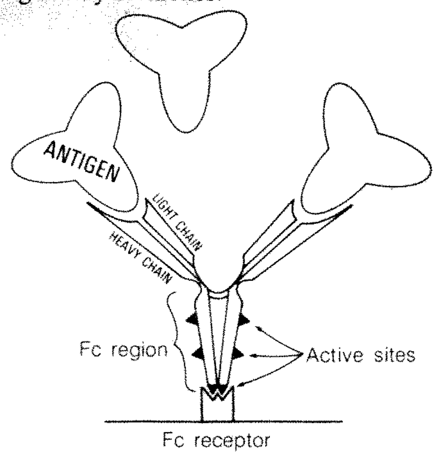

Fig. 1 Schematic of an antibody bound to two identical antigens and to an Fc receptor. The antibody's single Fc region contains multiple active site peptides (filled triangles) that bind to the Fc receptor and possibly to other immunoregulatory receptors.

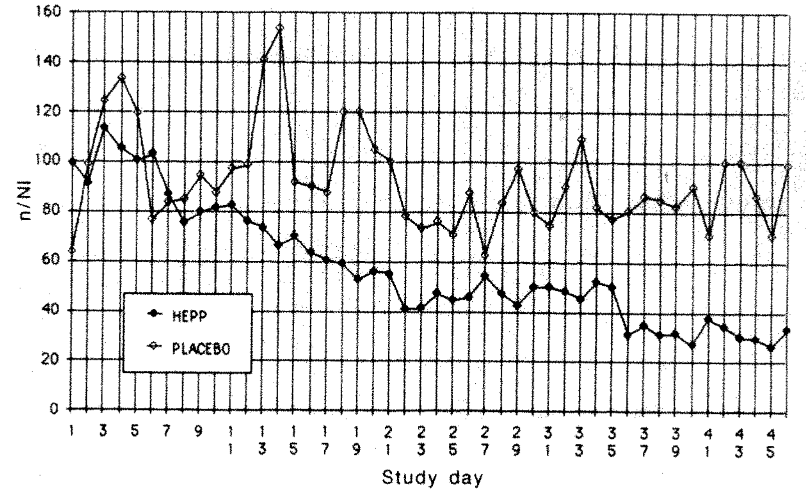

Fig. 2 Normalized stuffy nose intensity index (nIN1) during treatment with HEPP or placebo in 96 allergic rhintis patients.

A stumbling block may exist for the concept of Ig-derived ASP agonists though, as Igs are classically thought to trigger regulatory and effector functions only when two or more Igs cross-link multiple FcRs. This mechanism seems to exclude the possibility of FcR activation by small peptides, since the proposed peptides are too small to mimic FcR cross-linking. A critical point to consider in overcoming this conceptual hurdle is that the target receptors for ASPs may not necessarily be FcRs, but may instead be different immunoregulatory receptors. A low affinity FcR-binding peptide excluded as a potential ASP by conventional dogma is therefore an ideal candidate for an ASP according to these new concepts.

Small Ig-derived ASPs could have great potential as therapeutic drugs because, unlike Igs, ASPs are likely to be nonallergenic and inexpensive to manufacture. Most importantly, ASPs would probably be rapidly degraded to amino acids and would thus lack toxicity due to long-lasting metabolites.

The first ASP derived from any Ig was the tetrapeptide tuftsin isolated from enzymatic digests of human IgG. Tuftsin was shown to stimulate phagocytosis and other protective immune responses. As monomeric IgG does not stimulate phagocytosis, it was suggested that tuftsin must first be enzymatically released before expressing activity[1].

Subsequent studies have demonstrated the existence of other Ig-derived peptides whose immunoregulatory activities appear to be unrelated to traditional Fc/FcR interactions. The tetrapeptide rigin, and an unnamed decapeptide containing the rigin sequence, stimulate phagocytosis like tuftsin[2]. In addition, a 23-amino acid peptide enzymatically released from human IgG, containing both the rigin and the decapeptide sequences, was reported to stimulate T cell-dependent antibody synthesis with suboptimal concentrations of antigen[2]. A nonapeptide from the C terminus of human IgE (igercin) is also claimed to have kinin-like effects after enzymatic release, whereas an enzymatically released pentapeptide from IgM (IPM-5), located at a site in IgM spatially related to the rigin site in IgG, is claimed to exhibit thymic hormone-like activity[3].

Several ASPs have demonstrated therapeutic activity *in vivo*. Tuftsin given to mice with neoplastic tumours has been shown to increase the survival rate, and the 23-amino acid human IgG peptide mentioned above was reported to augment natural killer cell activity in mice. A short peptide from human IgG (73/He.2.80) substantially prevented experimental allergic encephalomyelitis in mice, as judged by neurologic deficit scores and by the reduction of central nervous system lesions, and is expected to be tested in human clinical trials on patients with multiple sclerosis[4].

Only one Ig-derived peptide, human IgE pentapeptide (HEPP), has been shown to have therapeutic activity in humans. HEPP's ability to inhibit IgE-mediated inflammation in humans was initially suggested to be due to competitive antagonism for the IgE FcR[5]. This concept was later proven untenable because of HEPP's low affinity for IgE FcRs. Figure 2 shows the effect of HEPP on 'stuffy nose' during a seven-week, double-blind placebo-controlled trial in 96 allergic rhinitis patients, in which the subjects recorded daily symptoms for one week prior to treatment and for six weeks during treatment (days 8–46)[6]. As an Ig-derived ASP, HEPP's activity is unexpected based on traditional concepts of Ig/FcR interactions.

The potential identity of some of the receptors for which Ig-ASP's may act as agonists is suggested by tantalizing sequence similarities of certain ASPs and other biologically active molecules. IPM-5, for example, is identical except for one amino acid to thymopentin, an ASP of the thymic hormone thymopoietin[3]. The first three amino acids of IPM-5 (Arg-Pro-Asp) are nearly the same as the binding site of fibronectin and its molecular relatives vitronectin, laminin and fibrinogen (Arg-Gly-Asp)[7]. The IgE-derived igercin resembles the inflammatory peptide bradykinin[3]. IgG-derived tuftsin resembles the N terminus of Substance P (SP-4) and has been shown to bind to Substance P receptors, and when injected intracerebroventricularly, tuftsin induces analgesia (Substance P antagonism). SP-4 has similarly been demonstrated to have tuftsin-like phagocytosis-stimulating activity[1].

New horizons

While certainly speculative, these curious resemblances suggest the possibility that Igs may have various releasable signals coded within their structures that act as short range hormones upon non-FcR systems. This greatly challenges the conventional concept of Ig structure and function, and demands explanations for the observed biological activities of ASPs that seem unrelated to known Fc/FcR interactions. The exciting possibility that Igs may serve as design templates for novel classes of immunoregulators may serve to redirect the thinking of molecular immunologists whose initial research may have revealed only a small fraction of the potential of Ig-derived peptides to serve as therapeutic drugs. □

Immunotech ideas

More and more monoclonals are on the market, plus the equipment to produce them.

Becton Dickinson has introduced **simultaneous two-colour immunofluorescence** with the new Simultest line of monoclonal reagents (Reader Service No. 100). Simultest makes use of a combination of monoclonal antibodies conjugated with fluorescent dyes that are excited at the same wavelength, so that multiple tests can be run with one assay. Intended for research applications only, Becton Dickinson's reagents are currently available for identification of T cells, B cells and certain other lymphocyte populations. The cost for the Simultest T and B Cell Test is $285 (US), and it contains enough reagent for 50 runs.

Simultest makes cells glow

Culturing hybridomas for monoclonal antibody production requires a **serum-free medium**. ICN Biochemicals produces Hybri-Clone SF specifically for this application (Reader Service No. 101). Provided in liquid or lyophilized form, Hybri-Clone SF is also suited for growth of primary or established cell lines. A 100 ml bottle sells for $17.50 (US).

Serum-free for purer cultures.

A Brandel **multi-probe cell harvester,** suitable for receptor binding assays, is now available from Semat Technical, Ltd. (Reader Service No. 102). Models equipped with 12, 24, and 48 wells are available, that Semat says perform cell harvesting from most sizes of test tubes within 30 seconds. Options include a hot-cold valve to separate radioactive from nonradioactive waste, a wash timer, and a collection box allowing the individual collection of filtrate. The basic 12-well M-12R model has a price tag of £2,395 (UK).

To ensure the **recovery and concentration of monoclonal antibodies** and other recombinant proteins in their biologically active forms, Sterogene has developed its ActiSept Immunoaffinity Purification System (Reader Service No. 103). The complete system includes an activated resin immunoadsorbent with a flow rate of 170 ml cm^{-2} h^{-1} (for Actigel A-Superflow) that immobilizes antigens and antibodies at physiological *p*H, and a nondenaturing eluent that Sterogene claims allows recovery of active proteins with a 98 per cent yield. The basic kit of 100 ml of Actigel A or Actigel A-Superflow resin plus 1 litre of elution medium costs $270 (US). Immunogels containing anti-mouse and anti-rabbit antibodies, as well as Protein A-Actigels for the isolation of IgG, are also available.

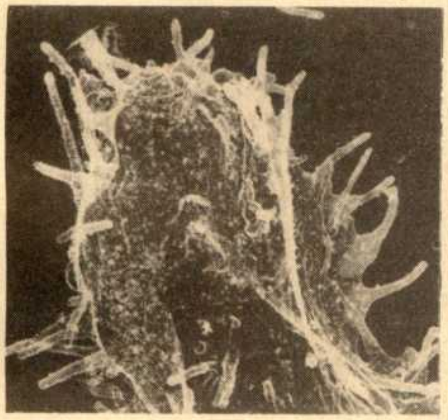
More monoclonals

For ease in identifying cell origins during cancer and other cell culture research, Du Pont Ltd offers its Cytolite line of **monoclonal antibodies specific to cytoskeletal proteins** (Reader Service No. 104). Du Pont's monoclonals are available for vimentin, actin, tubulin and keratin, allowing experimenters to assign major cell type origins. The monoclonals typically cost £84 (UK) for sufficient antibody for 50 assays, and each order is accompanied by instructions outlining the exprimental procedures for rhodamine or fluorescin detection.

Customized antibodies are available from BAbCO (Berkeley Antibody Company) (Reader Service No. 105). Its free 16-page guide outlines an extensive range of polyclonal and monoclonal antibody services. Ancillary immunological services are offered, including hapten-carrier conjugation, ELISA, and pharmacokinetic studies. BAbCO's services are keyed to researchers on any size budget, and preparations are made directly from client antigens.

MicroGeneSys, Inc. offers up-to-the-minute **products for AIDS research** purposes (Reader Service No. 106). Its MGStandard HIV gp160 protein is isolated from the expression of the virus envelope protein *env* in insect cells, and is thus free of contaminating mammalian cell proteins. The protein is complete except for a small deletion of approximately 100 amino acids at the C terminus, introduced for stabilization, that does not affect the two hydrophobic domains present near the C terminus of the gp41 portion. MGStandard HIV gp160 is supplied as a tested 50% pure solution in a sterile aqueous buffer at a concentration of 100 mg ml^{-1}, and a 25 mg sample costs $385 (US). For convenience, the AIDS envelope protein precursor is also available in prepared 96-well plates for ELISA, and in impregnated nitrocellulose strips (3–4 mm × 10 mm) for Western blot analysis.

Known for radiochemicals as well as for radioligands for use in receptor detection, Amersham International has recently expanded its product line to include a range of **monoclonal antibodies** (Reader Service No. 107). Amersham's new receptor monoclonals are specific for epidermal growth factor receptor, interleukin-2 receptor, and transferrin receptor. To accompany the antibodies, Amersham also sells detection systems using biotin-streptavidin, streptavidin–gold, and DAB silver enhancement.



Transferrin receptors on human laryngeal carcinoma cells visualized with streptavidin-gold.

Flow Laboratories is now distributing Hybritech's expanded range of **monoclonal antibodies,** and Hybritech has recently announced three additions for research applications (Reader Service No. 108). Monoclonals for T-cell surface antigens include antibodies for interleukin-2 receptor for the detection and enumeration of activated T cells, andd those for suppressor/cytotoxic and TA 5.9 T-cell antigens, useful for lymphocyte phenotyping as well as T-cell activation. Immunohistochemical detection of human, monkey and porcine chromogranin, indicating the presence of endocrine-derived cells, is

Reader Service No.32

possible with Hybritech's monoclonal LK2H10. LK2H10 is also useful in Western blotting and purification of chromogranin from human adrenal glands. Monoclonal antibody to group B streptococci (Type III) is also available. Hybritech say their monoclonals are suitable for flow cytometric analysis as well as fluorescence staining, and all products are lyophilized and stable for at least one year. Prices range from £98 (UK) for a 0.2 mg sample of antibody for cell surface antigens, to £198 (UK) for 0.5 mg of antibody for tumour antigens.

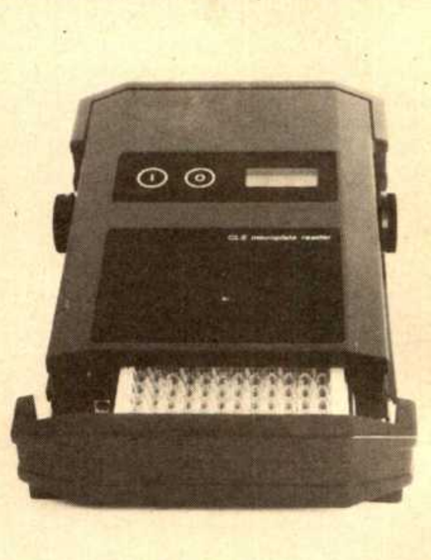
Microplate machines

A microprocessor-controlled Fluorescence Plate Reader is available from Perkin-Elmer as an accessory to be used with its LS-3B or LS-5B fluorescence spectrometers (Reader Service No. 109). Perkin-Elmer's suggested applications for its scanner include monitoring fluorescence immunoassays and monoclonal antibody screening. The £950 (UK) plate scanner operates by using fibre optics to transmit excitation and emission energy to and from the fluorescence spectrometer, as excitation energy absorbed by the sample produces fluorescence that is detected by the emission fibres in the light pipe head.

Microplate washing and aspirating can be tedious and time-consuming. Dynatech's Ultrawash II automates the process, and allows the operator to pre-select dispense volumes, soak times between 0 and 90 s, rates of aspiration and number of wash cycles (Reader Service No. 110). The £2,412 (UK) machine has 96 channels, and incorporates alternative dispense/aspirate heads to allow the selection of single or multiple rows as desired.

Dynatech's Ultrawash II is designed for those who hate to wash plates.

Cambridge Life Sciences is making **microtitre plate readers** affordable, claiming that its reader is half as expensive as the average instrument, with top quality (Reader Service No. 111). The fully portable CLS 961 is provided with a carrying case and costs £895 (UK). The CLS 961 reads 96-well ELISA and other microwell assays, and offers a choice of wavelengths of 405, 450, 492, 540, 615 and 690 nm. The more expensive CLS 962 has greater sensitivity and a wider absorbance range, and can be connected to a computer or printer.



Carry the CLS 961 anywhere.

Fitting Solutions

. . .To your reagent needs with Becton Dickinson Monoclonal Antibodies. The largest available range of antibody formats for research and diagnostic work provides the solution, whatever the pattern of your workload.

Another example of innovative products resulting from Becton Dickinson's commitment to research and development for the clinical laboratory, the BD Monoclonal Antibody range is the widest and of the highest quality available for research and diagnostic work on leukocytes in tissue and blood. Supplied ready to use in solution, with a minimum shelf life of six months, and two years on purified immunoglobulins at 2-8°C, they combine guaranteed reliability and quality with cost-effectiveness. Convenient to use and with the best possible supporting user literature, BD MABS are used by leading scientists in the fields of AIDS, leukaemia, cancer, multiple sclerosis and transplant research.

What more fitting solution to your Monoclonal Antibody needs?

- Anti -IL2 Receptor : Activated T. cells and HTLV infected cells.
- Anti -HPCA–1 : Human progenitor cell associated antigen, reacts with acute leukaemia specimens and unipotent and multipotent progenitor cells.
- Anti - Cytokeratin (CAM 5.2) : reacts with adenocarcinomas and mesotheliomas
- Anti - Calla : human common acute lymphoblastic leukaemia antigen.

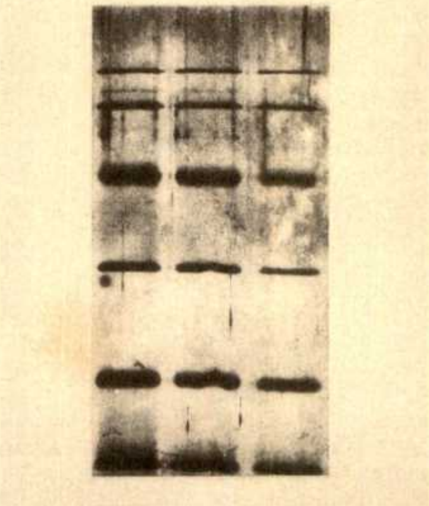
Bio-Rad's array of modular electrophoresis products.

Collecting, detecting, and dispensing

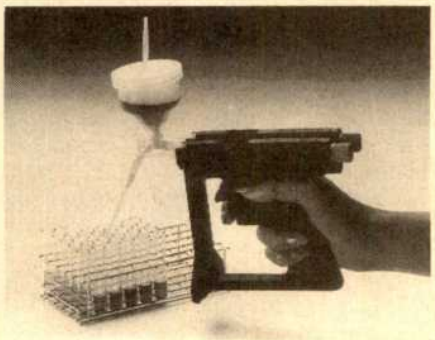
Bio-Rad has developed three **interchangeable electrophoresis modules** to expand its Mini Protean II electrophoresis cell into a complete system (Reader Service No. 112). The insertion of the Mini Trans-Blot module after the initial electrophoretic separation is completed allows electrophoretic transfers to be performed within an hour, according to Bio-Rad. By switching the module again, to the Mini Tube Cell, first dimension IEF tube gels for 2-D applications are produced. With another change of modules, the Electro-eluter recovers proteins and nucleic acids from the gel. Each module may be purchased separately, or the entire system, including the Mini Protean II basic cell, is available for £1,075.50 (UK).

Bio-Rad also offers a **colloidal gold protein detection kit** for the detection of proteins bound to nitrocellulose membranes (Reader Service No. 113). The Enhanced Colloidal Gold Total Protein Detection Kit is sensitive to as little as 400 picograms of bound protein, and includes the Colloidal Gold Protein Stain, Tris, Tween-20, a Gold Enhancement Kit, and an instruction manual. The Gold Enhancement Kit deposits a layer of silver over all membrane-bound gold molecules, turning the band from red to black, and thereby increasing its visibility. The total assay time ranges from two hours to overnight. The kit has a sensitivity equivalent to silver staining of polyacrylamide gels, according to Bio-Rad, and provides protein detection blots identical in size to the immunostained membrane. Bio-Rad claims that its kit also eliminates the shrinking problem associated with anionic dyes.



Enhanced detection with gold and silver.

Manual **sample dispensing and dilution** is the purpose of Labsystems' Finnpipette Diluter (Reader Service No. 114). The hand-held gun has one chamber for sample and one for diluent, and allows the sample to be aspirated, diluted, and dispensed with one fire of the trigger. The diluent chamber can be removed easily to change reagents quickly, according to Labsystems, and is autoclavable for sterile applications. The £249 (UK) Diluter has a volume range of 0–100 μl for samples and 90–1,000 μl for reagents, and can prepare dilution ratios of between 1:1 to 1:200.



Shoots dispensing worries.

To satisfy laboratory needs associated with the increased use of radioimmunoassays (RIA), V.A. Howe & Co. Ltd. distributes a line of **Hamilton diluter/dispensers** (Reader Service No. 115). The £3,370 (UK) Microlab MT is a microprocessor-controlled four-channel dispenser designed for microtitre plate work used in ELISA. V.A. Howe also sells the smaller Microlab M for routine work, and the Microlab 1000 for high dilution ratio (1:5,000) applications.

Erratum: Zeiss microscopes

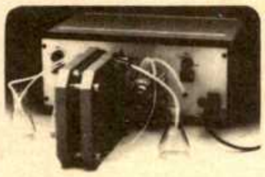
A review published in the 3 July issue of *Nature* (**322**, 93) incorrectly stated that "budget priced" Zeiss microscopes were available from Gallenkamp. While Gallenkamp does supply a wide range of Zeiss microscopes, the "budget" microscopes mentioned are not manufactured by Zeiss, and are badged Gallenkamp.

ADVERTISEMENTS

LIPOSOMES

NEW

REPRODUCIBLE – HOMOGENEOUS – EXTREMELY RAPID



Our new LIPOSOMAT guarantees rapid (5ml within 60 minutes) preparation of uniformly sized unilamellar liposomes. Liposome size is selectable between 25 and ca. 600 nm diameter. Sample volume is normally 5-10ml or up to 200ml if used in combination with an additional instrument. Lipid concentration can be up to 300 mg/ml.

The VERSAPrep-GT grows with you.

The VERSAPrep series of **modular preparative HPLC instruments** offered by Varex Corp. allows researchers to expand according to their specific needs (Reader Service No. 116). The basic VERSAPrep-GT costs $25,465 (US) and may be operated at flow rates of up to $180\ \mathrm{ml\ min^{-1}}$ at a maximum pressure of 3,000 p.s.i. according to Varex. Samples may be introduced with a valve-loop injector, the main eluent pump, or an accessory analytical-scale pump. Varex's HPLC offers a variety of accessory modules. A Control/Automation Module fully automates the basic VERSAPrep, while the Fraction Collection Module adds four collection ports to the VERSAPrep-GT's capabilities. The Programmable Events Module permits complete computer control, and the Column-packing Module allows the operator to slurry pack columns up to one inch in diameter. Varex says the precolumn module minimizes elution time by trapping extraneous, late-eluting components, and can be back-flusheda with solvent. The introduction of the Multi-Column module expands the VERSAPrep by making it possible for two columns to be selected, either individually or sequentially, as required for a given run.

Catalogues etc.

Pharmacia is giving away a **free wall poster** describing chromatographic techniques for the purification of monoclonal antibodies (Reader Service No. 117). The 70 × 100 cm poster is designed as a useful as well as decorative addition to a laboratory, and features charge-specific, FC-region specific and immunospecific methods for chromatography and FPLC. Pharmacia's new catalogue of separation products for immunology includes information on products for cell affinity chromatography, DNA synthesis, cell culture, cell separation by centrifugation, analytical and preparative electrophoresis systems, monoclonal antibody purification and cell studies.

Accurate Chemical has recently published a **catalogue** of its Axell Antibodies (Reader Service No. 118). The 84-page catalogue lists nearly 3000 primary and secondary antibodies, including ready-to-use diluted primary antibodies and negative controls. Accurate Chemical also provides a selection of immunochemistry kits and reagents.

Arms, hostages and petroleum

The inquiry into the dealings between the United States and Iran has so far concentrated on the supply of arms. What promises have been made about the price of oil?

PRESIDENT Ronald Reagan's discomfiture at the revelation in the past two weeks of his secret and possibly illicit dealings with the government of Iran is understandable. The proposition that the United States has a natural interest, but also a kind of public responsibility, to cultivate good relations with seemingly hostile governments makes sense so far as it goes, and might be regarded in the Congress as justification for an attempt at rapprochement with Vietnam, North Korea or (come to that) the Soviet Union. But Iran? With the memory of the capture of the staff of the Tehran embassy's staff still so fresh? That alone would expose Mr Reagan to the complaint that deals with hostage-takers can serve only to put further potential hostages at risk. So much is so clear that it is inevitable that people should believe what the president denies, that the "small shipment" of arms to Iran was a consideration for Iranian influence with the captors of several US hostages still held in the anarchic Lebanon. No doubt the tail-enders of the 99th Congress will get nearer to knowing what really happened.

Meanwhile, there is a larger question to be explored than that of whether some part of the US administration was prepared to make a deal most other people would have considered unwise. When the news filtered from Iran at the beginning of this month that Mr Robert McFarlane, director of the US National Security Council until a year ago, had taken to Tehran not merely a small shipment of arms, but a bible and a cake, the word was that the United States was also willing to use its influence to bring about a general increase in the price of oil, from something like $15 a barrel now to something like $18. While attention centres on the arms and the bible (it is harder to imagine what symbolic purpose the cake may have served), the price of oil tends to be overlooked. yet on the assumption that dealing over hostages will now become unfashionable, this is a more lasting and more serious issue.

Circumstantial evidence suggests that something odd may have been going on. As a member of OPEC (the Organization of Petroleum Exporting Countries), Iran has recently vociferously expressed its discontent at the fall by more than a half, even in nominal terms, of the price of oil on the international market. Its own income from petroleum has been cut not merely on this account, but by interruptions of the movements of oil tankers from its terminals at the head of the Persian Gulf. But for the past several years, as for most of the time since OPEC's beginning in 1969, the market in oil has been determined by the policies of Saudi Arabia, whose reserves of cheap oil are now even more dominant than before 30 years of vigorous exploitation in the Middle East. Apparently exasperated by OPEC's failure to agree on production quotas tight enough to sustain a higher price, Saudi Arabia has for the past two years gone for market share instead, increasing its own production and letting the price find its own level to the general benefit of the industrialized West and the discomfort of relatively high-cost producers of oil, Iran for one and Britain (not a member of OPEC) for another.

That policy has now been turned on its head. Sheikh Ahmad Zaki Yamani was dismissed his post as oil minister of Saudi Arabia a month ago, since when his successor has arranged a meeting of OPEC advertised as one at which the price of oil should be increased. There are several explanations, of which one is that the United States has successfully exerted its influence with the Saudis, in the manner suggested by the shadowy (but at least partly accurate) sources in Tehran. It goes without saying that this sequence of events affecting the price of oil may be as plausibly explained by Saudi exasperation that the United States had begun dealing with Iran again; Saudi Arabia may even have resolved that, if anyone deals with Iran, it should do so itself. There are also many other explanations in which President Reagan's little shipment of arms plays no part.

For the time being, the US administration's interest is that it should if possible be cleared of the suspicion that it has been prepared to monkey with the price of oil on the international markets. In its way, this charge is as serious as is the charge that the United States has been prepared to trade with those who support or encourage kidnappers, thereby helping to institutionalize political hostage-taking. Not that Iran would be the only beneficiary of even a modest increase of the price of oil. The British chancellor of the exchequer would benefit, as would his opposite numbers in Nigeria and Mexico (not to mention those who worry about Mexico's debts). So too would US oil producers in Texas and California. But the gret majority of those who buy OPEC oil, from Japan to Western Europe, would be hurt by an increased price of oil, while the flickers of hope that economic growth can yet be rekindled would become more fitful. These are the players who will want to know what, if anything, President Reagan and his emissaries have been telling the oil producers of the Middle East. □

Insiders outlawed

Cleansing the world's financial markets of fraud may be more difficult than supposed.

THE wave of righteous indignation about insider trading on Wall Street and, on a lesser scale, in London, is understandable but suspect. Not that those who use privileged information to play the stock markets to their own advantage are distinguishable from common thieves. Mr Ivan F. Boesky, the New York financier required by the US Securities and Exchange Commission two weeks ago to hand over $50 million in ill-gotten gains and to pay the same amount as a penalty, is the most spectacular case so far. But the case of Mr Geoffrey Collier, the director of Morgan Grenfell in London who was forced to resign his job after seeking to make £15,000 on a single insider trade, is more illuminating if only because it is easier to understand.

Collier's fault was to have sought to buy shares in a British engineering company in advance of a takeover bid of which he had private knowledge, gathered in the course of his work. The deal was executed on his behalf by an overseas company and through a New York stockbroker, which accepted the order to supply the stock at an agreed price even though it did not have enough on its books at the time. The stockbroker's calculation was that it could have bought the stock in the markets later in the day, but in the event it laid off two-thirds of the risk that the price might rise onto another New York firm, a subsidiary of Chase Manhattan. If the deal had not been cancelled, one firm would have lost £5,000 and the other £10,000.

So what? will be one cynical question. Stockbrokers are forever making huge sums of money by "dealing their books", so why weep when they risk a loss? The simple answer is that it is not their money that they risk, but ours, that invested in the international stock markets by pensions funds, savings institutions and by banks that take deposits from the general public. If Collier had pocketed his £15,000, the ultimate losers would have been ordinary people. Boesky's $50 million ultimately derives from the same source. But $50 million is only a tiny fraction of the funds belonging to the public invested in the international financial markets. Is the rest safe?

What worries the Securities and Exchange Commission now is that, in the United States, the huge amount of paper debt obligations called "junk bonds", perhaps as much as $100,000 million, which has sustained the recent wave of spectacular takeovers, may be suspect. These securities (if that is the right word) entitle the owner to high interest, but are not secured against assets and not traded on stock exchanges. Holders can get back their capital by appealing to the investment banks that issued the junk bonds, but the fear is that this procedure may have been infected by Boesky get-rich-easy principles; that could spell disaster, given the extent to which savings and loan associations in the United States have traded their clients' cash for junk bonds (which look better on a balance sheet).

So there is a strong case for making outlaws of the insider-traders. How is that to be done? This is the point at which righteous indignation comes a cropper. The case of Collier is straightforward; he acquired his inside knowledge because the firm of which he was a member had agreed to mount a bid for the British engineering company (on behalf of Mr Robert Maxwell, the proprietor of Pergamon Press). To seek to profit personally from this knowledge was a violation of his firm's internal regulations, of the London Stock Exchange's rules and of British government law (hurriedly brought into effect in time to put Collier under pressure). Boesky's is a more complicated case; so far, he has been accused only of using inside information provided by a true insider, Mr Denis Levine, arrested by the Securities and Exchange Commission earlier this year and who has since traded immunity from further prosecution for the repayment of $1.5 million and continued cooperation with the commission's inquiries; who, in law, is the real felon, Boesky or Levine?

The truth is even more complicated. Without accepting the arguments of the Chicago economists who say that insider trading is virtuous because it brings reality more speedily into effect and thus make the markets more efficient, it is fair to ask whether stockbrokers who commission studies of industrial sectors, ostensibly for the benefit of clients, should then be allowed to speculate in the stocks concerned. And should the 'analysts' who carry out the research be allowed to speculate on their own accounts, knowing as they must that at least some of their company's clients will believe what they say? When is it improper to act on (and profit from) rumour? Or even to take advantage of special knowledge of the health (or sickness) of publicly-quoted companies gathered in quite different connections, as a journalist, for example?

The righteously indignant will quickly say that there should be no limits to the most simplistic writ. (Simplistic Senator William Proxmire is alarmed at the way in which corporations have been saddled with huge amounts of debt after successfully defending against a takeover bid, but that is another issue for which directors are responsible.) Others will recognize that there is an urgent need for a legal definition of a boundary between right and wrong that will make sense, and will endure. Governments, poor things, will know that the problem is complicated by the international character that the financial markets have now acquired. □

Teachers in travail

Is the proper education of the young too important to be left to teachers?

Like motherhood in the old days, the education of the young has become an important social objective, and for good reason; economic survival depends on social or technical innovation, which requires innovative young people. So it is not surprising that governments in the industrialized West should be seeking to improve high-school education. In the United States, the new Democratic Congress has lost little time in saying that it wants the federal government to do more for state-supported school systems. (What will happen to the Gramm–Rudman budget deficit reduction act if the defence budget is not cut?) In Britain, the government is in the last bruising stages of an attempt to trade money (which teachers need) for a promise (which teachers' labour unions are reluctant to concede) that more able teachers will be better rewarded. Everywhere, the simple arithmetic is overlooked.

Here is the arithmetic. Most Western countries send their children to school for 12 or 13 years, in classes that average about 20 students per teacher. In round numbers, the schooling of each child requires roughly two-thirds of a teacher-year. But teachers' professional lives last for about 35, and are statistically much shorter, which means that for a demographically unchanging population, at least 2 per cent of the population of working age should be schoolteachers. Naturally, governments and the societies they represent require that teachers should have had the benefit of higher education, in which the participation rate in Britain (admittedly one of the worst) is merely 15 per cent. If all those leaving higher education followed professional careers for 35 years (which is far from being true), one seventh of the population would have to be schoolteachers. Allowing for the manpower needs of higher education, one should expect that roughly 20 per cent of college-leavers would be occupied in education. Is it reasonable to expect that those who teach the young will also be among the most talented?

There are three distinct answers to this question. In the United States, where the federal government has, for the past six years, stuck largely to exhortation, but where the quality of high-school education has become a general anxiety, some state governments are making valiant efforts to improve the performance of their schools, while institutions that train teachers are trying to enhance the reputations of those who teach in schools by requiring more from entrants to their courses. These private initiatives have not so far been well-rewarded because people will not pay particularly well-qualified teachers extra, while teachers themselves pretend that discrimination is anathema. In Britain, on the other hand, the government is willing to battle for its conception of a core curriculum and is also pleading for pay-discrimination; it should be known this week or next whether its offer of an extra 17 per cent over 18 months will be accepted on the teachers' terms or will have to be enforced. Only in Japan is there is a workable if unstable solution of the problem: put more than a third of the population through higher education, but then arrange that married women do not work, but stay home and teach their children.

Elsewhere, governments will have to learn to live with solutions far from their ideals. In North America and Western Europe, the chance of persuading the best and brightest of those leaving higher education to teach in schools is small, especially in those fields from which technology springs. Better to be reconciled to that than to keep tilting at a windmill. So the crying need is for a general recognition that schooling is not an end in itself but one of several means to functional adulthood, that the core curriculum should be stripped down so that it is no longer a test of the preternatural ability of gifted students but within the competence of all students and most teachers and that, whatever governments do, the results will not be perfect. □

Europe's framework research

Commission ready to pull out communal rug?

Brussels

THE European Commission could go so far as to drop the whole $8,000 million, 'framework five-year programme for European research and development' next month, if governments fail to agree to support the programme at a sufficiently high level. So observers were saying in Brussels last week, as the Commission began to field its strongest political musclemen, Commission President Jacques Delors and his team, in favour of what the Commission considers a sensible budget for the research programme.

Last week, the European Parliament's Energy, Research and Technology Committee voted to advise the Commission to withdraw the framework programme if the full budget requested — a reduction compared with the $10,000 million earlier requested and a "minimum" according to the committee — was not accepted.

Certainly research, which at the full amount of the framework programme would account for little more than a twentieth of Brussels spending, is now at the centre of Brussels politics, where it is feeling the full blasts of European summitry. The Commission wishes through research to confirm a new role for itself in the industrial regeneration of Europe. France, West Germany and the United Kingdom have been resisting both for financial reasons and, undoubtedly, because of the interference in national science and technology programmes that increased Commission activity would imply.

In fact, governments have accepted the principle of a major European programme of research and development coordinated by the Commission in the 'Single Act', the major treaty of union agreed by heads of state last year in Luxembourg and due to be voted in place by all members of the European Communities by the end of this year. The Single Act includes a place for the framework programme for research, and Delors sees the voting and proper financing of that programme to be a clear test of the 'New Europe'. He told British industrialists recently that European Communities research and development policy was "so relevant and so essential" because in the long term it bore directly on the creation of a single European market for European goods.

The framework amounts to less than 2 per cent of overall research and development in Community countries and "we are not, repeat not, out to enter into some kind of competition with the member states", Delors said. "We hear references to cost-effectiveness. But the microchip industry people tell us that their return on ESPRIT programmes is 400 per cent despite the cost of cooperation. We are said to be bureaucratic. But do people know that it takes two European officials to manage £1 million of research and development funds, and eight officials in the most efficient member states? Industrialists, and researchers, and academics are turning to us, to Europe, and saying they are ready to work together... I do not see why the most solemn undertakings by the heads of state and government [in the Single Act] are not being put into effect faster."

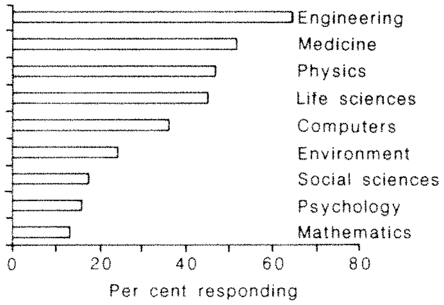
Robert Walgate

US universities appear in good shape

Washington

CONSTRUCTION in progress and planned over the next five years will increase research space at US research universities by between 14 and 26 per cent, according to a survey* by the National Science Foundation, at a cost of $7,500 million.

The survey covered all doctorate-granting institutions, and showed that the top 50 in terms of research and development spending (out of a total of 165) accounted for more than 50 per cent of work in progress and 60 per cent of planned work. Engineering, medical sciences and physical sciences departments were more likely to have construction in progress than others (see figure).



The survey produced one surprise for the doomsayers on university research facilities: over half of the same top 50 universities reported the condition of their research facilities as "good" or "excellent".

But of those ranked outside the top 50, over half replied "fair" or "poor". ☐

**Science and Engineering Research Facilities at Doctorate-granting Institutions*. National Science Foundation, 1986.

UK research appointments

Council breaks new ground

THE terms on which the Natural Environment Research Council (NERC) has made three senior appointments to its staff have occasioned some surprise among British academics.

Interest centres particularly on the arrangements under which the three directors of science appointed in the past twelve months have been promised that, if their five-year terms are not renewed, they will be kept on the payroll at a professional level.

The three appointments were foreseen in NERC's corporate plan, published nearly two years ago. The objective was that NERC's spending in three areas (Earth science, marine science and terrestrial and freshwater ecology) spanning its whole range of interests should be overseen by scientists of individual distinction. When the new arrangements were announced, some directors of NERC institutes expressed misgivings on the ground that their independence would be compromised and their access to the NERC council impeded.

The first appointment, of Dr P.B.H. Tinker (terrestrial and freshwater ecology) was made last December. Dr J.D. Woods (marine science), previously at the Kiel institute of oceanography, and Dr J.C Briden, previously professor of geology at the University of Leeds, were appointed in the summer of this year.

As part of the arrangement with the holders of the three posts, it has been agreed that they should remain active in research, for which reason it is intended that they should maintain modest research programmes at suitable academic institutions (All three have plumped for the University of Oxford, within driving distance of NERC's Swindon headquarters.) Dr J.C. Bowman, secretary of NERC, says on the telephone that the council of NERC has agreed that sums "of the order of 100K [£100,000]", taken from the budgets of the three directorates, should be used to support this research.

On NERC's promise of continued employment, Bowman says that the arrangements do not differ from those governing the appointment of scientists elsewhere in the council's network, who are normally offered employment until retirement age. Moreover, he says that the arrangements are not inconsistent with the British Treasury's rules on public appointments, but merely a "new wrinkle" on them.

Tinker will be 60, the normal retirement age from the public service, when his five-year appointment ends, but both Woods and Briden (now 47) will have some years to go.

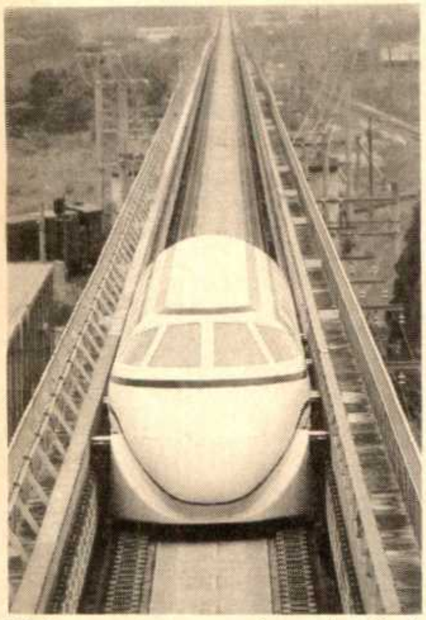
John Maddox

Magnetic levitation

Japan's railways look ahead

Tokyo

HIGH-SPEED magnetically levitated (Maglev) trains are in the news again. When Japan, which has been running a modest Maglev research programme, invented a



517 km per hour experimental train in 1979, few thought it could ever emerge from the test track. But the climate has suddenly begun to change and politicians are openly talking of a magnetically levitated bullet train that could transport passengers from Tokyo to Osaka in little more than an hour.

A prototype train that can carry up to 80 passengers is now under construction. Wind tunnel tests on a 7-m scale model of the prototype were successfully carried out at Nissan Motor Company's Technical Centre two weeks ago, and the prototype itself should be ready for test runs on Japanese National Railways (JNR)'s 7-km test track in Mihazaki, Kyushu, next spring.

The break-up and privatization of JNR has been the catalyst. Years of profligate government spending and intransigent unions have left JNR with debts of $230,000 million, more than the combined national debts of Mexico and Brazil. Interest payments alone have been running at more than $20 million a day.

Eight bills have raised through the Lower House of the Diet tailored to break up JNR into six regional passenger railways, a freight railway and a holding organization for the profitable bullet train lines (Shinkansen) which will be leased back to the passenger railways. More than 3,000 hectares of JNR land, much of it in prime areas, will be sold off to recoup some of the debt and 61,000 JNR employees will have to find employment elsewhere. Yet apart from a few radical attacks on the railways communication system which brought temporary chaos to commuters (see *Nature* **318**, 405; 1985), opposition to the privatization plan has failed to materialize and many union members have capitulated for fear of losing their jobs.

After the break-up in April 1987, JNR's research laboratories will be reborn as a research institute backed by a foundation. More money is to go into Maglev. Maps for new Shinkansen lines, pencilled in during Japan's high-growth era, are being taken out of the back drawers of filing cabinets for reappraisal. It is hoped that one of these lines could carry a Maglev train.

The Maglev train floats on the magnetic field of superconducting niobium–titanium magnets mounted below the car floor. As the magnets pass over aluminium coils set in the U-shaped trackway, electric currents induced in the coils set up a repulsive magnetic field off the same polarity that levitates the vehicle about 10 cm off the ground. Guidance and propulsion are provided by electromagnets set in the walls of the trackway.

The train offers a smooth, silent and bump-free ride at more than 400 km per hour, and in commercial service will be controlled by ground stations at 50-km intervals along the track. One slight problem, however, remains. In an earlier test, the maximum magnetic flux on the floor of the car was 200 gauss. Passengers complained that their watches stopped. In the prototype the disposition of the train's superconducting magnets will be adjusted to try to overcome this effect, according to Yoshihiro Kyotani, manager of the Maglev project.

Kyotani already has the most likely route for the first commercial Maglev line dotted on a map in his office, the Chuo (Central) Shinkansen, which would run from Tokyo to Osaka via Nagoya.

Although nobody is yet discussing construction costs, Kyotani points out that the trackway for the new vehicle would cost less than that for a conventional railway. But he admits that the cost of the Maglev vehicle itself will probably be higher than that of an ordinary train.

David Swinbanks

SERC scoops pool

EARLIER this week, it seemed certain that the Science and Engineering Research Council (SERC) would be given the lion's share of the extra £25 million for research provided three weeks ago by the British government. This appears to have been the

CERN
PLEASE HELP SERC. THANK YOU

decision of a meeting last week of the independent members of the Advisory Board for the Research Councils (ABRC), the government's cake-cutting committee, and is unlikely to be overturned by a meeting of the full committee arranged for Wednesday this week.

SERC's success is a pyrrhic victory. The extra funds channelled in its direction will be used exclusively to pay the increased cost (in sterling) of subscriptions to overseas research organizations, among which the European high-energy physics research centre at Geneva (CERN) is the largest. The cost of the CERN subscription, now roughly £45 million, has risen because of the devaluation of sterling relative to the Swiss franc. □

Soviet reservations on IAEA conventions

THE Supreme Soviet has approved the two new conventions of the International Atomic Energy Agency (IAEA) formulated during the summer in the light of the Chernobyl catastrophe. The signing is hardly remarkable; the effect of Chernobyl was to crystallize ideas that had begun to take shape among IAEA members after the accident at Three Mile Island. But Soviet media and government spokesmen have consistently claimed the new conventions as a specifically Soviet initiative.

But the Soviet Union has ratified the treaties only in part. A special reservation has been added to the effect that the USSR will not consider itself bound by the provisions of Article 11.2 of the Convention on Prompt Notification of a Nuclear Accident nor by Article 13 of the Convention on Assistance in the Event of a Nuclear Accident or Radiation Emergency. These provisions refer to the possibility of submitting any dispute arising under the terms of the conventions to arbitration or to an international court at the request of any side. The Soviet Union, says the reservation, declares that the consent of all sides is necessary before any dispute is referred to arbitration or to an international court.

US polar research

NSF break with Coastguard?

Washington

PLANS for polar research have been upset by the US Coastguard's recent downgrading of one of its ships, *Glacier*, which is no longer classified as an "icebreaker", but described as "ice-strengthened" instead. As a result, the National Science Foundation (NSF) may break with the US Coastguard, and find polar research vessels elsewhere.

Glacier was considered the most suitable of the Coastguard's icebreakers for research, and the discovery that its hull has been seriously weakened by corrosion has re-opened the debate about whether Coastguard ships are still suitable as research platforms for NSF. Two new Coastguard icebreakers should be completed in 1992 or 1993, but NSF will have to span the gap from now until then.

The nub of the problem is that Coastguard ships are primarily military vessels not well equipped for research. Two years ago, NSF leased one small research icebreaker, *Polar Duke*, and is also now taking research space on the West German icebreaker *Polarstern*, which has superior research facilities. But restoring *Glacier* to icebreaker status would cost $20 million and NSF considers the cost would be too great.

Instead, officials want the use of a dedicated research icebreaker from another source, either by collaboration with another country or by leasing. Without NSF support, the Coastguard cannot justify large expenditures on *Glacier*, although it says no final decision has been taken. Loss of the NSF account would mean about $2.3 million a year.

Scientific interest in Antarctica seems to be increasing year by year. Investigation of the Antarctic ozone hole seems now to guarantee that interest will not wane. NSF, as well as using *Glacier*, has also frequently used two other Coastguard icebreakers, *Polar Star* and *Polar Sea*. But these are unpopular with researchers and in need of refits.

Glacier is working this season in the Antarctic ice edge zone, pushing but not breaking ice. Research has not been unduly affected this year, but it could be if NSF were tied to the ship. The two new vessels due next decade will provide better accommodation and facilities than any existing Coastguard ship. Meanwhile, NSF is looking at its options. **Tim Beardsley**

First leptonic collisions at Japan's KEK

Tokyo

TRISTAN, the giant accelerator at Japan's High Energy Physics Laboratory (KEK), burst into action last week when electrons and positrons were smashed together at a record-breaking centre-of-mass energy of 50 GeV in the accelerator's 3-km main storage ring. And with foreign competition breathing down its neck, the TRISTAN team is now racing to get its experimental programme into full swing.

After successful tests of the electron and positron beams at 25.5 GeV earlier this month (see *Nature* 324, 7; 1986), KEK scientists set the counter-rotating beams in the main ring on collision course and the first hadronic-like event was picked up by the partially instrumented VENUS detector shortly before midnight on 18 November, followed a few hours later by a collision producing large-angle Bhabha scattering.

The record set by TRISTAN exceeds the maximum of 47 GeV achieved by the PETRA ring in Hamburg. But the maximum luminosity obtained, 2×10^{29} cm^{-2} s^{-1}, is barely a hundredth of TRISTAN's design capability, and the electron- and positron-beam currents, at present operating at around 1 mA, will have to be raised before a serious search for new elementary particles can begin.

Aerial view of the TRISTAN complex.

AMY, a detector built in collaboration with teams from the United States, Korea, China and Japan, has just been rolled into position in one of the four experimental halls on the main ring. And the TOPAZ detector, now undergoing tests with cosmic rays, should be in place next spring ready for the full experimental programme to begin in early May 1987.

TRISTAN thus has a head start on its most immediate rival, the Stanford Linear Collider, whose even higher energy electron–positron collisions are not expected for at least a few months. Even then, the linear collider will be limited to a single energy, producing showers of intermediate vector bosons (the Z^0), TRISTAN will have about two years as the world's most powerful flexible electron–positron ring collider until the LEP ring at CERN comes on line in 1988. Optical interferometry

Large grant for new instrument

Sydney

THE University of Sydney has won a grant of A$500,000 to begin construction of a 640-m baseline high-resolution stellar interferometer. This development is a milestone for stellar astronomy (and for the Chatterton department of astronomy at Sydney) as well as for the Australian Research Grants Scheme, whose budget is so small that projects on this scale have so far been beyond its scope.

The new instrument will be a larger version of a prototype instrument built by Sydney over the past 15 years. Only about 30 stars, mostly bright giants, have so far had their apparent diameters measured to an accuracy within 5 per cent by this technique. The new interferometer telescope will be able to measure the apparent diameter of 50,000 stars (brighter than 8th magnitude) with an accuracy of 2 per cent or better.

Measurement of the apparent size of stars whose distance is known should allow the establishment of fundamental scales of stellar diameters and luminosities to be established. Observations of close binary stars can give all the parameters of the system, including their orbits, temperatures, luminosities, diameters and distances. Other problems the interferometer could help solve include mass loss, by observing how a star's envelope appears to grow at longer wavelengths, and stellar rotation, by observing the flattening of the poles.

All the essential technology for the interferometer telescope has been proved in a prototype developed by the Sydney University team, led by Dr John Davis, over the past 10 years. The prototype has an 11.4-m baseline with a steerable mirror at either end. The mirrors capture the light from a star which is then reflected to a central optical bench where the beams are combined and interference fringes observed. The prototype will form the heart of the new instrument.

The principle on which the new interferometer will operate is amplitude interference, its design being a development of Michelson's classic interferometer. Amplitude interferometry has not previously been a workable option because of the blurring caused by atmospheric 'seeing' effects. Until this year the Australian Research Grants Scheme has been restricted to grants of less than A$150,000. The $150,000 grant for the interferometer marks the beginning of the government's policy of more funds for the scheme concentrated into fewer but more highly rewarding grants (see *Nature* **323**, 98; 1986).

Charles Morgan

Environmental databases

NOAA slipping further behind

Washington

THE attempts by the US National Oceanic and Atmospheric Administration (NOAA) to bring up to date its overstretched environmental data archiving and distribution system have run into trouble. The agency's proposed new system, NOAANET, is intended to supply retrospective environmental data from satellite and other sensors for researchers during the 1990s and into next century. But political obstacles have prevented NOAANET from finding its way into the agency's budget for fiscal year 1988, which starts next October, and there are fears that the administration's outmoded technology could slip even further behind.

NOAANET was cut out of the agency's 1987 budget by the Office of Management and Budget. This year, it did not even get that far: NOAA has been told by its parent agency, the Department of Commerce, to see whether the system could not be run by the private sector. Nonplussed NOAA officials say prospects for making a profit out of environmental data archives are not immediately clear.

Virtually all researchers agree that NOAA has fallen way behind in the push to computerize access to environmental data, even though it has a legal mandate to provide such an archive. Requests for data can take months to be processed, and there is no on-line catalogue, let alone data access. The problem will worsen as new advanced satellites will generate data in ever-increasing quantities. The National Aeronautics and Space Administration (NASA), in contrast, although supposedly a research agency, has already established data centres with much more advanced capabilities and is starting to link them up. The new 'NASAnet' will enable researchers to examine catalogues of data from different sensors across various disciplines and make selections from their computer terminals.

The difficulties result, some say, from NOAA's disadvantaged position within the Department of Commerce. The department's bureaucrats are less likely to be sympathetic to projects benefiting research than to those of NASA, for example. NASA's initiatives to make use of computers for data handling and distribution have been generously funded: the agency recently signed a $240 million contract with Boeing Computer Services for project support for a new network.

There are nevertheless those who are critical of NOAA's preliminary plans for NOAANET. Frank Eden of the Joint Oceanographic Institution questions whether there have been adequate consultations with NASA and the National Science Foundation, for example, which is also constructing a large computer network based around its five supercomputer centres.

The lack of a formal scientific advisory body to advise NOAA on how to implement the project is also a source of concern. But Gregory W. Hunolt, NOAANET project manager, says NOAA plans to bring in external advice shortly; meetings with NASA have already started and a definition document has been circulated in the academic community. High-level contacts between the agencies had been delayed by a NOAA proposal to put its orbiting meteorological instruments on a private satellite, Omnistar, but that idea has now been dropped. But without a commitment by the Department of Commerce to seek the several tens of millions of dollars that NOAANET would cost, progress seems unlikely.

Tim Beardsley

AIDS

WHO plans megaprogramme

Washington

THE World Health Organization (WHO) last week said that prevention and control of AIDS (acquired immune deficiency syndrome) has become one of its top priorities and that efforts to combat the disease need to be as urgent as those against smallpox in the 1950s. WHO estimates there will be between 500,000 and 3 million AIDS cases by 1991, with up to 100 million people infected with the virus.

Dr Jonathan Mann, head of WHO's AIDS programme, says those figures could be serious underestimates if AIDS spreads quickly in Asia and in South America. WHO estimates the worldwide cost of fighting the disease at $12,500 million by the eary 1990s.

The WHO AIDS programme officially started in May of this year, and has already raised $4.5 million in special contributions from member governments. The agency is seeking to raise $200 million for next year. By next decade it wants $1,500 million a year, 50 per cent more than its entire budget at present.

WHO will concentrate on the exchange of information among researchers working on prevention and therapy, as well on direct assistance to countries needing to set up their own control programmes. The research component will include coordination of vaccine field trials and the establishment of an international virus bank.

Mann estimates that about 100 countries will need technical assistance in setting up their own prevention and control programmes. These should be based on research on how the disease is transmitted and public education, and should include "hard-headed" social science research into the availability and usage of condoms and hypodermic needles, for example. WHO will also foster operational research into the development of cheap antibody testing for blood banks worldwide.

Tim Beardsley

- The British government last week launched a £20 million campaign to educate the public on the danger of AIDS. "Don't die of ignorance" is one of the slogans that are to confront the British public in a wave of publicity including television, radio and maildrop advertising. The campaign began this week with national newspaper advertisements.

At the end of the year, a month-long television campaign using a 40-second commercial will pave the way for the maildrop. In the new year the 23 million homes in the United Kingdom each receive a letter containing an explicit warning on the danger of AIDS.

A minute-long radio commercial will also be broadcast at the end of the year, narrated by a top disk jockey to attract the attention of the young. **Bill Johnstone**

India screens foreign students for AIDS

New Delhi

MEDICAL screening for AIDS has been made compulsory for all foreign students seeking admission to Indian educational institutions. Under the new guidelines from the health ministry, foreign students provisionally admitted may be liable for deportation if tests confirm the presence of antibodies to human immune deficiency virus (HIV).

The government directive was issued last month after the detection of HIV antibodies in an African student in Madras. He is the only male seropositive case among 22 cases so far identified in the city.

India has an estimated 30,000 foreign students, mostly from Africa and eastern Asia. AIDS screening has been proposed for fresh admissions, but is likely to be made mandatory for foreign students already here. The Indian Council of Medical Research has set up 19 centres to screen sera using imported ELISA (enzyme-linked immunosorbent assay) kits.

There have so far been three deaths from AIDS in India — two of the patients had received blood transfusions in the United States and one was an Indian settled in Malawi. Some 30 antibody-positive cases, most of them prostitutes, are under observation.

K. S. Jayaraman

Japanese volcano

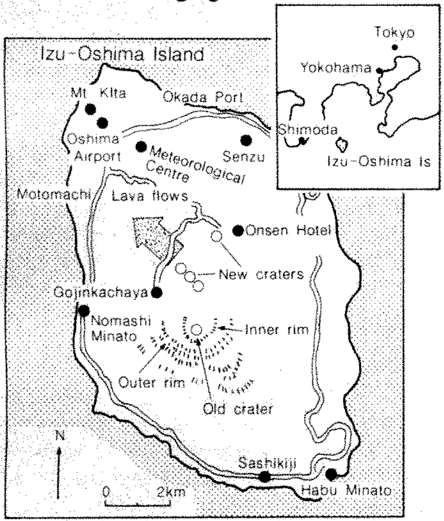
Islanders flee surprise eruption

Tokyo

JAPAN's volcanologists were taken by surprise when Mount Mihara on Izu-Oshima island south of Tokyo exploded in a series of violent eruptions last Friday, forcing the overnight evacuation of the island's 10,000 inhabitants as a river of lava threatened to engulf the main town.

Izu-Oshima is the first in a chain of volcanic islands that extends southward for more than 1,000 km into the Pacific along the edge of the Philippine plate. A submarine volcano at the southernmost end of the volcanic arc temporarily broke surface during an eruption earlier this year (*Nature* **319**, 441; 1986), and Miyakejima, Izu Oshima's immediate neighbour, erupted in 1982. But Izu-Oshima itself has been silent for the past 12 years, and an eruption on the present scale has not occurred in the past two centuries.

The first signs of activity came in July when the island was rocked by volcanic tremors. But surveys by the Meteorological Agency and Tokyo University's Earthquake Research Institute showed no evidence of the 'bulging' of the Earth's crust that typically precedes major eruptions as magma rises to the surface. And at the end of October the Volcanic Eruptions Prediction Liaison Council declared that there were no signs that a large-scale eruption was imminent.



Even after eruptions began on 15 November, the council confidently predicted that lava flows would be confined to the caldera by the outer rim of the volcano, and Oshima enjoyed a temporary boom as hundreds of tourists flocked to the island each day to enjoy the spectacular eruption and lava flows.

After 10 million cubic metres of lava had spilled over the inner rim of the volcano and the rivulets of lava in the caldera had frozen in their path, the Meteorological Agency announced that activity appeared to be decreasing and the island's residents were in no immediate danger. Hours later the evacuation order came.

What nobody had foreseen was the opening of a new line of vents that cut through the outer rim, something that had not occurred in more than 500 years. As the new vents burst into life, lighting up the night sky in a curtain of fire, a river of lava set forests ablaze as it surged towards the main town of Motomachi.

By dawn the island was deserted, the 10,000 residents and 2,000 tourists having been evacuated to the mainland. All that remained were abandoned domestic animals, a farmer who stubbornly refused to leave his 5,000 chickens, and some baffled volcano experts.

On Monday, the lava front lay within a few hundred metres of Motomachi, but volcanic activity seemed to have switched to the southeast coast of the island, where plumes of discoloured water in the sea suggest submarine volcanic activity.

David Swinbanks

Biotechnology insured

Response to product liability

Washington

THE high cost of US product liability insurance has stimulated the Association of Biotechnology Companies (ABC) to plan a captive cooperative insurance company for the industry. If enough companies join the risk-sharing enterprise, it could offer "attractive" rates for insurance in respect of product liability as well as for the actions of directors and officers of companies, according to Bruce Mackler, ABC's general counsel.

Many smaller biotechnology companies have apparently not been able to obtain insurance at reasonable cost; some have had to proceed with none. ABC says one (unnamed) biotechnology company was recently quoted an annual premium of $400,000 for total coverage of $1 million.

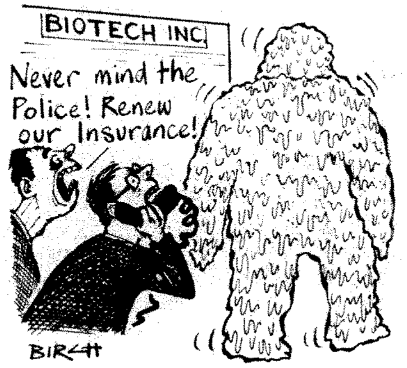
Part of the difficulty is the recent inflation of product liability claims, and of insurance premiums. The insurance industry is also under pressure from the number of product liability suits in federal courts, up by 750 per cent since 1974, and the average jury award, which has risen from $400,000 to more than $1.8 million during the same period, according to the American Insurance Association.

Insurers are especially fearful of the doctrine, recently introduced in California, of "joint and several liability", which means that a party only partly at fault can be obliged to become the "deep pocket" from which a whole claim must be met. Chemical, pharmaceutical, aircraft and car manufacturers are most at risk.

This, say insurance companies, is why they prefer to stick to the devils they know, such as automobile insurance and workers' compensation, than to take on unknown quantities such as biotechnology. They fear that huge claims may be made in the light of future knowledge, as they have been for medical products, when initial ignorance of harmful effects may not be a defence.

The ABC scheme was recommended by a study conducted by insurance brokers Johnson and Higgins of New York. Twenty-four companies from around the world, including well-known companies such as Celltech and Charles River, have chipped in enough to establish the biotechnology insurance cooperative legally in the state of Vermont; it should be ready for "activation" by early December. Membership will be open to any company in the field, but 30 members will be required to make it viable. The Industrial Biotechnology Association, which represents generally larger companies, has considered and rejected such a scheme, as many of its members are able to carry their own insurance.

The ABC captive insurer will provide only modest coverage at the outset: $1 million of either primary or "excess" coverage, with an aggregate ceiling of $3 million. But coverage would increase if the scheme expands; 44 companies have asked for quotes. ABC hopes the scheme will include insurance against environmental damage for such products as microbial pesticides, but admits that may be expensive. All participants will be inspected by risk management experts to ensure they are "doing things by the book".



BIOTECH INC
Never mind the Police! Renew our Insurance!
BIRCH

The American Insurance Association is generally sceptical of captive insurers, saying that insurance costs reflect the costs of meeting claims, no matter who does the underwriting. The insurance industry says that the provision of medical malpractice insurance through similar "risk retention groups" is now as expensive as through commercial agents.

Tim Beardsley

CNRS

Union power may not erode

The 20,000 staff, £600-million budget French national research council, CNRS, is to be given a lighter management structure and put back in the hands of the 'best' scientists after years of technocratic rule from the top and foot-dragging by trades unions.

That at least is the theory now being put out by the new CNRS administration, encouraged by the French prime minister, Jacques Chirac. Last week Chirac and his ministers gave approval for a new de-unionized structure for the research council's elected evaluation committee, the 1,000-strong Comité National. This gives back to CNRS power lost earlier in the year when the previous Comité National was declared illegal on a technicality, and clarifies at least part of the new government's policy towards science.

According to Serge Feneuille, director-general of CNRS, one of the new slogans will be that "science cannot be unionized", and the restructuring of the Comité National confirms it. In the elections, which will probably be complete by April 1987, at least half the candidates, especially the most senior, will no longer have to declare a union affiliation but may stand under their own name. Places on the committee for the engineers, technicians and administrators who are most unionized are to fall.

But although these developments are meant to loosen the hold of the unions over the system of promotions and grants, the new structure, according to its opponents, will shift power from the unions to another sector that could be equally conservative, university lecturers who do no research, but who will now be free to vote and stand for election. This move is a concession to university opinion that would have preferred CNRS to be dismantled. The resulting compromise, say critics, will merely hamstring the scientists in a new way. In the life sciences, many non-researching physicians from teaching hospitals will be joining the evaluation committees to make their opinions of French biology, and biologists, felt.

Whatever the politics of the Comité, there is some relief among 'les admissibles', the 512 young hopefuls who were appointed to full-time life-long CNRS research positions earlier this year by the previous Comité National, only to have the Comité declared illegal. At least now there is a legal Comité to look into their case, but, according to CNRS, they will have to take their examinations again. The same number of posts, 512, will be made available, and the resulting appointments will be counted as 1986 appointments with no bearing on the level of further recruitment in 1987. The proper 1987 appointments round (some 400–450 posts) will then take place in September and October, with a return to a normal spring timetable in 1988.

Meanwhile, Feneuille is known to have considerable interest in the introduction of short-term postdoctoral positions into the French research system which now locks itself into the appointment of a scientist for life at the age of 26. Feneuille believes that French industry, in which science is severely under-represented is in need of 'irrigation' with scientists. He argues that a system of postdoctoral appointments to CNRS in excess of the long-term need would allow the scientific irrigation of industry, as happens regularly in the United States and Britain. Such a change, however, could be political dynamite in France. **Robert Walgate**

Soviet academy

Marchuk in ministerial mode

The Soviet Academy of Sciences, already regarded by Soviet planners as the chief coordinator of all pure and applied research in the Soviet Union, is to acquire a new role. Addressing the Supreme Soviet (the Soviet Union's bicameral parliament) last week, Gurii Marchuk, the new president of the academy, said that it is to start producing forecasts for the major areas of science so as to identify the parts of the national economy ripe for development.

The new role of forecasting is part of a major reorganization of the structure and management system in line with the restructuring of the whole Soviet economy launched by Mr Mikhail Gorbachev last year. Under the new scheme, Marchuk said, the "specialized departments" of the academy will play a larger part, so as to direct scientific institutions towards the most important problems of fundamental and applied science.

How these changes will work is not yet clear. The major innovation so far of the Gorbachev era in science and technology, the "interbranch scientific-technical complexes" (MNTKs) are, in Marchuk's words "producing stress and difficulties". These organizations were supposed to "accelerate scientific and technical progress" by cutting across the interdepartmental bureaucracy and the barriers between science and industry. (At present the gap between initial breakthrough and large-scale production is said to be as much as 11 years.)

But as yet, the only MNTK to have received official commendation is the Paton Institute of Electric Welding of the Ukrainian Academy of Sciences, which has existed for many years and which served as the model for the MNTK concept.

Marchuk also repeated in his speech the targets outlined in the draft plan for 1987 (computers — both main-frame and personal; plasma, radiation and laser treatment of specialized materials; powder metallurgy; and biotechnology) and the Comecon Comprehensive Programme for Scientific and Technical Progress up to the year 2000. But, he warned, if the Soviet Union's "fine scientific and technical foundation for attaining the highest world standards" is to be properly employed, the planners, and in particular those involved in the capital construction of new enterprises, must play their part.

This is a new line. Hitherto, scientists have blamed industrialists for not using their results; more recently industrialists have begun to retaliate, saying that the results they were offered were unsuitable in practice. Marchuk now seems to be arguing that scientists can produce what industry needs only if the planners properly specify what is required.

But the real novelty of Marchuk's speech was not so much what he said but the fact that he addressed the Supreme Soviet in a virtually ministerial manner. As former head of the State Commission for Science, of course, he is no stranger to the Supreme Soviet. But the fact that he would have addressed it in this way at this early stage suggests that his presidency of the academy will be more vigorous than that of his predecessor. **Vera Rich**

Networking the begging-bowl

Strasbourg

The general assembly of the European Science Foundation (ESP), the most penniless and self-effacing of European science institutions, came to no particularly decisive conclusions last week. But the foundation did agree that it would ask its members (emphatically not governments but the research councils that governments support) for extra funds to keep its network programme alive.

That programme springs from an inquiry by ESF two years ago, at the behest of the European Commission, which showed that European researchers were too often isolated from each other. Largely because of a donation of a million French francs, the network programme last year brought 400 people together at 35 international meetings. The flavour, this year, is polar research, on which everybody is keen. But there are no funds, whence the begging bowl. Robert Walgate

Technology database

Best buys in UK research

EVERY researcher in Britain is to be mailed on behalf of an on-line computer database, designed to sell British talents to industry worldwide. Called British Expertise in Science and Technology (BEST), the commercially run database has been endorsed by the British government and the Science and Engineering Research Council (SERC).

Researchers in universities, polytechnics and the research councils are being asked to take part in the programme, in part intended to provide the supposed missing link between researchers and industrialists. Thirteen thousand records on researchers and their work now constitute the core of the database. A typical record will show a researcher's qualifications, publications, past and present research work, specialities, peripheral interests, industrial experience, current and previous positions. With the appropriate telecommunications link, the database can be tapped from any part of the world.

The database is part of the response by British universities to the publication in June 1983 of the report by the government's Advisory Council for Applied Research and Development (ACARD), which urged closer links on research between higher education and industry. In 1984, the universities set up a committee representing government departments and agencies as well universities and polytechnics. The committee selected the best proposal by Longman Cartermill, part of the Longman publishing house, from among other bids submitted.

Since the launch of the database in the spring, the operators claim to have attracted more than 100 industrial subscribers. Data entries to the system are free. Revenue will derive from subscribers, who are charged £200 for a single search or fees ranging up to £10,000 a year for full corporate use.

The terms of an agreement between SERC and the operators have yet to be concluded, but to start with, SERC will provide information on its research grants in return for access to the database for its own purposes. **Bill Johnstone**

- Meanwhile, the British Library is to launch its separate on-line computer database this week. That will focus more on research projects than researchers. The database contains 65,000 records of research being conducted in Britain. The system, called Current Research in Britain (CRIB), has evolved from an annual printed publication produced by the library. It has a £50-an-hour connection charge and is operated for the British Library by Pergamon InfoLine. □

Information technology

Filling the post-Alvey gap

A £1,000 million five-year plan to strengthen Britain's research in and application of information technology was proposed last week by the IT86 committee, set up this spring under Sir Austin Bide, the now-retired chairman of the Glaxo pharmaceutical group. The request for funds on this unprecedented scale is meant to continue the five-year Alvey programme of research and development in information technology, whose £350 million is now almost fully committed.

More than 300 projects have been approved under the Alvey programme, but the Bide committee considers it too soon to evaluate their success except to say that they have been successful in drawing industry and universities together more closely "than was previously the case". The committee also says the programme has stimulated collaboration between companies normally in competition.

Of the total £1,000 million, the committee proposes that roughly £425 million should come from the British government and the remainder from industry. The government contributed £200 million to the total cost of Alvey projects.

The Bide committee estimates that the research element in the continuation programme will cost £550 million, of which the government is expected to contribute £300 million. As under Alvey, academic research would be fully supported by government, but research by industrial companies receives only half-support.

The committee also endorses some of the conclusions of a report by the British government's Advisory Council for Applied Research and Development (ACARD) which, earlier this year, was critical of the British software industry. That document forecast a continued increase in the British trade deficit in information technology.

Much of the Bide committee's emphasis is on the need for converting research into marketable products. The committee says that applications schemes must involve collaboration between researchers and industry and that academic contributions to joint ventures should "go well beyond" traditional information-technology departments. The report also includes a long shopping-list of projects to be supported. Among applications projects, it singles out security systems, clinical data processing, interactive distance learning aids, distance learning for management, manufacturing control, electronic funds transfer at point of sale and software for railway signalling.

On research, the Bide committee recommends a number of areas to which effort should be directed, including systems design and management and new programming tools. Not all the support now requested need be new money; part of it may come from the funds already earmarked for the second phase of the European Strategic Programme for Research and Development in Information Technology (ESPRIT).

No doubt in recognition of the difficulty of extracting large amounts of money from the budgets of individual government departments, the committee says that the funds should come not only from the original sponsors of the Alvey programme (the Departments of Trade and Industry and of Defence and the Science and Engineering Research Council) but from other departments with an interest in the applications suggested, either as sponsors or as users. **Bill Johnstone**

Dissent disallowed in Singapore

SIR—There exists an interesting juxtaposition of events in Singapore this week. On the one hand, scientists from all over the world are gathering for the Fourth Federation of Asian and Oceania Biochemists (FAOB) meeting, to present and discuss work freely. This meeting is important, as it is timely, to the powers that be in Singapore, in that it precedes the opening of the new Institute for Molecular and Cell Biology there, for which the talents of the international scientific community are being anxiously courted. In stark contrast, the voice of dissent in Singapore's parliament, Mr Joshua Jeyaretnam, is effectively silenced this week; together with the chairman of the opposition party, Mr Wong Hong Toy, he finds himself in the cells of Singapore's Changi Prison.

The history of events that have led to fines, imprisonment and the removal of the leader of the opposition from his seat in parliament is adequately dealt with in such publications as *Time Magazine* (8 September 1986), *Financial Times* (12 November 1986), *Far Eastern Economic Review* (4 September and 20 November 1986) and the *Asian Wall Street Journal*. As a result of these articles, in which the motives of the government and the independence of the judiciary are called into question, two of these publications have incurred sanctions. The net overall effect of these events is to suggest that the voice of dissent in Singapore, be it from individuals, editors or members of parliament, is to be silenced at any cost. It is against this political backdrop that the Singapore government, advised by a number of eminent scientists from the United Kingdom, the United States of America and West Germany, seeks aggressively to recruit internationally scientists upon whose cooperation the success of the FAOB meeting and that of the Institute for Molecular and Cell Biology rests.

This situation, taken as a whole, raises some quite difficult questions, addressed especially to those advising or considering working at the Institute for Molecular and Cell Biology in Singapore. When a scientist enters into a commitment of research in Singapore, does he retain his right to comment on what he sees? If the independence of the judiciary and the freedom of the press are called into question, who is left to take the responsibility of safeguarding the rights of the individual to criticize? This responsibility sometimes comes to rest in unexpected quarters. In this case, because their services are of value to the Singapore government, some of this responsibility lies squarely with the international scientific community. It is up to us to satisfy ourselves (the facts are on record) that the individual in Singapore who wishes to voice legitimate criticism has the freedom to do so. If this freedom does not prevail, then the scientific community at large, being in a position of influence, must not flinch from the responsibilities associated with this position, and must use this influence to foster the necessary change of attitude within the government in Singapore.

No government should assume that it can, through institutions such as the Institute for Molecular and Cell Biology in Singapore, exploit the talents of the international scientific community and expect the scientists concerned to turn a blind eye to the fate of the people in whose country they work.

Fluoridation

SIR—The 1983 Anglesey study[1] does not demonstrate the effectiveness of fluoridation, as Francis B. Reed claims[2]. Apart from its questionable late selection of a known high-caries non-fluoridated control population different from that originally planned, without pre-fluoridation information on the populations being compared — making its "strictly blind conditions"[2] worthless — its concluding assertion of "the universal finding that caries experience in a fluoridated community is consistently lower than in neighbouring non-floridated communities" is shown to be untrue by the many studies cited in Diesendorf's Commentary[3]. In New Zealand we have dental health figures for our entire child population, not just for samples as in "fluoridation trials". The figures for Auckland show that the children in the non-fluoridated part of the city require fewer fillings, not more[4]. The non-fluoridated off-shore island children also need fewer fillings, just like the fluoridated island of Anglesey.

UK performance

SIR—Your contributors have recently reviewed two influential reports on British performance in research[1,2]. One concludes that "the main findings are that in basic research in science as a whole, UK performance has deteriorated since the early 1970s both in absolute terms and relative to other countries, notably FRG and Japan". The figures that most strikingly emphasize this point are the citation rates.

This broadbrush conclusion disguises a more precise relationship. The relative proportions of each of the competitors' total research budgets spent on defence in the early 1980s have respectively been 0.5, 0.2 and 0.02, demonstrating a clear negative correlation between the proportion of research funding for defence and the corresponding civil research performance.

One can only guess why this should be so, if indeed the relationship is real at all, let alone representative of the world at large, derived as it is from only three (very important) examples. Yet if it is real it smacks of a sort of logic: the greater the proportion spent on defence, the greater the number of defence scientists required to spend it and consequently, from a limited resource, the smaller the number in civil research; also the greater the proportion spent on defence, the greater is the restriction on research reports available for citation. The former points towards a real problem for UK civil research; the latter to a possible mitigating explanation of its apparent recent lacklustre performance.

Backfiring boycott

SIR—The signatories of the Strategic Defense Initiative (SDI) boycott pledge (see *Nature* **323,** 747; 1986) may find themselves in an embarrassing position, should the United States and the Soviet Union agree on how to regulate laboratory research on SDI. Would they recant their position, and on what grounds? The research programme (and that is all that the academics are involved in) will certainly not become technically any less dubious simply by receiving Mr Gorbachev's blessing. And were the Western scientists to continue their boycott unilaterally, they would simply be paving the way to a technological breakthrough by the Soviets, tempting them to break out from the Anti-Ballistic Missile Treaty. Is this course of action any less misguided than participation in SDI research? The most disturbing feature of the anti-SDI pledges circulating in the United States and now in Europe is that they are black-and-white statements that do not allow for any shades of grey.

How to make antimatter last

An experiment at CERN has shown that antiprotons can be kept for several minutes in an electromagnetic trap. But the prospect of making reality of the science fiction remains remote.

SCIENCE fiction writers, ingenious people as they are, include among the standard props of their trade a ready supply of antimatter, the most portable of all high-explosives. During the past few years, there has also been a disturbing trickle of accounts in the popular press suggesting that the world's accelerator laboratories are hard at work on the development of techniques for making antimatter for use in military operations. A glance at one of the first published accounts of success in storing antiprotons (*Phys. Rev. Lett.* **57**, 2504: 1986) should persuade all those concerned that it will be some time before the fiction can become reality.

For other reasons, the new development is interesting and important. Working at CERN, the European high-energy physics laboratory at Geneva, a group from the University of Washington at Seattle (Gabrielse, Kei, Helmerson, Rolston, Tjoekler and Trainor), two people from the University of Mainz (Kalinowsky and Haas) and one from the Fermi National Accelerator Laboratory (Wells) have been able to decelerate antiprotons to the point at which their energy is sufficiently small to allow them to be captured in an electromagnetic trap. The experiment is a technical achievement in its own right, but the prospect that it will now be possible to study antiprotons essentially at rest, and stable for some minutes, raises the prospect of a series of previously impossible experiments.

CERN's advantage in this connection is the facility called the Low Energy Antiproton Ring (LEAR), which is a device for storing bunches of antiprotons produced by the Super Proton Synchrotron (as modified so that protons and antiprotons travel in opposite directions) and reducing their individual energy by four orders of magnitude to 5 MeV or thereabouts. Novel experiments are possible even at this energy (see Batty, C.J., *News & Views, Nature* **323**, 487; 1986). But even 5 million volts is far greater than the electrostatic potential well of the kinds of traps that might be constructed in the laboratory.

The obvious way to make possible the trapping of antiprotons would be a further elaboration of the LEAR storage ring, but although CERN has ambitions in that direction, the extra equipment has not yet been built. Accordingly, the Washington–Mainz group has fallen back on the simplest of all devices for robbing fast charged particles of energy — that of making them traverse a dense target of matter, a solid beryllium window. In practice, the experiment uses virtually instantaneous bunches of antiprotons, each of them containing between 10 million and 1,000 million particles.

Inevitably, the process is inefficient. With the thickness of the window chosen to be the range of antiprotons, at the energy discharged from LEAR, in beryllium, only about 1 in 10,000 of the original bunch emerges from the target with an energy less than 3 keV, which means that typical bunches leave only some 10,000 antiprotons for catching in a trap.

That consists of two components, of which the simplest is a powerful axial magnetic field to prevent slow antiprotons moving too quickly away from the axis of the experiment. The other is a conceptually simple but technically sophisticated pair of electrodes, each with a hole in the centre (a third of a centimetre across) to allow the passage of the antiproton beam, and roughly a dozen centimetres apart. Before the arrival of an antiproton bunch, the first electrode is at earth potential and the second, or more distant, has a potential of −3 kV so as to repel antiprotons less energetic than 3 keV. But while the bunch is travelling the length of the trap, the voltage of the first electrode is switched, in a matter of nanoseconds, to match the potential of the first.

For the time being, the objective is to see how efficient such a simple trapping technique may be. As these things go, the mechanism seems to work as well as anybody expected in advance. The population of antiprotons can be measured at any time by abolishing the repulsive potential on the more distant of the two electrodes, whereupon the antiprotons are guided by the axial magnetic field to a target where they annihilate, yielding pions which can be counted. Apparently, the counting equipment is not yet fast enough to measure the population of a newly filled trap, but typical records show that, after a millisecond, the trap may contain 300 or so antiprotons. One of the published records shows that after storage for 100 seconds, it was still possible to record 31 antiprotons, spread over a mere 5 microseconds. On balance, it seems as if it is possible to catch roughly 3 in a million of all the particles discharged as a bunch from LEAR.

At this rate, sheer numbers are less important than the other properties of the trap, which will determine what use can be made of a supply of essentially static antiprotons. The authors of the experiment brim over with suggestions for what may happen next. One scheme is to make single atoms of anti-hydrogen, perhaps by building two traps alongside each other, one for antiprotons and one for positrons. Firing a beam of positronium atoms (pairs of positive and negative electrons) at antiprotons in a trap might be a simpler way of accomplishing the same goal. The prospect of precision measurements of quantities such as the antiproton mass, or even of the gravitational acceleration of antiprotons, will intrigue many observers of this new development.

Technically, the improvement of the present means of trapping antiprotons is an obvious line of evolution, but the authors write of the still more promising line of development in which antiprotons trapped as they describe would be transferred, bunch by bunch, to a trap whose geometry is not constrained by the need to capture as many particles as possible from LEAR. Such a device would therefore be better suited for keeping even these unstable particles for long periods of time, a day or even longer. That is what will have to be done if some of the more interesting measurements now suggested are to be carried out.

All this is of course a long way from what the science fiction writers require of antimatter. While the best that people can do is to store a few hundred antiprotons for an hour or so, the prospect of antimatters weapons will remain very distant. The essential difficulty is a score or so of orders of magnitude. True, the annihilation of an antiproton by, say, a proton of the kind that turns up in ordinary matter is more energetic, by a factor of say a hundred, than the fission of a uranium nucleus. But Avogadro's number (6.10^{23}) works emphatically in the other direction. So long as numbers of antiprotons that people can collect in antiproton traps are small enough that it is feasible to think of counting them, the popular newspapers' accounts of what high-energy physics is really for will remain in the realm of fantasy. It is nevertheless outrageous that there have been in the past few years, such a torrent of tales along these lines. They will always be fairy stories. So, too, perhaps sadly, will be the relevant parts of science fiction.

John Maddox

Evolution

Contemplating life without sex

John Maynard Smith

FROM the selfish-genetic point of view, there are obvious advantages to parthenogenesis. A gene that suppressed meiosis in female diploids would be transmitted to all female offspring instead of only to half and thus would, all else being equal, double in frequency in each generation. Why then, does parthenogenesis not replace sex? The answer has to be that all else is not equal. Why not? One good reason for studying parthenogens is for the light they may shed on the evolution of sex, and the problems of parthenogens were the topic of a recent symposium* from which it is clear that for one reason or another it is very difficult to give up sex once you have it.

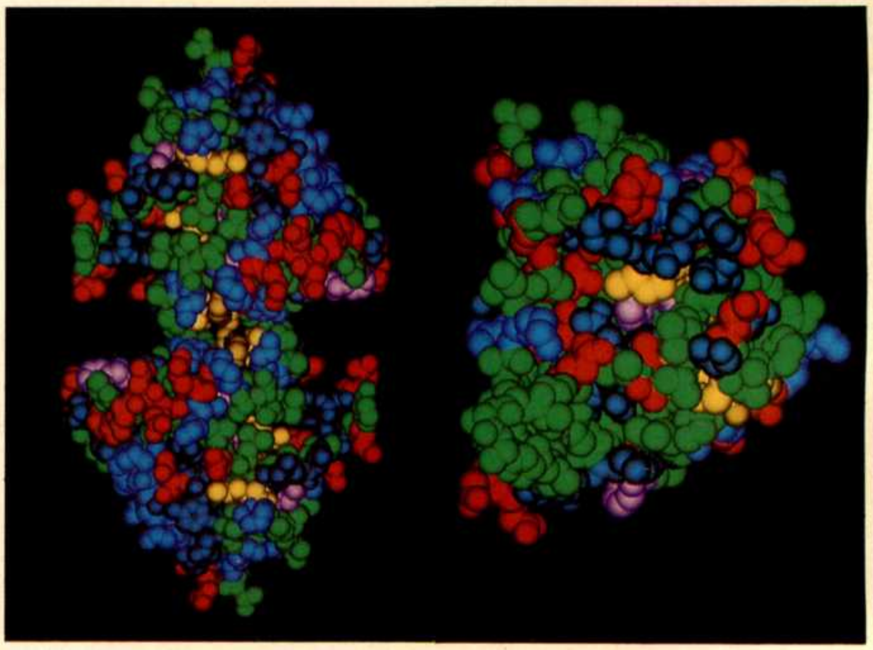
Most existing parthenogens have evolved from sexual forms and are hampered to varying degrees by the persistence of mechanisms appropriate only to their ancestral lifestyle. As so often, the fruitfly *Drosophila* provides a good example. Females of many species lay an occasional egg that develops without fertilization. But it is a long way from the occasional egg to functional parthenogenesis (A. Templeton, Washington University, St Louis). Parthenogenetic laboratory strains now exist in several species, including *D. melanogaster*, but it took much selection to establish them. Before selection, unmated females lay few eggs, and even fewer start development. Of those that do start, most die because of genetic homozygosity resulting directly from the mechanism of parthenogenesis. The mechanism is known as automixis: the egg undergoes meiosis, and diploidy is restored by the fusion of two of the four products. Because natural populations carry many deleterious recessive genes, automixis results in heavy mortality. The only species which is parthenogenetic in nature, *D. mangabeiri*, has overcome this problem in an ingenious way. First, the two haploid nuclei that fuse are those that are separated at the first meiotic division; second, there is no crossing over. Together these devices ensure that the offspring are genetically identical to the parent: heterozygosity is preserved. Crossing over is prevented by inversions.

The picture that emerges from these studies of *Drosophila* is probably typical. The disadvantages suffered by recently arisen parthenogens are the direct result of their sexual ancestry; but these 'sexual hang-ups' can be overcome by selection. The precise means of overcoming them varies. Some parthenogenetic animals, and many plants, opt for abandoning meiosis altogether — apomixis; this is the pattern in the cyclically parthenogenetic aphids and cladocerans. Alternatively, in the parthenogenetic lizards of the genus *Cnemidophorus*, there is a premeiotic doubling of the chromosomes, followed by the pairing of sister chromosomes in the first meiotic division. This has the same genetic consequence as the meiosis of *D. mangabeiri*: offspring are genetically identical to their parents, and do not suffer the enforced genetic homozygosity that is the usual result of automictic parthenogenesis. The parthenogenetic species *C. uniparens*, which is a highly heterozygous species hybrid, consists of a single clone: members of the species accept scale grafts from each other.

Another common type of sexual hang-up in parthenogenesis is the persistence of the need for sperm to trigger development — pseudogamy (that is, the stimulation of egg development by a sperm whose chromosomes do not participate in forming the new individual).

In some lower vertebrates (discussed by H. Hotz and T. Uzell, University of Illinois and R.C. Vrijenhoek, Rutgers University), the sperm is probably needed to provide a centriole. (No such need, however, exists in lizards.) Pseudogamy is not uncommon in insects. In plants, a nucleus from the pollen tube may be needed to fertilize the endosperm, even if the embryo is parthenogenetic. Some parthenogenetic frogs (*Rana*) and fishes (*Poeciliopsis*) have evolved what is perhaps the strangest mechanism of all for dealing with this requirement. It is known as hybridogenesis. *Rana esculenta*, for example, is a hybrid between two sexual species, *R. ridibunda* and *R. lessonae*. In the germ line, *lessonae* chromosomes are thrown out, so that the egg contains only the *ridibunda* component. If, as is typical, the hybrid female mates with a *lessonae* male, the hybrid *R. esculenta* is reconstituted. Clearly, pseudogamous and hybridogenetic forms cannot wholly replace their sexual ancestors. In some major taxa, for example mammals and gymnosperms, parthenogenesis has not been reliably recorded, but the nature of the hang-up is not known.

Despite the widespread occurrence of sexual hang-ups there are many parthenogens that seem to have escaped the disadvantages derived from their sexual ancestors. The taxonomic distribution of parthenogens, however, suggests that they may be successful in the short run,



THESE three-dimensional views of β-lactoglobulin show two identical monomers tenuously linked. Each monomer is similar to plasma retinol-binding protein and each contains a non-polar pocket similar to that occupied by retinol in retinol-binding protein. The non-polar pocket is in the centre of view in the right-hand figure. The function of β-lactoglobulin, a milk protein, has long been unknown; these new models suggest that it is a transport protein. The structure is described in more detail by M.Z. Papiz and colleagues from the Universities of Leeds, Edinburgh and Uppsala, on pages 383–385 of this issue. The colours represent different types of amino-acid residue: red, acidic; dark blue, basic; light blue, polar; purple, aromatic; yellow, sulphur-containing; green, non-polar. Computer program by Dr H. Nakamura. □

---

*A meeting on parthenogenesis organized by L. Kirkendall and N.C. Stenseth at Finse, Norway, 17–22 September 1986.

but are short-lived on an evolutionary timescale Thus, most parthenogens have close sexual relatives It is rare for a taxon higher than a species to consist wholly of obligate parthenogens The parthenogenetic order Bdelloidea of rotifers, and the tribe Tramini of aphids, are important exceptions that challenge further research

Among higher plants, taxa such as *Taraxacum* (dandelions) and *Rubus* (blackberries) that contain many parthenogens also contain sexual species, and new clones are continuously arising Two theoretical reasons have been suggested for this short evolutionary life expectation First, evolution to meet changed circumstances will be slow in the absence of genetic recombination Second, there may be a tendency to accumulate slightly deleterious mutations (Muller's ratchet[1]) Although the theory is clear, it is hard to provide empirical support A major difficulty lies in deciding how old particular clones may be, and in distinguishing between variation that has arisen by evolution within a clone and that which reflects multiple origins from sexual ancestors No-one was prepared to make even a rough estimate of the age of any clones

The simplest picture is as follows Most parthenogenetic 'mutants' fail to establish themselves because of various sexual hang-ups Some, under intense selection, overcome these difficulties and achieve short-term ecological success Despite their twofold reproductive advantage, however, success is short-lived on an evolutionary timescale because of their relative inability to adapt, and perhaps because of the accumulation of mutations

Is any further explanation needed? Williams[2] argued that it is, essentially because the coexistence of closely related sexual and asexual populations implies that sex must confer some immediate advantage He thinks that this advantage arose from the genetic variability associated with sexual reproduction This can take two forms first, a sexual population will be more variable than an asexual one, and second, the offspring of a single sexual female will vary more than the offspring of an asexual one

The variability of a sexual population may be relevant in the following way A single clone, with a single genotype, is unlikely to displace its sexual ancestor over its whole ecological and geographical range Vrijenhoek has called this the frozen niche hypothesis (Bell's[3] tangled bank model is, I think, similar), and argues that, as the number of different clones increases, the relative success of the sexual species should decline He finds that, in *Poeciliopsis,* clones do differ physiologically and in their ecological adaptations, and that the proportion of the population that is sexual declines as the number of distinct clones in a stream decreases In *Poeciliopsis*, however, parthenogens need to be mated, so they cannot wholly replace their sexual ancestors Clonal diversity is now being studied, using biochemical markers (and, in vertebrates, immunological methods), in many plants and animals, and this should help us to decide on the importance of population variability in conferring an immediate advantage on sexual populations

The Williams 'balance' argument may also be relevant to cyclical parthenogens such as cladocerans (M Lynch, University of Illinois) and aphids (N Moran, University of Arizona) We must be cautious, however, because there is often an ecological difference between the sexually and asexually produced eggs For example, in *Daphnia* the resistant winter eggs are often produced sexually If this was a universal rule, the maintenance of sex could be explained by the need to produce winter eggs But there are obligately parthenogenetic strains of *Daphnia,* some of which produce winter eggs asexually The situation is similar but more complex in aphids Most aphids have two plant hosts, and the sexual forms attack the secondary host No obligately parthenogenetic aphid has retained the ability to utilize two hosts, but there are many cyclically parthenogenetic aphids that are confined to a single host, and these have given rise to many obligately parthenogenetic strains Some modification of the frozen niche hypothesis, therefore, may be needed to explain why all cladocerans, and aphids with only one host, do not wholly abandon sex

Williams argues that genetic variation among the offspring of a single female may also be important He uses the famous analogy that a parthenogenetic female is like a man who buys 100 tickets in a lottery and finds that they all have the same number I have argued[4] that this model only works if the offspring of one female compete with one another, but showed that, provided that there is sib competition, the model can give rise to a twofold advantage to sex

But do we need to take into account the genetic variability of individual families, or are the other explanations outlined above sufficient to explain the failure of parthenogens to replace sexual forms? There is one context in which within-family variability may be relevant

Consider a population of diploid parthenogenetic females, that is, females that produce some of their offspring parthenogenetically and some sexually Why does such a population not evolve towards obligate parthenogenesis? From the point of view of its own proliferation, there would be an intrinsic advantage to a gene that suppressed meiosis, and it is hard to believe that there would not be some genetic variance affecting the proportion of offspring produced asexually and on which natural selection could work We cannot appeal to the greater variability of the sexual population, because the range of genetic variability is the same in the sexually and asexually produced offspring The sib competition model might, therefore, be necessary

Do such facultative parthenogens exist? In animals, I know of no clear example Populations with a female-biased sex ratio usually consist of a mixture of obligate parthenogens and a bisexual population But there are many case that merit further investigation In plants, there do seem to be examples One, the diploid form of *Potentilla argentea,* was described (S Asker, Lund) These cases need genetic and ecological study

I formed the strong impression that the study of parthenogenesis is, at last, beginning to tell us something about the evolutionary significance of sex Much remains to be done The Bdelloids remain something of an evolutionary scandal We need to know the age of at least some natural clones, the extent of genetic diversity that can arise within them, and whether deleterious mutations accumulate in them by the ratchet mechanism Further studies of clonal diversity will show how important the frozen niche and tangled bank models in fact are The suggestion[5,6] that sex is needed in the evolutionary race against parasites should be investigated The few clear cases of diploid facultative parthenogenesis should tell us whether sib competition is relevant I think that the problem of the maintenance of sex in higher eukaryotes is different both from the problem of the evolution of recombination in prokaryotes and from the origin of meiosis and syngamy in single-celled eukaryotes The three problems may have different solutions Indeed, I am reasonably sure that the first two do have different solutions, because the primary function of recombination in prokaryotes is probably the repair of damaged DNA Although DNA repair is also needed in eukaryotes, I do not think that the suggestion[7] that meiosis and syngamy serve a repair function is tenable indeed, one of the reasons why parthenogens are interesting is that they demonstrate that this suggestion is mistaken As far as the maintenance of sex in organisms like ourselves is concerned, I think the main theoretical explanations have already been formulated, and our task is to decide on their relative importance □

Nuts to tough ceramics

Paul Calvert

MACADAMIA or Queensland nuts are much used in high-class cookies but are very difficult to remove from their shells without special equipment In a recent article, J S Jennings and N H Macmillan (*J Mater Sci* **21**, 1517, 1986) discuss the properties of the fibrous macadamia nutshell and shed some light on the prospects for fibre-reinforced ceramic materials which are currently thought to be the route to tough ceramics for use in engine components

Jennings and Macmillan looked at the microstructure of the nutshells and measured the mechanical properties of various sections of the shells in the wet and dry states It is very difficult to obtain reproducible mechanical measurements on biological materials because the properties are frequently dependent on the age and moisture content of the tissue and vary with orientation and position in the organism as well as being vulnerable to flaws This creates something of a philosophical problem for engineers who are faced with a natural system, when they are more used to uniform properties measured on large pieces of material In this (nut) case the properties are surprisingly uniform and are best described as those of 'isotropic wood' That is, the moduli, strength and toughness are comparable with the geometric averages of those parallel to the grain and across the grain of a softwood A nice recent example of this grain effect is a study of kelp (Vincent, J F V and Gravell, K *J Mater Sci Lett* **5**, 353, 1986), which forms 'leaves' by the tearing action of the sea along the weak direction parallel to the fibres The work of fracture decreases by 500 times from fracture across the fibres to fracture parallel to the fibres

The Young's modulus (elasticity in tension) of the nutshells is about 5 GPa, where wood is about 10 GPa parallel to the grain and 0 5 GPa across the grain The (fracture) strength of the shells is 50–80 MPa, where wood is about 100 MPa along the grain and 5 MPa across In terms of a complete nut this corresponds to a hungry gourmet needing to exert about 50 kilos of force on a normal pair of nutcrackers The fracture toughness is calculated from the stress needed to propagate a crack in a notched sample, and is thus a measure of one's ability to open the nut by making a small cut and levering on it This value is in the range from 0 8–2 MPa m$^{1/2}$ for the nutshell whereas wood is 1 and 2 MPa m$^{1/2}$ parallel and perpendicular to the grain, respectively As Jennings and Macmillan point out, these properties are not terrific when one takes into account the fact that the density of nutshells is 2 5–3 times that of wood The advantage of this design seems to lie in the isotropic properties which ensure that the shell is not weak along any particular direction and so cannot be split like wood, on the same principle that plywood gains strength by having layers with crossed grains This toughness precludes attacking the nut by a shrewd wallop with a hammer and chisel

The shell is made up of fibrous cells, each about 30 µm in diameter, which are arranged in bundles of tens or hundreds of parallel rods The bundles then pack to fill the volume When the shell breaks, the fracture either goes through the rods or around them, depending on whether the crack is perpendicular or parallel to the rods The toughness then arises from the need for the crack to change direction as it traverses the shell, possibly with some microcracking within and around the fibres that significantly adds to the energy needed to drive the crack This is illustrated by recent work of A R Sanadi, S V Prasad and P K Rohatgi (*J Mater Sci Lett* **5**, 395, 1986), who looked at fracture of polyester resins reinforced by fibres of sunhemp They observed extensive splitting and deformation of the fibres during fracture of the composite, and argue that this would give higher toughness than found in an equivalent composite reinforced with a brittle fibre such as glass The sunhemp composite has 15 times the work of fracture of the polyester resin alone

At a recent meeting on ceramics in Pennsylvania, United States (15–19 June 1986), A G Evans (University of California, Berkeley) summarized the requirements for the successful application of ceramic (for example, alumina or silicon nitride) parts in engines These were a toughness of 20–25 MPa m$^{1/2}$, a strength of 300 MPa and a creep strain of less than 1 per cent at high temperature (>1,000°C) All these properties can be achieved, but not all in the same material at once and not reliably The toughness of the ceramic can be raised by two methods one is to incorporate some tetragonal zirconia which raises the toughness by a martensitic transformation process similar to that in steel from 3–5 to 10–20 MPa m$^{1/2}$ This has the disadvantage that the toughening is not stable to high-temperature treatments The second is to incorporate fibres or whiskers of another ceramic to make a ceramic-toughened ceramic composite Because we want to make moulded parts rather than bars or sheets, the fibres must be randomly oriented to produce a structure very similar to that of the macadamia shell This structure is quite different from conventional composites where the fibres are either all parallel or are arranged in layers and where a hard, strong fibre is used in a soft but tough matrix, as in glass-fibre reinforced plastics

Silicon carbide whiskers about 0 6 µm long are commercially available from pyrolysed rice hulls These whiskers have been used to reinforce alumina, producing a doubling in toughness to 6–9 MPa m$^{1/2}$ Because the system was hot-pressed, the fibres were in a random-in-plane orientation rather than isotropic At loadings higher than 20 vol per cent, the whiskers did not increase toughness because they cause extensive cracking in the alumina during sintering (Wei, G C and Becher, P F *Am Ceram Soc Bull* **64**, 298, 1985) The questions that we now wish to ask the nut are what is the maximum toughening we can expect from whiskers in hard matrix systems, and how can we achieve high loadings of fibres into an isotropic, packed-bundle arrangement? □

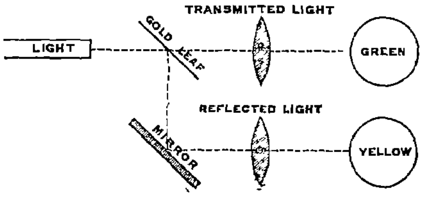
100 years ago

WE are apt to think of gold as being essentially and distinctively golden-yellow, it may, however, possess a wide range of colours A leaf of gold when seen by transmitted light is either green or blue, according to its thickness Here is such a leaf of green gold as seen when light is actually sent through it, so as to project a green disk on screen A portion of the light will be *reflected* from its surface, and this reflected ray may be caught in a mirror and thrown on the screen so that you have, shown side by side, the green disk of transmitted light and the golden *one of reflected light from the same leaf of gold*



It would be easy to show that light is similarly affected by other metals, but I have selected gold for the purpose of illustration because it is easy to maintain it in a state of purity, however finely divided it may be

We must therefore modify any views we may have formed as to a metal having exclusively a special colour of its own, because it will be evident that a particular colour is only due to a definite state of arrangement of its particles

Semiconductors

An optical Stark effect observed in gallium arsenide

John Ryan

Electromagnetic radiation interacts with atoms to modify many of their fundamental properties including the atomic energy levels themselves The most famous example of this is the Lamb effect, which occurs spontaneously in the absence of an applied electromagnetic field (in other words the field is 'virtual', arising from quantum fluctuations in the vacuum), in atomic hydrogen small energy-level shifts of the order of 1 GHz arise from the effect In condensed matter, the intrinsic energy levels are broadened considerably by interatomic interactions so that such small shifts are not normally detectable However, André Mysyrowicz and colleagues at École Polytechnique in Paris now report (*Phys Rev Lett* **56**, 2741, 1986) the observation of a remarkably large shift of around 500 GHz in the energy levels of the semiconductor gallium arsenide, GaAs On the basis of their results, the authors believe that the effect can be observed quite generally in semiconductors, and that it has potentially important applications in high-speed optical switching

The semiconductor studied by the Paris group is a composite material known as a quantum-well structure it consists of thin slabs of GaAs containing about 50 atomic layers sandwiched between equally thin slabs of GaAlAs such that the potential barrier formed at the interface between the two materials causes electrons and holes to be confined to the GaAs The energy state under investigation was the intrinsic exciton, which is a hydrogen-like bound state of an electron and hole having a Bohr radius of approximately 100 Å In GaAs quantum wells, the resonant generation of excitons by light gives rise to a well-defined absorption line which is sufficiently sharp to be a useful probe of electric-field-induced energy shifts

In the experiment, an electromagnetic field was applied in the form of an intense ultra-short laser pulse of 150 femtosecond duration The electric field produced is equivalent to a potential difference of about a tenth of a volt over the exciton, which is in fact greater than the electrostatic field experienced by the electron or hole due to the presence of the other Under these conditions large energy shifts are expected

Previous experiments by the authors (Hulin, D *et al Phys Rev* **B33**, 4389, 1986) and by a group at AT&T Bell Laboratories (Schmitt-Rink, S , Chemla, D S and Miller, D A B *Phys Rev* **B32**, 8027, 1985) had previously detected a pronounced blueshift of the exciton absorption line under conditions of resonant pumping, that is when the laser wavelength coincides with the absorption line This effect was shown to be due to exciton–exciton interactions, with the shift persisting during the exciton lifetime, typically several nanoseconds In its latest experiment, the Paris group now detects a large blueshift for non-resonant below-band-gap pumping (where no excitons are generated) which persists only during the pump laser pulse Mysyrowicz interprets this as evidence of an electric-field-induced energy shift or optical Stark effect

To explain the result, the authors adopt a quantum-electrodynamical model of 'dressed' excitons which are mixed states of excitons and photons The state with n_e excitons and n_p photons $|n_e, n_p>$ is nearly degenerate with the state $|n_e+1, n_p-1>$, and when the exciton–radiation interaction is included, the new mixed states are found to be split in energy by an amount which depends on the strength of the field This model therefore explains qualitatively the observed blueshift of the exciton absorption line, the magnitude of the shift can also be predicted theoretically, but there is some uncertainty in the actual value of the electric field strength inside the semiconductor that prevents a precise quantitative comparison

The Paris group has already extended its measurements to bulk GaAs and again detected an optical Stark effect These are important fundamental observations that open the way to the study of quantum-electrodynamical effects in condensed matter For the time being, however, the suggestion of practical applications looks somewhat premature because of the very large field strengths required ☐

Plant pathology

Host antifungal agents

Richard A Dixon

Unlike animals, which can defend themselves against microbial attack by producing circulating antibody proteins, plants respond to fungal and bacterial pathogens by synthesizing a number of proteins that produce a localized 'antimicrobial environment' around the invading pathogen[1,2] Lectins are thought to play a role as they have the potential to bind fungal or bacterial cell walls[3], and hydrolases (chitinase and 1,3-β-D-glucanase) have the potential to degrade macromolecular components of fungal walls The report by Schlumbaum *et al*[4] on page 365 of this issue now suggests that chitinase is an important component of the plant's antifungal arsenal and shows that the antifungal activity of plant lectins results from contamination with chitinase

The microbially induced plant gene products that have received most attention have been the enzymes involved in the synthesis of low molecular mass antifungal products termed phytoalexins[1,2] A large body of mainly correlative evidence suggests that the *de novo* synthesis of phytoalexins from intermediary metabolites, a process which in legumes such as bean probably requires the induced transcription of about 10 different genes, is a major determinant of active defence against microbial pathogens This complexity is daunting for the development of disease-resistant plants using gene-transfer techniques, hence the attraction of chitinase which is a single antifungal product

Previous reports have shown that this enzyme has no apparent endogenous substrate in plants but can release chitin oligomers from purified fungal cell walls, and is induced in plant tissues by fungal infection or exposure to the gaseous plant growth regulator ethylene Schlumbaum *et al*[4] now show that purified bean chitinase is highly inhibitory to the growth of the fungus *Trichoderma viride,* at concentrations similar to those found in crude extracts from infected or ethylene-treated bean leaves The antifungal activity of bean leaf extracts is almost completely inhibited by anti-chitinase antibody, suggesting that chitinase is the major protein inhibiting the growth of *Trichoderma* that is present in these extracts At similar concentrations, chitinase shows the same antifungal activity as the bean phytoalexins but, significantly, it is about 300 times more potent than the lectin wheat-germ agglutinin, whose inhibitory effect on the growth of *Trichoderma* had previously led to the suggestion by Mirelman *et al*[5] that plant lectins (particularly those with binding specificity for *N,N′*-diacetylchitobiose and *N,N′,N″*-triacetylchitotriose) may act as natural antifungal agents

Schlumbaum *et al*[4] have re-evaluated

the antifungal activity of potential chitin-binding lectins Their results indicate that wheat-germ agglutinin, when prepared by the method of Mirelman *et al* [5], is contaminated with chitinase and has antifungal activity Four commercial preparations of wheat-germ agglutinin, which were not contaminated in this way, could not inhibit the growth of *T viride* Unfortunately, wheat chitinase is not recognized by antibodies raised against the bean enzyme, and it was not therefore possible in this case fully to exclude the involvement of other minor components (possibly even other lectins) in the antifungal activity of the preparation The demonstration of chitinase contamination in antifungal lectin preparations from tomato, potato and pokeweed, its absence from all lectins not showing antifungal activity, and the total inhibition of the antifungal activity of the tomato and potato lectins by anti-bean chitinase antibody strongly suggests that lectins do not inhibit fungal growth But they still have the potential to function in plant–microbe recognition associated with, for example, the binding of symbiotic bacteria to legume roots or the reception of polysaccharide elicitor molecules whose binding may trigger responses which include the synthesis of phytoalexins and chitinase

The studies of Schlumbaum *et al* [4] have relied upon the non-pathogenic *T viride* as the test organism, it is therefore now important to consider the effects of bean chitinase on true bean pathogens such as rust (*Uromyces phaseoli*) and anthracnose (*Colletotrichum lindemuthianum*) Induced resistance to the latter organism comprises, in addition to induction of chitinase, the accumulation of several isoflavonoid phytoalexins, hydroxyproline-rich glycoproteins and cell-wall-bound phenolic compounds[1], and the relative importance of these individual components to the overall outcome of the host–pathogen interaction is as yet unknown

A simple, direct test for the antifungal contribution of chitinase *in vivo* is not obvious, although the enzyme can be induced by ethylene, the relation between ethylene production and pathogen-induced defence responses is still unclear, and the use of inducers and inhibitors of ethylene production has nearly always yielded equivocal results[6]

Chitinase complementary DNAs and genes have recently been cloned from both plant (R Broglie, unpublished, C J Lamb, personal communication) and microbial[7] sources, and it may therefore soon be possible to assess the effects of heterologous chitinases on the disease resistance of transgenic plants It should be remembered, however, that chitinase alone may not have sufficient activity, Schlumbaum *et al* [4] refer in their paper to recent unpublished work suggesting that mixtures of chitinase and 1,3-β-D-glucanase (which are often co-induced in plants) may be more effective

The induction of chitinase in infected bean plants may be a direct response to the action of elicitor molecules A polysaccharide elicitor from the cell walls of *C lindemuthianum* can induce the enzyme in cultured bean cells[8] It has been known for some time, however, that chitosan, a partially depolymerized, de-acetylated form of chitin, acts as an elicitor of phytoalexin synthesis in peas and can also inhibit the growth of the pea pathogen *Fusarium solani*[9] The rapid accumulation of chitosan in infected pea pods would clearly require the action of constitutive chitinase and *N*-acetylglucosaminidase More recently, chitosan and chitin oligomers have themselves been implicated as elicitors of defence-related lignification in wheat[10] Future work will tell whether more than one chitinase gene exists in some plants, or whether the different functions of chitinase are exclusive to different host–pathogen interactions In the meantime, the potential importance of a naturally occurring, inducible antifungal agent arising as a single gene product should not be overlooked □

Retroviral immunization

Problems with AIDS vaccines

Peter Newmark

CURRENT hopes for a vaccine against AIDS (acquired immune deficiency syndrome) focus on the use of the whole or part of the envelope protein of the human immunodeficiency virus (HIV) as the protective antigen It is too soon to say whether or not this approach will succeed but the signs were not encouraging at a meeting held in Paris at the end of October* Participants were left doubting that envelope protein alone can induce the antibodies that would provide protection against the virus, suspecting that cell-mediated as well as antibody-mediated immunity will be needed, and worried about the availability of an adequate animal model and sufficient animals on which to test potential vaccines

At present, chimpanzees are the only animals considered to be suitable for testing AIDS vaccines They do not develop an immune deficiency as a result of exposure to HIV-1 but at least there is a persistent viral infection which should be prevented by any effective vaccine But first, any potential vaccine needs to be tested in chimpanzees for its ability to stimulate the immune system sufficiently for there to be a good prospect of protection — yet there are insufficient chimpanzees for all the testing that is and will be necessary The solution, according to Donald Francis (State of California Health and Welfare Agency) is for the initial tests to be carried out in humans His suggestion is that the immune system's response to any potential vaccine is first tested on human volunteers, who might particularly be found among health-care workers and monogamous homosexuals The vaccines inducing the strongest response would then be tested in chimpanzees for their ability to protect the animals against infection with the virus Success at that state would warrant vaccination trials in humans that fall into 'at-risk' groups

Meanwhile, at least one very small-scale trial of a potential vaccine in chimpanzees is nearing completion (Shiu-Lok Hu, Oncogen, Seattle) Two animals were immunized with a recombinant vaccinia virus carrying the HIV-1 envelope protein gene Not only did the animals raise antibodies against the protein but there was also evidence of cell-mediated immunity in the form of proliferating T cells and cytotoxic T cells (which released radiolabelled chromium from target cells infected with the recombinant vaccinia virus The animals have now been challenged with the AIDS virus and the outcome is awaited with interest

If this trial fails — and nobody was betting on a successful outcome — it will be particularly bad news in view of the observed immune response, which is the first to include the generation of cytotoxic T cells It seems unlikely that antibodies alone will provide an effective measure against viral infection and yet most potential vaccines other than the recombinant vaccinia virus induce antibodies but no clear cell-mediated response Even the antibodies they induce are of limited value in that they are usually unable to neutralize strains of the virus that are not closely related to the immunizing strain (Robin Weiss, Institute of Cancer Research, London, Dani Bolognesi, Duke University Medical Center) To mimic the more broadly neutralizing antibodies present in AIDS patients, it will probably be necessary to use a multivalent vaccine, incorporating the envelope proteins of several different strains of HIV-1 and perhaps also viral proteins that are not exposed on the surface of infected cells and yet might be important for the generation of a cell-mediated response (as in the case of influenza virus — see, for example, Ronald Germain's *News and Views* article in *Nature* 322, 687, 1986)

---

* *Retroviruses of Human AIDS and Related Animal Diseases*, Marnes-La Coquette, France 29–30 October 1986

There will be additional problems in designing a vaccine that provides protection not just against HIV-1 but also against HIV-2 (otherwise known as LAV-2 or HTLV-4) This virus, which is only rather distantly related to HIV-1, is the predominant HIV in western Africa, where it has been found both in association with AIDS (Luc Montagnier, Pasteur Institute) and in many symptom-free people (Myron Essex, Harvard School of Public Health) Essex reported 25 cases where both HIV-1 and HIV-2 were present as well as evidence that cells first infected with HIV-2 can still be infected with HIV-1, albeit with somewhat reduced cytotoxic effects Complementary data came from Patricia Fultz (Centers for Disease Control, Atlanta), who reported that a single chimpanzee infected with HIV-1 was still susceptible to HIV-2

Because HIV-2 seems to be closely related to simian immunodeficiency viruses (SIVs), there is some hope that it will be much easier to have an effective animal model for vaccines against AIDS produced by HIV-2 than by HIV-1 Ideally, HIV-2 would be found to produce AIDS in rhesus monkeys or some other species whose availability is not a problem But first results are not promising no virus could be isolated from rhesus monkeys following their infection with HIV-2 (Fultz, Ronald Desrosiers, New England Regional Primate Research Center) In the case of two baboons infected with HIV-2, virus was recovered for the first 3–4 weeks but not in the next 8 weeks (Desrosiers)

An alternative approach is to use a SIV as a model for HIV Indeed, Murray Gardner (University of California, Davis) reported that a killed vaccine was successful in protecting rhesus monkeys against simian AIDS But the virus that causes the disease is a type D retrovirus and, as such, is unrelated to the other human and simian viruses that cause AIDS, all of which are type C retroviruses Thus the general relevance of this success is in doubt (see Jerome Groopman's *News and Views* article in *Nature* 323, 489, 1986)

Indeed, an initial equivalent trial with a type C SIV was not successful (Desrosiers) In that trial two groups of four rhesus monkeys were vaccinated with an inactivated form of the type C SIV isolated from rhesus monkeys For one group the virus was given with threonyl muramyl dipeptide (a promising new adjuvant which was used in Gardner's successful vaccine), for the other group the vaccine consisted of viral proteins in the form of an iscom (immune stimulatory complexes in which the proteins are attached to a matrix) Eighteen weeks after vaccination the monkeys were challenged with the SIV Despite the fact that both vaccines induced a reasonable antibody response (although it was not determined whether neutralizing antibodies were present), when the monkeys were challenged with the rhesus SIV, the virus became established in the animals with a viraemia that has persisted for fifteen weeks, which is the duration of the experiment so far

For now, anybody who states that an AIDS vaccine will be available in 3 or 5 or 10 years time is simply hazarding a guess But reports of at least partly successful vaccines against two type C retroviruses — a recombinant vaccinia vaccine against Friend murine leukaemia virus (Bernard Moss, National Institutes of Health) and an iscom vaccine against feline leukaemia virus (Bror Morein, Swedish University of Agricultural Sciences, Uppsala) — suggest that the problem can be solved ☐

DNA structure

A simple solution to the stability of the double helix?

Maxim Frank-Kamenetskii

Why are different forms of DNA stable under different ambient conditions? This question becomes more and more important as the structural polymorphism of DNA (the left-handed Z form as well as the right-handed A and B forms) and its biological significance is more generally recognized. But is there a simple answer? Wolfram Saenger *et al* elsewhere in this issue (*Nature* 324, 385–388; 1986) claim that there is.

Their answer is the principle of hydration economy. In the B form of DNA the phosphate groups are far apart and are independently hydrated. In the A and Z forms the phosphate groups are brought closer together and are bridged by water molecules. Thus, in contrast to the B form, the A and Z forms are economically hydrated. As a result the latter two forms are stable under a water deficit, whereas the former is stable under a water excess.

This simple answer is based on much work in recent years in the field of DNA X-ray crystallography. Until recently X-ray diffraction studies of DNA were restricted to DNA fibres. In those studies water molecules were completely obscured. The structure of the DNA hydration shell emerged only after X-ray crystallography was applied to DNA fragments by A. Rich, R. Dickerson, O. Kennard and their co-workers in the 1980s. The first concept based on these data was the water spine, which is situated in the minor groove of B-DNA and stabilizes its canonical structure (Grew, H.R. and Dickerson, R.E. *J molec Biol* 151, 535–556; 1981). Now Saenger *et al* introduce the concept of hydration economy.

This novel concept is based on the fact that in the A and Z forms the free oxygen atoms of phosphate groups are, respectively, 5.3 and 5.1 Å apart and are bridged by water molecules. In B-DNA the distance between the oxygen atoms is 6.6 Å, too large for a water molecule to bridge. Hence the major conclusion of Saenger *et al* is that the A and Z forms should become more advantageous compared with the B form under a water deficit.

This concept readily explains the long-known fact that DNA dehydration (through drying or substituting alcohol for water) induces the B–A transition In poly(GC) poly(GC), dehydration induces the B–Z transition Saenger *et al* hypothesize that the mechanism of the famous salt-induced B–Z transition in poly(GC) poly(GC) is the same, as the salt pumps water molecules out of the polynucleotide.

Not everybody will share the latter viewpoint. Many believe that the high-salt B–Z transition is governed by electrostatic interactions of phosphate groups with each other and with the salt ions. In such a polyelectrolyte model, water does not play a structural role and only dampens the interactions between charges Doubtless the principle of hydration economy is just another factor in a very complex balance of interactions that governs the stability of double helical conformations. But its importance can no longer be ignored. ☐

Celestial mechanics

Orbital evolution of comets

Julia Heisler

A FLAW in our understanding of the orbital evolution of comets is that the number of short-period comets — those with orbital periods less than 200 years, such as comet Halley — is much greater than theory predicts The discrepancy is enormous, the observed number is two orders of magnitude larger than expected[2] Relying partly on some newly recognized perturbations acting on comets, Bailey[3], on page 350 of this issue, presents a possible solution to this problem

In 1950 Oort proposed that the Solar System is surrounded by a spherical cloud containing 10^{11} comets, today it is believed that a typical 'Oort cloud' comet orbits the Sun at a distance of 25,000 astronomical units (AU) Until recently it was thought that the orbits of comets are mainly perturbed by random stars that pass within about one parsec of the Solar System In the past year, a second, more important perturbation source has been recognized The relatively smooth gravitational potential of the galactic disk in which the Solar System is embedded is responsible for a tidal effect upon comets that is proportional to the total density of material (stars, gas and dark matter) in the solar neighbourhood (This is analogous to the orbital precession of the Moon because of the pull of the Sun)

Both perturbations — from passing stars and galactic tide — gradually alter the orbital angular momentum carrying some comets into the inner Solar System and under the gravitational influence of the outer planets Those comets that pass within 5 AU of the Sun are observable from the Earth and are called 'new' comets, as they are probably making their first passage through the planetary system A new comet is recognized by its extremely small orbital energy (in absolute value), after one passage through the inner Solar System the orbital energy is typically increased sixfold Oort cloud comets that pass within 10 AU of the Sun are either ejected from the Solar System entirely or captured into short-period orbits However, even using both perturbations, the number of short-period comets derived from this capture process is still a small fraction of the observed number

A solution to this problem is that the short-period comets come from a source other than the Oort cloud, from a second, closer comet reservoir Current ideas[4] are that a comet belt extends outwards from the planetary system and departs from the ecliptic to blend in with the spherical outer Oort cloud at about 10,000 AU Comets at distances between a hundred and a few thousand AU are virtually unperturbed by stars, galactic tides and planets The comets from the inner region drift into the planetary system with perihelia well outside the detectable limit of 5 AU, and thus no significant flux of observable new comets is produced (In the case of the outer Oort cloud, the perturbations are stronger and some comets can be directly perturbed into orbits that are observable from the Earth) As a result of the lack of observable new comets from the inner Oort cloud, the spatial (or energy) distribution is very uncertain, and *ad hoc* assumptions are unavoidable However, Bailey[3] turns the short-period comet problem around, and demonstrates that the number of short-period comets constrains the choices, allowing one to give a crude determination of the spatial distribution

Bailey assumes a spherically symmetric cloud with a power-law energy distribution of unknown index He demonstrates that up to about 30,000 AU the galactic tide perturbs far more comets into the planetary region than stellar encounters do, and hence one can neglect stellar perturbations when calculating the injection rate into the planetary system This conclusion has been checked independently by numerical experiments[5] Bailey computes the fraction that will evolve to short-period orbits and multiplies that fraction by the average lifetime of observed comets to derive the expected total number of short-period comets To explain both the numbers of new and short-period comets, the energy distribution must be fairly steep For a comet lifetime of 3,000 years and an inner Oort cloud radius of 3,000 AU, 97 per cent of the comet population must be inside 10,000 AU This conclusion implies that most short-period comets originate in orbits near the cloud's inner boundary, whereas new comets originate at distances greater than 10,000 AU The short-period comets come from the inner Oort cloud and the new comets from the outer Oort cloud Furthermore, using entirely analytical methods and without invoking any other perturbations aside from the galactic tide, Bailey is able to derive the correct number of observed short-period comets

A massive inner cloud has also been invoked to explain biological extinction events on the Earth as a result of comet showers The related suggestion that large impact craters and extinctions over the past 250 million years occur periodically every 26–30 million years has received much attention, but there are doubts that the claimed periodicities in the data are genuine[6,7] It is also unlikely that comet showers are responsible for either periodic or random events on such short timescales Periodic comet shower theories include the proposals of a solar companion (Nemesis)[8,9], a tenth planet (Planet X)[10] and catastrophic encounters with giant molecular clouds during galactic plane crossings[11] The difficulty with the galactic plane crossing suggestion is that although the Sun does pass through the galactic midplane every 30 million years, the amplitude of its oscillation is small, about 70 parsecs Giant molecular clouds have a similar scale height, and therefore encounters can occur at all times during the Sun's oscillation, giving no statistically significant periodicity[13] In fact, despite the Sun's motion, the density of material near the Sun is fairly constant, implying that the comet flux induced by the galactic tide is also fairly uniform Finally, even random comet showers caused by close stellar encounters are unlikely to explain the crater record because an encounter capable of creating a shower is expected only once every 100 million years[5] Encounters with giant molecular clouds occur even less frequently, about once every 500 million years Hence, the crater data may reflect only a few comet showers This conclusion is supported by identifications of impact material at eight large craters up to 200 million years old, only two of the craters could have been formed by comet impacts, the rest were probably made by asteroids[14]

If Bailey's bold extrapolation of the total comet population is correct, the short-period comet problem is solved, it is satisfying that this problem is soluble using perturbation effects we already understand However, our theories about the inner region of the Oort cloud are still speculative, and we must proceed carefully, because unlike the situation for the classical Oort cloud, there are no observable new comets that directly sample the proposed inner comet cloud □

Role of HTLV III/LAV envelope protein

SIR—Sodrosky *et al*[1] recently reported that the envelope protein of HTLV III/LAV, the virus that causes AIDS (acquired immune deficiency syndrome), might cause the lysis not only of infected T-helper cells (T-4), but also of uninfected T-4 cells. This would explain the total depletion of T-4 cells, even though only some of them are infected with the virus. I would like to draw attention to another possible role for the protein in the pathophysiology of AIDS.

Developmental stages of AIDS are characterized by a selective major histocompatibility complex II (MHC II) restricted immunodeficiency which shows a striking resemblance to class I graft-versus-host immunodeficiency in mice[2,3]. This immunodeficiency is immunologically mediated by parental T-4 cell recognition of class II MHC alloantigens on the host's B-lymphocytes and results in a polyclonal proliferation of these B-cells and the formation of autoantibodies against a variety of polymeric antigens and also against envelope proteins of murine leukaemia virus bound on kidney cells[4]. These autoimmune processes lead to different pathophysiological symptoms, such as the selective immune deficit and autoimmune glomerulonephritis[4].

In the case of AIDS these antibodies might be especially focused on the envelope protein of HTLV III/LAV on T-4 cells. The antibodies against the envelope protein might initiate an autoimmune destruction of T-4 cells so that a vicious circle between T-4-cell immunodeficiency and T-4 directed autoimmunity can develop. This autoimmune destruction of T-helper cells might synergistically amplify the direct T-helper cell impairment by LAV/HTLV III and its envelope protein.

It is noteworthy that other autoimmune phenomena in patients with AIDS also show a striking resemblance to those in class II graft-versus-host disease in mice[4] and some human connective tissue diseases[5].

I suspect that not only classical cellular and antibody-mediated cytotoxicity[6] but also polyclonally activated transformed B cells might play a major role in the pathophysiology of AIDS. Strategies which inhibit this polyclonal B-cell proliferation might therefore delay T-4 deletion in early AIDS.

What is an extended probability?

SIR—While grateful for your open-minded discussion[1] of my review of extended probabilities[2], I should correct one minor point. I introduced the term 'extended probability' not (only) to avoid the charge of sensation-mongering but because probabilities exceeding unity are closely connected to, and in fact a consequence of, negative probabilities. Hence, the former have to be taken into account — if the latter "exist".

I confess my desire that somebody should give meaning to the term extended probability, but considering that Leonardo of Pisa in the thirteenth century was the first to interpret negative solutions of algebraic equations as debts, and even Descartes in the seventeenth century called them "false solutions" (the common term at that time), I do not believe this will happen in the near future. I have to disagree with the definition of negative probability given by D E Parry[3]. If, for instance, extended probabilities are used to obtain a formal resolution of the Einstein–Podolsky–Rosen paradox[4] they have to obey the following rule: an event leading with negative probability to a certain result has to extinguish not only the observation of a (hopefully) preceding exhibition of this result, but has also to extinguish the observation of this event at all, that is it has to reduce the number of accumulated events. (This is why a negative probability cannot be interpreted as a positive probability for observing some extinguishing counter-result, but only as a positive probability for the reduction of the number of preceding events.) And, of course, extended probabilities can only then creep into the picture when we deal with sets of indistinguishable results, as in the domain of quantum mechanics.

Unfortunately, no known physical mechanism allows for this kind of interaction or, therefore, provides a local and realistic resolution of the Einstein–Podolsky–Rosen paradox in terms of extended probabilities. Thus, the paradox will presumably continue to bother 'realistic' physicists, perhaps until this species becomes extinct.

Migration and hominid bipedalism

SIR—Discoveries in palaeoanthropology have taken the story of hominid evolution back to a time just subsequent to the evolution of bipedalism[1]. The outstanding evolutionary question now is: what was the selection pressure that produced bipedalism? The current explanation[2] suggests that bipedalism evolved when the gathering of plants for food became necessary in a drier savannah habitat, and arms were needed to carry food back to a home site. Although this idea is feasible is it not compelling. We suggest a new idea in which bipedalism developed for long distance migration to scavenge from migrating ungulate populations, the only population that could provide sufficient food by scavenging. Bipedalism was a necessary adaptation to exploit this food supply.

In Serengeti, Tanzania, several ungulate species perform long-distance annual migration[3]. Migration provides an abundant and constant food supply, and hence these populations are large compared to sedentary populations of the same species. Mammal predators and scavengers do not follow the migrations because their young are slow growing and cannot travel with adults. Consequently breeding predators are sedentary. If a scavenger could migrate it would have access to an abundant and constant supply of carcasses (at least 1 carcass per 20 km^2 per day)[3], an order of magnitude greater than in non-migratory systems. In fact, humans can find enough to eat by following the wildebeest migration on foot[4]. Almost 70 per cent of carcasses are the result of undernutrition[3,5], so hominids would not be displacing predators from their kills.

Two vulture species follow the migrating ungulates, and they are considerably more numerous than sedentary species[5]. Vultures, however, have the disadvantage that they cannot easily break through the skin of intact carcasses. Therefore, there is in Africa an unfilled niche for a mammalian scavenger that can follow migrating ungulates, but such a mammal would need to carry its young.

We suggest that the selection pressure for the evolution of bipedalism in early hominids was access to this new rich and constant food supply. Morphs that had developed the ability to walk long distances would increase rapidly in number and displace the less numerous sedentary quadrupedal types dependent on plant gathering.

We envisage the protohominid quadruped as a plant gatherer and occasional scavenger, much like the baboon. For this type to follow migrating ungulates two essential adaptations are required simultaneously. First, members of the type must carry their young efficiently. This requires arms for carrying, and an upright stance. Chimpanzee females carry their young for at least the first year, so do humans, and thus it is reasonable to assume that early hominids also did so. Prolonged upright stance for efficient carrying would require adaptations of the hip joint, such as those in *Australopithecus afarensis* onwards[6] Second, they must travel long distances efficiently For this, the primitive foot with opposable big toe must change to the modern foot as a propulsive lever, and this change must coincide with changes in the hip

The alternative hypothesis is that bipedal hominids were plant gatherers in a savannah home range[2,6] Plant gathering required hands for carrying food, gradually the hominids' diet changed to include scavenged meat, using tools This idea is less compelling for two reasons First, modern baboons and chimpanzees are plant gatherers, and they can live in hot dry savannahs[7] Chimpanzees do not travel far (usually less than 4 km a day) Hence plant food gathering in dry environments need not lead to either bipedalism or long distance travel In contrast, efficient long distance travel (10–20 km a day) is necessary to follow the migrations If arms are used to carry young, bipedalism is the only efficient means[8] Second, a plant gatherer within a fixed range has few opportunities for finding ungulate carcasses, mortality of nonmigratory ungulates in Serengeti produces one carcass per month in 10 km^2 Thus selection to use tools would also be very small

The migration hypothesis suggests that tool use was an adaptation to speed up the butchering of carcasses and avoid competition with other stronger mammal predators Indeed, tools were used for scavenging 2 million years ago in Serengeti[9] The opportunities for hominid migrations to evolve were numerous, for savannah Africa was dominated by migration ecosystems[5]

The two hypotheses are testable and can be distinguished by the timing of changes in the foot For migration, hip and foot changes are both linked and essential Plant gathering, however, does not predict simultaneous changes in the foot because long-distance movement is not essential Unique hominid foot characters have been identified[10], for example the length of the foot is less than 25 per cent of the leg In future fossil finds, particularly for the period when bipedalism was evolving, it is such characters that will distinguish between the two hypotheses

^{131}I in milk and rain after Chernobyl

SIR—Radioactivity in rain water attributed to the Chernobyl plant was first detected in Japan on 3 May 1986, a week after the accident[1], and included ^{131}I We have monitored ^{131}I both in milk sold in markets and in fresh milk from dairy cows We found that the concentration of ^{131}I in milk in Nagoya, Japan at a distance of 8,000 km from Chernobyl was 4–5 times higher than that in rain water, and that both concentrations decreased with approximately the same effective half-life

Rain water was collected by a 0 305 m^2 collector between 3 May and 24 June The rain water with added carrier was concentrated by evaporation Gamma-ray spectroscopy showed the principal radionuclides to be ^{131}I, ^{103}Ru, ^{134}Cs and ^{137}Cs The ^{131}I concentration ranged from 980 pCi l^{-1} observed on 3 May to 0 019 pCi l^{-1} on 24 June, decreasing with an effective half-life of 5 2 ± 0 3 days (Fig 1)

The Ministry of Science and Technology announced that, in milk between 4 May and 12 May, ^{131}I activity ranged from 57 pCi l^{-1} to 400 pCi l^{-1} fresh milk and from 20 pCi l^{-1} to 160 pCi l^{-1} for commercial milk The northern jetstream which may have carried radioactive materials to Japan, passed over Nagoya, in central Japan We accordingly began a survey of the ^{131}I concentration in milk from five local dairies Because the ^{131}I concentration varied from dairy to dairy, no doubt due to the variety of feed furnished to cows, we decided to monitor fresh milk from individual cows mainly fed on fresh grass

Fresh milk sampled from 20 dairy cows at the university farm affiliated to the School of Agriculture of Nagoya University, was monitored between 19 May and 14 July Sixteen cows were of Holstein breed, and four were first-generation crosses between the Japanese breed and the Aberdeen Angus The cattle were each fed on fresh Italian ryegrass (34–35 kg per day) and concentrates (5–6 kg per day) The total milk volume from 20 cows amounts to 300–330 litres a day One litre weekly samples were placed in plastic bottles and mounted on a Ge(Li) semiconductor detector for gamma-ray spectroscopy ^{131}I was the only radionuclide identified in almost all of the samples, but a few gave extremely low ^{137}Cs signals For the last two samples, ^{131}I was chemically extracted and measured with a well-type Ge detector The ^{131}I concentration decreased with a half-life of 5 0 ± 0 2 days (Fig 1), similar to the half-life in dairy milk reported in Britain[2]

The ^{131}I concentration in milk was about 4–5 times greater than that in rainwater between 19 May and 14 July, a rainy season in Japan Judging from the ^{131}I concentration in rainwater and from that in milk announced by the ministry, it is reasonable to assume that the concentration in fresh milk reached a maximum on 4 May and declined with a half-life of 5 days

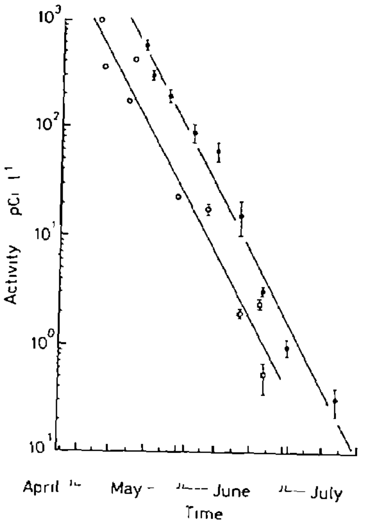

Fig 1 The ^{131}I concentration in dairy cow milk (black dots) and rain water (open circles) in Nagoya from 26 April, the date of the Chernobyl accident, to 20 July 1986

JOURNALS FROM MACMILLAN

☐ *ANTI-CANCER DRUG DESIGN*

NEW JOURNAL FIRST ISSUE PUBLISHED OCTOBER 1985

(Quarterly)

Editors S Neidle S T Crooke

The development of new clinically-useful anti-cancer agents is increasingly dependent on rational scientific principles drawn from a wide range of disciplines This new journal aims to promote such approaches, providing a common meeting ground for medicinal chemists, pharmacologists, biochemists, biophysicists and oncologists involved in both fundamental and clinically orientated aspects

This journal is published with the support of The Cancer Research Campaign

NEW JOURNAL FIRST ISSUE MAY 1986

☐ *BONE MARROW TRANSPLANTATION*

(Quarterly)

Editor J M Goldman Co-Editor R P Gale

A new journal which will publish clinical results in man and experimental results with animals, allografting and autografting, HLA and other methods of selecting donors, graft-versus-host disease and all types of methods to prevent and treat it, and much more

☐ *BRITISH JOURNAL OF CANCER* *(Monthly)*

The Journal of the Cancer Research Campaign

Chairman D G Harnden Editor M Moore

One of the leading cancer journals in the world publishing articles on all the major scientific disciplines

Publishes papers from researchers throughout the world and the proceedings of meetings of the British Association for Cancer Research and other symposia

☐ *HUMAN TOXICOLOGY*

(Bi-monthly)

Secretary to the Editorial Board· P Turner

Covers all aspects of human toxicology embracing both animal research with direct relevance to man and studies with humans

Hard cover DM 298,-
ISBN 3-540-15566-X

Contents: Technical Terms English-German-Japanese - List of Synonyms. - Technical Terms Japanese-English-German - List of Synonyms - Technical Terms German-English. - List of Synonyms - Appendix.

This "Dictionary of Biotechnology" is the outcome of several years' work with English, German and Japanese texts in this field. It contains nearly 6 000 terms and is divided into three parts 1. Alphabetically listed technical terms in English accompanied by translations into German and Japanese, 2. Alphabetically listed technical terms in Japanese accompanied by translations into English and German, 3. Alphabetically listed technical terms in German accompanied by translations into English
Each of the main parts is followed by a list of synonyms in the word entry language An appendix defines over 300 abbreviations using all three languages The English terms are classified according to n(noun), vb (verb), and adj (adjective). The spelling of German scientific terms is tending to adapt to Anglo-American patterns The German terms are followed by an indication of gender (m, masculine, f, feminine; n, neuter, pl, plural). For the sake of easier legibility, the Hepburn method has been selected for transcribing the Japanese terms into the Roman alphabet ("roma-ji"). The division of lengthy transcribed terms into roots conforms with a didactic approach

The patient's dilemma

D.J. Weatherall

Unnatural Selection? Coming to Terms with the New Genetics. By Edward Yoxen.
William Heinemann: 1986. Pp. 208. £12.95.

GEORGE Bernard Shaw once observed that all professions are conspiracies against the laity, a view that has permeated much of the bad press to which doctors have been subjected in recent years. What has gone wrong? Paradoxically, the successes of the medical sciences in the post-war period, which saw the development of antibiotics and the eradication of many childhood infections by vaccination programmes, may be partly to blame. These remarkable achievements raised the expectation that the control of cancer, heart disease, arthritis and other major killers would soon follow. When it became apparent that this was not to be, and that these conditions could only be managed, often unsatisfactorily, by increasingly sophisticated patch-up procedures involving the use of expensive drugs, a bewildering array of machinery and the replacement of almost every organ except the brain, a sense of disillusionment with scientific medicine set in. Hospitals came to be perceived as terrifying places to visit, let alone in which to be ill, and it was widely believed that the pastoral needs of patients had become lost in a maze of high technology. Alternative forms of therapy were sought, and "holistic" medicine, a term which simply means good doctoring, was rediscovered.

It is hardly surprising, therefore, that when terms such as *in vitro* fertilization and genetic engineering appeared on the scene further public suspicion was generated; the technocrats were at it again, now breeding monsters in test tubes and tinkering with people's genes. The situation was exacerbated by sensational television programmes which featured parents wandering around "gene supermarkets" stocking their baskets with traits that they hoped to see expressed in their children. Memories of Nazi Germany and the eugenics movement were revived, committees of inquiry set up, and hastily constructed and ill-thought-out bills put before the British Parliament in an attempt to prevent any form of research involving human embryos.

Considering the complexities of molecular and cell biology, and the speed with which these fields have advanced over the past few years, it is not surprising that the clinical applications of these new techniques have been greeted with apprehension; the medical profession itself is only just starting to get to grips with their potential. Clearly, a long period of public debate and reflection is required before we shall be in a position to assess how far we wish to go in interfering with our reproductive activities and manipulating our genomes. This new book by Edward Yoxen should be a valuable catalyst for pointing the discussions in a sensible direction.

Like Jane Austen and J.D. Salinger, Yoxen believes in the analeptic effect of a racy opening paragraph: "There is a great deal of sex in this book, quite enough to shock the faint at heart". After an introductory section (which rapidly disillusions even the not so faint at heart), successive chapters deal with artificial insemination, *in vitro* fertilization, surrogacy, sex predetermination, antenatal diagnosis, new forms of genetic intervention and gene therapy. In each of these controversial areas the author faces up to the ethical and pastoral problems that are posed and gives a balanced discussion of the benefits and risks involved. By and large he subscribes to the value of these developments, while at the same time showing great sensitivity to the views of those who find many of them distasteful. It is to be hoped that his sane account of such an emotionally-toned topic will be read by teachers, politicians, church leaders and, in particular, members of the many pressure groups that are attempting to prevent further research without evaluating the evidence.

Yoxen makes little attempt to explain the scientific basis of the advances in reproductive physiology and genetics that have given us these powerful new tools, and, in most cases, simply states what is or is likely to be possible and the moral dilemmas that may arise. Presumably he feels that this is as far as he can go at the moment, given the level of biological sophistication in society. Many will agree. In discussing the problem of scientific communication, Francis Crick has described how he had to explain to a lady visitor to the Salk Institute that worms are not spontaneously generated in apples. And, as Yoxen points out, it is not all that long since those of the British aristocracy who wanted male heirs submitted to hemicastration in the belief that sperm from the right testicle produce sons — *noblesse oblige* indeed.

Such tales may not be the best guide to the level of scientific knowledge in the world at large, but there is no doubt that if Yoxen's goal is to be reached — that of an individual who can say "I fully understand the step that I am taking, I have chosen it freely, having sought advice and considered the options available, and I recognize my responsibilities to myself and to others in what I do here" — we shall have to do some fundamental rethinking about education. To no country does this apply more than Britain, in which children are encouraged to specialize at the age of 14, and in many cases to ignore science completely thereafter, and which, with a few exceptions, is very badly served by its media in scientific matters. Thus far, prejudice and ignorance have characterized many of the views on the topics discussed in this book. Anyone who doubts that there is a problem should read *Hansard's* account of the parliamentary debate on embryo research.

There is another question that is touched on several times in Yoxen's book, but which is never fully developed. What is it that motivates scientists in this field? Why is it, for example, that in the United States there may well be nearly as many research workers trying to replace the defective gene in a rare genetic form of immune deficiency as there are patients with the disorder? And why has at least one worker jumped the gun in a premature attempt at gene therapy? Are patients becoming stepping stones on the way to scientific "firsts" and fame and fortune? As part of the dialogue that is essential if public confidence in modern medicine is to be restored, biologists and medical scientists will have to provide better insights into how science works. They should also ask themselves why it appears that so much talent is being directed into research that gives rise to increasing public concern when, at the same time, there seems to be much less interest in many of the more immediate medical problems of society. ☐

D.J. Weatherall is Nuffield Professor of Clinical Medicine at the University of Oxford, John Radcliffe Hospital, Headington, Oxford OX3 9DU, UK.

Taking the soft tomato

THE business of reviewing scientific books is one apart from the reviewing of works of literature. But anyone whose book has been roughly handled in a review can find comfort in *Rotten Reviews: A Literary Companion*, which contains such comments as this: "Here all the faults of *Jane Eyre* (by Charlotte Brontë) are magnified a thousand fold, and the only consolation which we have in reflecting upon it is that it will never be widely read". Thus one James Lorimer in a review of Emily Brontë's *Wuthering Heights* (1847).

Rotten Reviews, edited by Bill Henderson, is a 93-page, small-format volume which contains extracts from 175 scathing notices of books that have proved to be of enduring appeal. Publisher is Pushcart Press, and distributor W.W. Norton, New York. Price is $12.50.

Beastly creations

Martin Kemp

The Rhinoceros from Dürer to Stubbs, 1515–1799. By T. H. Clarke. *Sotheby's Publications/Philip Wilson, Russell Chambers, Covent Garden, London WC2E 8AA, UK: 1986. Pp. 219. £29.50.*

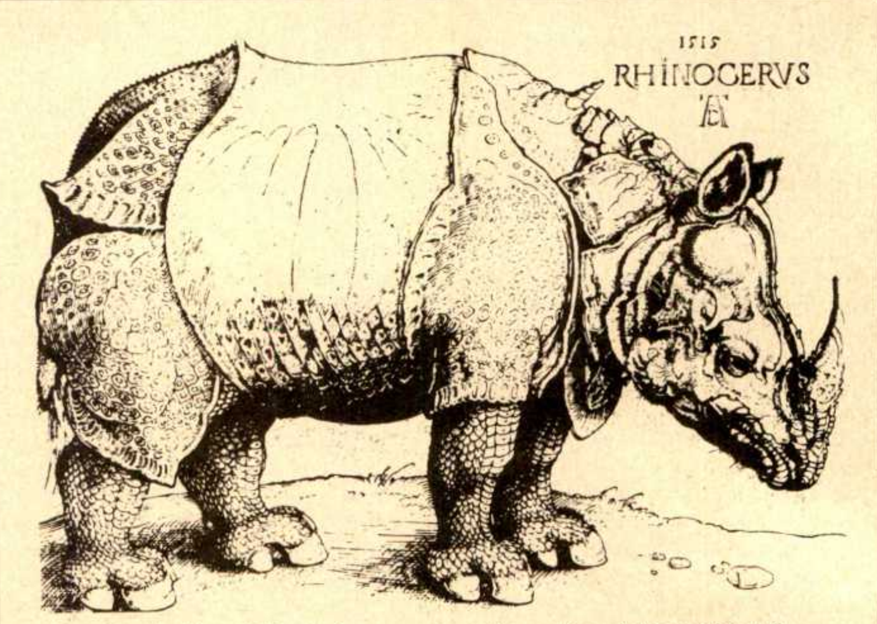
RHINOCEROTICA rules. We might expect an obsessional study of images of a single exotic animal over three centuries to be rich with informative detail. We would not necessarily expect it to be fun. T. H. Clarke's book is both.

The author does not attempt to rival the scholarly detail of L. C. Rookmaaker's *Bibliography of the Rhinoceros* (A.A. Balkema, Rotterdam; 1983). Rather, he has provided a lively compendium of artistic images, ranging from soberly naturalistic records to elaborate fantasies in all kinds of media — painting, sculpture, drawing, engraving, embroideries, tapestry, pottery, porcelain, glass, furniture, and arms and armour. The text is written with a nice wit that only occasionally becomes tiresome.

The rhinoceros is unusually well suited for such a study. It was a rare enough sight for European observers to be the subject of wonder and even fantasy, yet there are enough documented instances of rhinos on European tours to provide a series of identifiable animals from which the great majority of the images sprang. Clarke discusses eight peripatetic visitors between 1515 and the 1790s. In addition to the host of craftsmen who took advantage of the rhinomania occasioned by exhibition of the animals by showmen, a number of accomplished artists were involved. To mention only Albrecht Dürer, Hans Burgkmair, Pietro Longhi, Jean-Baptiste Oudry and George Stubbs will give some idea of the quality and the geographical range.

The involvement of considerable artistic talents in naturalistic illustration has obvious advantages. What is not so readily recognized is that their sheer skill brings dangers as well as benefits. The kind of artistry developed during the Renaissance revolution in representation — and so vividly manifested in Dürer's art — could be used to endow an image of fantasy with a sense of "naturalistic" credibility to match that of a representation taken from life. A skilful artist can make a dragon look as credible as a rhinoceros for someone who has seen neither.

This kind of potency in "fantastic naturalism" explains the immense hold of Dürer's engraving, which, as Clarke indicates, was based on secondary visual and written sources. Dürer's transformation of the leathery rhinoceros into a fearsome piece of late-mediaeval siege machinery resulted in an image of such power that it remained truer to the emotional response evoked by the animal than the more naturalistic versions. Clarke provides an abundant body of visual evidence to show that naturalistic illustration is a double-edged weapon, though he does not grapple head-on with this fascinating question.



Dürer's rhino, 1515 — "a fearsome piece of late mediaeval siege machinery".

From *The Rhinoceros from Dürer to Stubbs*

The greatest strength of the book is the remarkable range of media, particularly from the applied arts, that is illustrated and discussed with authority. Its two most obvious weaknesses relate to the history of natural history on one hand, and iconographic art history on the other. Historians of natural history will be disappointed that the great succession of zoological encyclopaedias is so little exploited, while art historians might reasonably have expected a fuller discussion of the emblematic and symbolic meaning, including the sexual connotations of the "horn". These are not separate matters; for the encyclopaedist, nature was full of meaning, just as meaning for the emblematicist was regularly borne in a natural vehicle. Clarke's approach largely excludes such issues, but it does permit a wide measure of visual delight. ☐

Martin Kemp is Professor in the Department of Art History, University of St Andrews, Fife KY16 9AL, UK.

Nervous activity

D. Regan

Evoked Potentials. Edited by Roger Q. Cracco and Ivan Bodis-Wollner. *Alan R. Liss/Wiley: 1986. Pp. 551. $96, £70.*

OUR knowledge of the cellular and neuropharmacological organization of the brains of experimental animals has advanced enormously over the past decade. How this new knowledge can be used to deepen our understanding of human vision, hearing and motor control, and how it can help to prevent and alleviate visual, hearing and spinal cord disorders, is an immediately challenging problem. It is unfortunate that many of the important advances in neuroscience have been achieved through techniques that, for ethical reasons, can seldom be used in man. A major role of evoked potential recording is to bridge the gap between the human brain and the results from cellular-level experiments on animals.

The term "evoked potential" (EP) covers the electrical responses of the entire peripheral and central nervous system, including peripheral nerve action potentials, spinal cord responses to stimulation of peripheral nerves, the responses of the auditory brainstem, midbrain and cerebral cortex to sounds, the responses of somatosensory brainstem and cerebral cortex to tactile stimulation of the skin, and the responses of the retina and visual cortex to light. The term also covers the electrical activities of the brain associated with the evaluation of the meaning of a stimulus, such as a spoken word, rather than with the physical nature of the stimulus. In this book the "evoked potential" takes on an even wider meaning: Williamson and Kaufman describe how the magnetic responses, 10^{-7} weaker than the Earth's field, that are produced from neurones in the depths of the brain can be clearly picked up by a quantum interference device placed near the head, and the location of the neurones defined to within a few millimetres!

Evoked potentials can be recorded

from metal electrodes held onto the scalp or over the spine without discomfort or risk. Although they are very small (often less than one microvolt), a domestic microcomputer is quite adequate to extract the EP from the electrical "noise" produced by muscle and by the rest of the brain. Evoked potentials thus offer access to the electrical activity of the human brain's visual, auditory and tactile areas while the brain's owner is describing and measuring what he or she sees, hears and feels. In this way the technique can help us to understand the neural activities that underlie normal sensory experience. By the same token, EP recording is a tool for investigating the neural abnormalities associated with disorders of sight, hearing and motor control in human adults, infants and neonates.

This book contains a selective collection of 49 admirably concise mini-reviews on a wide variety of topics, each written by an internationally recognized authority. Illustrating how EPs can be used functionally to "dissect" a sensory pathway, Bodis-Wollner's opening chapter describes the parallel visual subsystems for pattern, flicker, motion and so on. Arguably, the most promising clinical role of the EP technique is in studying disease mechanisms in paediatric patients. After pointing out that the early identification of hearing loss can avoid the disastrous consequences of speech delay, Galambos, and Stockard and Stockard, go on to review the recent advances in identifying hearing defects in newborns by EP recording. Sokol, and Levi and Manny, describe how visual EP recording can aid the management of infants with amblyopic visual loss and help to prevent lasting visual impairment. The possibility of using spinal EPs to assess spinal cord trauma incurred during birth is reviewed by Cracco and Cracco. The applications of EPs in neurology and ophthalmology are extensively discussed, including a useful analysis of visual evoked potentials in multiple sclerosis by Blumhardt and three papers on Parkinson's disease and neurotransmitter abnormalities. The sections on surgical monitoring and on psychiatric disorders in adults and children are instructive and thorough. The book contains an excellent group of papers on the neural sources of sensory and cognitive EPs.

The editors are to be congratulated on putting together such a coherent survey of basic and clinical human electrophysiology. All 49 chapters are carefully and concisely written, and are remarkably free from errors. A uniformly high standard is maintained throughout, and several chapters are quite outstanding. This is the best and most up-to-date book on the topic. ☐

D. Regan is a Professor in the Departments of Ophthalmology and Medicine, Dalhousie University, Gerard Hall, 5303 Morris Street, Halifax B3J 1B6, Canada.

Developing policies

Ronald Coleman

The Biotechnological Challenge. Edited by S. Jacobsson, A. Jamison and H. Rothman. *Cambridge University Press: 1986. Pp.181. £22.50, $34.50.*

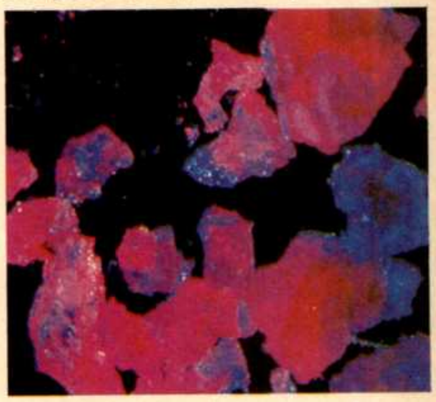
MANY nations, both developed and developing, have attempted to define strategies for the application of biotechnology to improve their overall national economic performance over the next 10 to 20 years. Any such strategy must take account of the science base of the country concerned, the availability of trained manpower and the state of other, complementary technologies, as well as the overall national industrial performance and the ability to deliver goods to the marketplace. This book offers advice on the potential of biotechnology for developing countries.

The editors have brought together experts in their respective fields to outline the current status of the technology, and also present some case-studies relevant to developing countries. For policy-makers, the techniques underpinning modern biotechnology — genetic engineering, and enzymes for biotransformations and fermentation — are well presented in adequate detail. But the choice of case-studies could have been better, and it is unfortunate that none of them relates to health care.

One of the studies deals with the production of high-fructose corn syrup. This is the largest scale industrial use of modern biotechnology, and it has been successful in the developed world, particularly the United States, because the syrup can compete successfully, both in performance and price, with a traditional agricultural product (in this case sugar). But in a developing country sugar production must surely remain the preferred route for the supply of sweeteners: with corn syrup, the possibility of competing successfully for export markets is remote, and it makes no sense to import the necessary technology for a new sweetener in order to achieve a marginal improvement for home markets.

The account of the Brazilian experience in the conversion of sugar cane into alcohol, as a replacement for petroleum, is much more illuminating. Simple economics suggest that the process is less efficient than selling sugar on the world market and using the income to import petroleum. Given the current constraints on Brazil, however, the strategy seems to be both appropriate and successful. The natural advantages of an equatorial country — abundant sunshine, rain and cheap labour — have been used effectively to incorporate a biotechnological process into a large national programme to develop an alternative energy source. Part of the Brazilian experiment is the forward integration of the programme so that the alcohol derived from sugar is used in specially designed engines produced internally, further reducing the outflow of foreign currency. There is little prospect of much competition from manufacturers in the developed world, and the possibility of export opportunities to other countries with a capability of producing alcohol but with a less developed industrial base.

The discussions of biotechnology in food production, particularly aimed at an increase in protein for developing countries, are dated and do not give adequate recognition to the current surpluses of carbohydrates everywhere in the world except Africa. The use of simple technologies, such as the immediate drying of harvested materials to prevent spoilage by fungi, is likely to give a much better return than investment in advanced biotechnological techniques.



Colour display — the picture (of interferon crystals) is reproduced from Biotechnology: Strategies for Life, *by Elizabeth Antébi and David Fishlock, a large-format, highly-illustrated popular book newly published by MIT Press. Price is $39.95, £29.95.*

It is an especial pity that the book does not include a concluding chapter by the editors, with advice on the prerequisites of a successful process or industry based on the biological sciences. The technology itself is only a small part of the overall picture, and at this stage is probably best imported through licence agreements or joint ventures with leading companies. In the longer term, the commercialization of biotechnology will require substantial investment in trained manpower, and the development of a broad-based research and development programme, and industrial production facilities. Meanwhile, the best hope for the developing countries must be in forming suitable partnerships with other nations. *The Biotechnological Challenge* contains this message, but in only muted tones. ☐

Distillation to the basics

D.H. Watson

Fundamental Virology. Edited by Bernard N. Fields and David M. Knipe. *Raven: 1986. Pp.784. $54.50.*

JENNER may seem to have been anachronistically prescient in writing of smallpox *virus*. Of course, he only used "virus" in the then-conventional sense of something unpleasant (literally venom or poison). The more restrictive use in the present century was promoted by the observations of Iwanowski and Beijerinck that the causal agent of tobacco mosaic passes through a filter capable of impeding bacteria. Similar properties were soon demonstrated for some organisms infecting animals, followed by recognition of bacterial viruses which, despite their later discovery, were to be the main focus of the early years of virology. A notable landmark was the introduction of physical methods and, in particular, of a rigorous quantitative approach, through the recruitment to the discipline of some distinguished physical scientists (whose scientific emigration has sometimes been attributed to their post-war disenchantment with aspects of modern physics).

Real advance in animal virology only came when animal cells could be cultivated with an efficiency approaching that of their bacterial counterparts. Most importantly, this led to Dulbecco's development in 1982 of reproducible plaque assays for animal viruses. Succeeding years saw accelerating progress in animal virology, which both benefited from and contributed to the growing power of molecular biology.

More recently, it has become clear that the molecular approach to the study of viruses causing animal and, in particular, human disease can lead to rational approaches to chemotherapy, new kinds of vaccines and useful insights into mechanisms of pathogenesis. As a result, modern textbooks on "medical" virology now refer to molecular aspects of the subject, as well as the more traditional clinical aspects of virus infections. The ultimate in this genre must be the encyclopaedic *Virology*, edited by Bernard Fields *et al.*, and published by Raven last year.

Fundamental Virology is a derivative ("exprint" perhaps?) of that earlier volume. It consists, in half the page extent of its parent, of the more basic, rather than the clinical or applied chapters.

The preface concludes with admirable confidence that the text will be useful for courses in general and molecular virology. I agree, but feel the editors may be a little too sanguine in anticipating that it will be used by senior undergraduates, although it will inevitably be the standard reference book at this level. It should certainly be used and studied at the postgraduate level, and by teachers and researchers.

It is perhaps a little harsh to cavil at the coverage of what is a large volume, even in the magnum, rather than jeroboam, version. Nevertheless, the title is a little misleading. Inevitably, from its provenance, the book deals with the fundamental virology of human viruses, whereas any course on molecular virology must by necessity address bacterial, plant and other animal viruses.

This apart, the volume covers its chosen field comprehensively and all of the chapters have been written by experts on their topics. No other book has such extensive coverage which is so up-to-date, with references up to 1984. □

John Treherne

Trillion Year Spree: The History of Science Fiction. By Brian W. Aldiss with David Wingrove. *Gollancz/Atheneum: 1986. Pp.511. Hbk £15, $19.95; pbk £9.95.*

BRIAN Aldiss and David Wingrove cast a wide net in their 500-page history of science fiction, a revised edition of Aldiss's *Billion Year Spree* published in 1973. Inhabitants of their pantheon range from Gilgamesh and Disraeli to Mickey Mouse and Ray Bradbury. Only poor Fred Hoyle, one of the few scientific professionals among British SF writers, is missing.

It all started in the halcyon years of the Regency, with Victor Frankenstein and his 19-year-old creator, Mary Shelley. Before Mary, there was only what the authors call "ur-scientific fiction" (that is, before the genre originated), with such promising "ur-SF" types as Dante, Voltaire, Daniel Defoe, Will Shakespeare, Erasmus Darwin and the writers of *Genesis*. After Mary, come the real SF-pioneers — Edgar Allen Poe and Bram Stoker, sustained by gothic nightmares of nasty things in dark airless chambers, headless corpses and Count Dracula; followed by Jules Verne, H.G. Wells and Conan Doyle — with giant space rockets, fearful weapons, squidgy creatures in long-legged machines on Cobham Common and the Earth ploughing through toxic interstellar gas — and Edgar Rice Burrows (Tarzan) and William Hope Hodgson, with swine-things that come up from the cellar while the Sun goes dull in the sky.

Meanwhile, "post-ur" auxiliaries were obligingly scribbling away in the wings: Samuel Butler and William Morris (with their Utopias); Thomas Hardy (whose astronomer-hero, Swithin St Cleeves, gazes at the night sky with Lady Constantine wondering if "horrid monsters lie up there?"); Robert Louis Stevenson (Dr Jekyll, *of course*); even the gentle, consumptive Richard Jefferies (imagining the worst in *After London*) and many, many more. All are lovingly recruited to the SF cause and accorded lengthy quotation.

Then on past Freud and the Nazi party; Čapek and Kafka, robots and *RUR*, the destruction of civilization; Aldous Huxley and the imbecility of industrial progress; Hollywood and C.S. Lewis; to the whole tottering panoply of late-twentieth-century SF with its intergalactic wars and time warps, bug-eyed monsters (still), supermen and genetic disasters, occasional romps on the wilder shores of psychology and pharmacology and, most surprising of all, the return to pure gothic fantasy with goblins and wizards, absolute evil, sandworm gods and beautiful princesses in Middle Earth, Dune and Gormenghast.

For most of us, I suspect, encounters with SF are limited to youthful passions for Flash Gordon, Dr Who or Captain Kirk and, in adult years, the occasional Asimov and Aldiss snatched in desperation at Heathrow or from a railway bookstall. The first requirement for the uncommitted SF reader — suspension of disbelief — can be difficult, especially for those of a pedestrian turn of mind. It is not only the convoluted plots and scientific improbability, there are all those silly names. Even Doris Lessing becomes a challenge in this scenario of one of her SF novels:

> Two mighty Galactic Empires, one — Canopus — spiritual, one — Sirius — technological, are interested in the degenerated planet Shikasta, once a paradise world called Rohanda. Agents from Canopus and Sirius walk its surface and witness stages in its development and decay...

But for Aldiss and Wingrove this is a serious business:

> Science fiction is the search for a definition of mankind and his status in the universe which will stand in our advanced but confused state of knowledge (science), and is characteristically cast in the Gothic or post-Gothic mode.

Undoubtedly they are right when the writers are Wells or Huxley or Kafka and, perhaps, to some extent even when they are L. Ron Hubbard or Arthur C. Clarke. Yet I suspect that most SF readers, like their Edwardian predecessors, are after a rattling good yarn in the realms of ultimate fantasy. And this SF clearly provides in great abundance, as is charted in this readable, scholarly and — despite much good humoured bravado — slightly apologetic book. □

The missing link

CULTEK is a Spanish Company founded in 1976, specialised in the distribution of instruments, reagents, chemicals and disposables for the biotechnologist. We represent a number of well-known manufacturers from around the world (i.e. Bio Rad, Flow, etc.) and sell and give service to over 2.000 customers throughout Spain, working in the following areas:

- *Molecular Biology*
- *Celular Biology*
- *Immunology*
- *Specialised diagnostics.*

Over the last decade, we have been the pioneers in Spain of these new technologies, which gives us a leading position in terms of experience and know-how in league with the world's best. We bridge the gap between manufacturers and users, overcoming financial, bureaucratic and linguistic barriers, and serve as technical consultants for both partners in the chain. In summary, we are the missing link.

If you plan to market or buy your biotechnology products in Spain, do not waste time and effort, come to an expert.

CULTEK'S HOUSE AGENCY.

A renaissance in the making

An OECD survey in 1984 placed Spain and Portugal among nations that "give little or no priority to research and development". But they now seem aware of the need to build scientific resources.

IT is hard to square the gloomy judgements of the OECD examiners with the reality of a visit to Iberia. Whether Madrid or Lisbon, science administrators are full of enthusiasm for the future and confident that much can be achieved. It is perhaps after all only human nature: things really are getting better and better and although research investment lags far behind Europe's major nations there is none of the despondency that comes with living in the declining north.

Wider horizons came with the ending of the dictatorships that had governed Spain and Portugal. Although a decade has passed since the first heady days of freedom ("when we talked politics 24 hours a day because we had never been able to before" as one researcher put it) there is still a sense that new opportunities are opening up. This year it is entry into the EEC.

Major challenges come with membership. Both Spain and Portugal are predominantly agricultural nations and lack powerful multinational companies. And while both receive enormous numbers of tourists each year (Spain considerably more than its own population), neither wants to see its involvement with Europe end in economic colonization by the wealthier north.

Names, money and thanks

IBERIAN names, as this correspondent found out, are rather complicated. Having signed my full name, Alun Mark Anderson, in a small hostel in Bilbao I found myself being addressed as "Señor Mark" for the duration of my stay. I might, I am told, have equally well have been addressed as "Señor Mark Anderson" or even "Don Alun" but no one would have committed the foolishness of calling me "Señor Anderson", my presumed maternal surname.

If surnames become muddled in the articles that follow, or if I have given some people more surnames than others, I apologize in advance for my ignorance. Doubtless there will be other errors for this survey is based on a trip to Spain and Portugal that was all too short. Whatever errors there are, they will not be the fault of the people who gave me special help in planning my trip and whose knowledge of Spanish (or Portuguese) science is much deeper than my own.

In Madrid special thanks go to Dr Paul S. Dick. Science Officer at the British Council and his staff for their hospitality and for arranging many of my visits. In Barcelona Dr Pedro Puigdoménech and Professor Juan Subirana deserve equal thanks for looking after every aspect of my visit. And in Lisbon various anonymous members of the Ministry of Education deserve thanks for arranging my schedule.

NOTE: £1 = 198 Spanish pesetas = 229 Portuguese escudos. □

The increase in agricultural and industrial productivity that both nations now urgently need is inevitably entwined with scientific and technological development. The scale of the problems faced by the two nations is, however, quite different. Spain has four times the population and six times the land area of Portugal. More important, it has a gross domestic product (GDP) per head of £3,087 (1983 figures) that puts it within shouting distance of those, like Britain (GDP per head, £5,542), at the back of the pack of advanced industrial nations. Portugal, with a GDP per head of £1,380, is still at an intermediate stage of development with parts of its agricultural system a century behind the rest of Europe.

Both countries have a history of spending appallingly little on research and development. Even the most optimistic estimates suggest that Spain spends 0.6 per cent of its GDP on research and development and Portugal 0.8 per cent, in comparison with Britain's 2.4 per cent.

Both countries inherited from their dictatorial past institutional structures ill-equipped to deal with rapid change. Their research organizations were fragmented, with different sections of activity separated from one another, and research separated from teaching in the universities. Arbitrary and autocratic control was exerted from above.

The first wave of change was catalysed by young and impatient men and women who had been trained abroad. Even before the dictatorships vanished, many of the brightest students had begun to go to foreign laboratories to gain doctoral degrees. The returnees now provide the core of many of the research groups of international standing and provide the impetus for change.

Spain has moved forward at some speed. Structures have changed and attitudes sometimes seem to be struggling to catch up. In the universities and research institutes, the psychology of the Franco era was expressed by autocratic professors presiding over miniature empires, and in concern with international politics and the skillful currying of favour over the cultivation and reward of excellence. The old Spain is still visible in the laboratories but it is dying, laid low by increasingly open competition for positions and grants.

Overall coordination of the whole spectrum of research is now being installed with a new law and a new interministerial body. National priorities will be set and national plans made. A centralized form of administration thus returns, but the government assures doubters that Franco's ghost will not be found within it: researchers have never had greater control over their day-to-day affairs. The new body will, however, have to choose the area in which grants will be given out, while still bearing in mind that the results of much of the research must eventually find application in Spain's agriculture and industry.

That this can be a difficult task is suggested by the failure of a national programme for biomass development launched by the new commission's predecessor. What makes picking winning areas particularly hard is the lack of clear signals from industry of the direction in which it is going. Research spending by industry has always been very low. The new commission will thus have the double task of promoting research that can find application while convincing industry that it should be taken seriously. The fear is that it will be easier to follow international fashions (biotechnology, electronics and new materials are bound to be the new litany) than to find areas in which Spain has a unique chance of success.

The pace of reform in Portugal has been slower. A perfectly good organization to coordinate science and technology exists, but only gradually is it being given the money and powers to do its job.

Meanwhile different research organizations and different sectors of the government happily go their own ways without any real coordination from the top and a curious university research system keeps hundreds of small groups isolated from one another without any real incentive to achieve excellence.

Portugal is saved from its lack of coherent planning by its size. The research community is still small enough for almost everyone to know everyone else, which often means that bureaucratic barriers are not so formidable in the laboratories themselves. Wisely, Portugal is concentrating efforts to develop its backward inner regions through the establishment of new universities and polytechnics with an emphasis on agriculture. Here the scope for improvement is so great that even a little technology transfer is likely to work miracles. □

Spain: political change

A high-speed ride to democracy

In June of this year the Spanish people re-elected a socialist government with one of the largest majorities in Europe. A little less than ten years earlier that party was illegal, defined itself as "Marxist...rejecting any path of accommodation to capitalism" and had a revolutionary programme intended "to socialize production, distribution and exchange by the working class".

In power the party has taken a very different line; it won a referendum to keep Spain in the North Atlantic Treaty Organization (NATO), took Spain into the EEC and is now busy selling off the vast state holdings accumulated during the Franco era to private industry. But that a radical party transformed itself into something like a conventional European social democratic party is but one of the wholly unexpected twists of history that has brought Spain, in ten years, from a fascist dictatorship to a parliamentary monarchy.

The Congress of Deputies takes cover as Lt Colonel Antonio Tejero Molina and the Civil Guard take over.

The roots of the peaceful transition can be found in the late 1950s when, with Spain close to bankruptcy, Franco allowed the economy to be liberated. Spain was opened to foreign investment and foreigners and as the tourists flocked in, hundreds of thousands of Spaniards went to work in the then booming industries of northern Europe. The results were dramatic; between 1961 and 1973, the "years of development", Spain grew faster than any country except Japan. By the time the boom was over in 1974, Spain found itself with a society much of which was middle class and which had a vested interest in the continuing stability of the country. In 1975 Franco died and a series of new actors appeared on the political stage.

Six years before his death Franco appointed his own heir (a prerogative he had granted himself). His choice — Juan Carlos, the grandson of the last king of Spain, Alfonso XIII, who been brought up under the tutelage of General Franco — was not a surprise. But the King was not to prove a mere follower to Franco. After Franco's death, he astonished the nation by appointing as Prime Minister, Adolfo Suarez, who had spent his life working for Franco and seemed totally unsuited to dealing with a nation demanding change. But the King's choice proved correct; Suarez's knowledge of the dictatorship was to prove the very strength that enabled him to dismantle it. Change followed at a giddy pace.

Suarez was appointed in May 1976; by November he had persuaded the Cortes, stuffed as it was with old supporters of Franco, to agree to the establishment of a two-chamber parliament and universal suffrage. In December 1977 the change was approved by a referendum; the following spring political parties were legalized, including even the communist party. In June the first general election was held. Not surprisingly, Suarez's own moderate party was the winner — but not by an overall majority. To the nation's astonishment (and the disappointment of those who thought Franco's death would herald a revolution) Suarez then proceeded to negotiate a comprehensive series of agreements, the Moncloa Pacts, with all the opposition parties and then, when this was done, to draw up by consensus a new constitution defining Spain as a parliamentary monarchy.

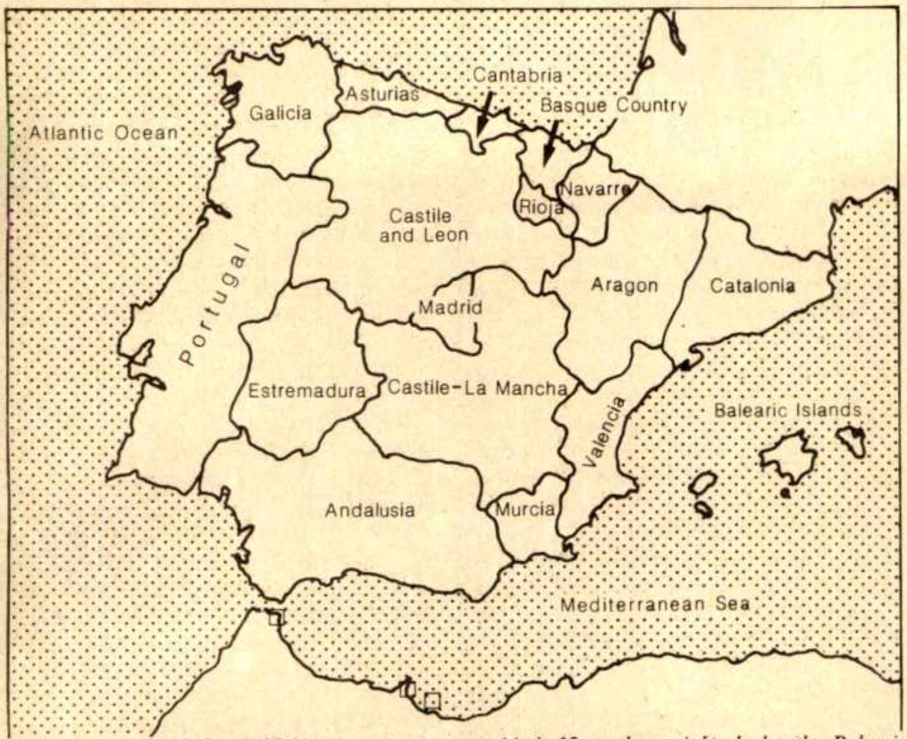
While it was that act in October 1978 that marked the official beginning of the new Spain, it was two and a half years later that democracy had its baptism of fire. On 23 February 1981 (a date which all Spaniards seem to know), with Suarez still in power but his own party increasingly divided, a group of senior army officers decided that democracy had gone too far. The Congress and virtually all of Spain's top politicians were seized by a group of Civil Guards. In Valencia tanks took to the streets. But the attempted military coup was to fail, largely through the prestige of the King. By remaining firmly opposed to the coup and persuading military leaders not to back it, King Juan Carlos was able to maintain control and peace was restored in twenty-four hours.

The following year the party that Suarez had led was in such disarray that he himself left to form a new one. That left the field open for the Socialist Party to win the general election with the 40-year-old Felipe Gonzalez as its leader. Just seven years after Franco's death Spain had an elected socialist government. Since then, Gonzalez has been skillfully piloting his party towards the political centre. After further success in the 1986 election he appointed the youngest cabinet in Europe, many in their early 40s and with a Minister of Industry and Energy who is just 35.

Alongside the establishment of democracy, other changes have taken place. Less well noticed abroad, but of great significance in Spain, has been the devolution of power to regional governments; Spain is half-way to becoming a federal state.

Devolution came in bits and pieces and was intended at first to provide for the demands of the Basque region — where violent demonstrations for independence had begun earlier — and Catalonia and Galicia; all regions with their own languages and culture. Spain now consists of 17 'autonomous regions'; each has its own ministers, president and administrative staff, but there similarities end. The Basques have gone furthest down the road to autonomy. They collect their own taxes and send on to Madrid their share (a little over 6 per cent) of the cost of 'central' services — defence, foreign affairs, aviation and the like — while keeping back taxes for local government, including health, housing, social welfare and agriculture. Catalonia, in contrast, is content to let the central government collect taxes and receive their share. The Basques also set up their own police force and both the Basque Country and Catalonia have their own television channels and bilingual road signs. These changes have helped to quieten separatists, but the problem remains; the main political wing of the Basque separatist movement has renounced violence, but its leftist military wing, whose own representatives are still able to win around 15 per cent of the Basque vote, has not.

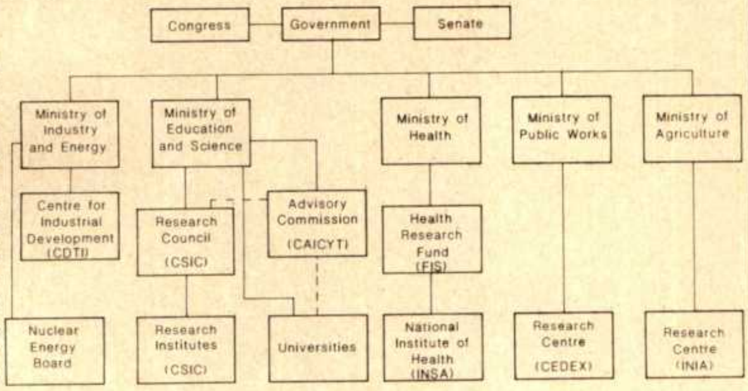
Science, technology and education remain a disputed area in which clear and universal transfer of authority has not been arrived at. The Basques and Catalans are responsible for the running of their universities and schools, but in about half the regions the universities remain firmly in the hands of the central government, for the time being at least. No region has been able to grasp full financial control of its science and technology budget, although both the Basques and Catalans have their own regional science administrations. The unwillingness of the central government to transfer these powers is still very much an issue of argument. ☐



Spain is now divided into 17 'autonomous communities'; 15 on the mainland plus the Balearic Islands in the Mediterranean and the Canary Islands in the Atlantic. With somewhat different status are the two tiny North African enclaves of Ceuta and Melilla located, aptly enough, just across the sea from Gibraltar. Morocco would like the two towns back.

Science bodies await a reshuffle

SPAIN's science is not run quite like this any more (see chart) for the new law for the "Promotion and general coordination of scientific research and technological development" is just beginning to make itself felt. Under the old system the Ministry of Education and Science looks after both the universities, which have not traditionally been active in research, and the Consejo Superior de Investigaciones Cientifica (CSIC), the science research council in whose various institutes research facilities are mainly concentrated. Grants for the research performed in both the universities and in the CSIC institutes are assessed by the Comisión Asesora de Investigacian Cientifica y Tecnica (CAICYT).



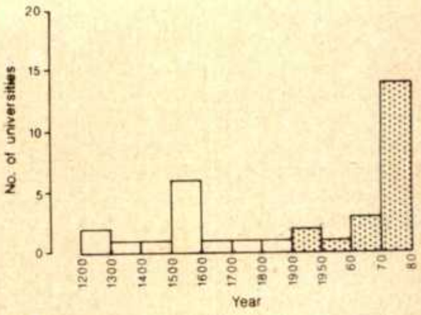
Congress
Government
Senate
Ministry of Industry and Energy
Ministry of Education and Science
Ministry of Health
Ministry of Public Works
Ministry of Agriculture
Centre for Industrial Development (CDTI)
Research Council (CSIC)
Advisory Commission (CAICYT)
Health Research Fund (FIS)
Nuclear Energy Board
Research Institutes (CSIC)
Universities
National Institute of Health (INSA)
Research Centre (CEDEX)
Research Centre (INIA)

The Ministry of Industry and Energy is responsible for nuclear power development and for industrial development through the Centro para el Desarrollo Tecnológica y Industrial (CDTI), an organization advancing money for research where the risk is too high to attract ordinary investors. Medical research is funded through a seperate granting agency, Fondo de Investigaciones Sanitarias (FIS). The Ministry of Public Works retains a large research centre, the Centro de Estudios y Experimentación (CEDEX).

Change came to the Ministry of Agriculture a few years ago when it lost direct control over most of its research centres in favour of the autonomous communities in which they were located. But it retains responsibility for overall coordination and for Madrid's Institute Nacional de Investigaciones Agrarias (INIA).

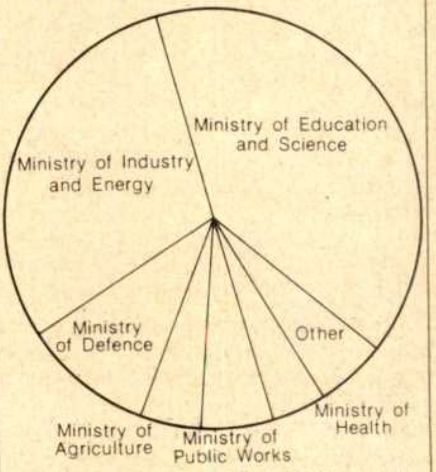
Under the new system the institutions survive but an attempt is made to improve coordination and planning through central control by the Interministerial Commission for Science and Technological Development which contains representatives from all the ministries. This will sit at the centre like an octopus with its tentacles reaching out to all the research agencies. Its responsibility will be to programme all their activities through the construction of national plans. Advice on the design of the plan, its objectives and its progress will fall on an Advisory Council (a transformation of CAICYT). Quite how the new system will function is not yet clear for the Interministerial Commission has only just met for the first time, a situation perhaps symbolized by new charts showing everything joined to everything else by dotted lines. □

Towards a second golden age



Why a second golden age? A glance at a chart showing when the universities were established shows that there has not been a boom like the past decade's since the sixteenth century. That was the time of the height of Spain's prosperity when riches were pouring in from the newly-colonized Americas (the Aztecs were conquered in 1519 and the Incas in 1532) and the King of Spain was also Holy Roman Emperor. Holland, Austria and much of Italy were under his control and Spain was the dominant power in Europe . Of the universities established then, Valencia, Santiago, Sevilla, Madrid (Complutense), Granada, and Zaragoza still survive. □

Education ministry is the big spender



THE Ministry of Education and Science is the big spender among the government agencies with responsibility for research, even bigger than the Ministry of Industry and Energy. Total funds expended by the public sector reached 119,000 million pesetas this year — 80 per cent of the total. The small contribution of the private sector contrasts strongly with industrial nations like West Germany, the United Kingdom and the United States, where more than half of all research is funded by industry. The discrepancy helps to explain why the percentage of Spain's gross national product spent on research is so low, at most 0.6 per cent, in comparison with the major industrial nations which score from 2.2 to 2.8 per cent. □

Law of science

More coordination from the top

"SCIENTIFIC research and technological development have traditionally taken place in Spain in a climate of apathy and lack of social stimuli, in the absence of the necessary apparatus to guarantee the efficient intervention of the authorities in the planning and coordination of the scant means available, with a lack of connection between the aims of research and the policies of the relevant sectors and, usually, between the research centres and producing sectors. It is hardly surprising, therefore, that Spanish contribution to scientific and technological progress has in general been small and inappropriate to the position Spain has occupied in other areas; and that, when this has not been the case, as in certain periods of the present century, the most worthy contributions have been the result of the isolated effort of particular individuals."

IT would be impossible not to applaud a government that is able to set down such a brutally frank appraisal of its own nation's shortcomings as that given above, taken from the introduction to the "Law for the Promotion and General Coordination of Scientific Research and Technological Development", passed by the Parliament earlier this year. Of course, the government finds it easier to make sweeping criticisms with the knowledge that the present defects can be blamed on the past dictatorial system. But even so the new law is a remarkable attempt to remedy the defects listed above, with the aim of ensuring that Spain can look forward to the day when it can speak on equal scientific terms with neighbouring countries.

The new law is not the beginning of the reform of scientific organizations in Spain. The ten years that have passed since the end of the Franco era "feel more like a century", as one researcher put it. The two largest concentrations of scientific talent, the institutes of the research council (CSIC), which have traditionally been the stronghold of research, and the universities, which have concentrated more on teaching, have both undergone considerable reform, as the following pages will make clear. What the new law really does is to reform the highest level of decision making and to bring it under the control of a new policy body answerable to parliament. That body is the Interministerial Commission for Science and Technology and it will be responsible for designing and overseeing the execution of the National Plan for Science and Technology.

The Interministerial Commission will contain representatives from all the ministries concerned with science and be chaired by the Minister of Education. It will have the power to decide the budgets, staff, and capital needed to carry out the national plan, to allocate funds to the various organizations involved in carrying it out and to coordinate the research activities of the different scientific bodies. Independent action by separate research organizations, each of them presenting its own budgets to the Ministry of Finance, will thus end. The plans of the commission will be debated by parliament and a yearly report on their progress made public.

It is not, however, the intention of the commission to impose rigorous control from the top over all aspects of scientific research. Within the national plan, there will be "National Programmes of Scientific Research and Technological Development" (in which information technology, biotechnology, and materials science are likely to feature strongly) designed by the commission. But the national plan will also incorporate "sectorial programmes" emanating from government departments and research bodies, and programmes from the autonomous communities. Overall control of the national supply of research personnel will be taken as the responsibility of the commission.

The status of a number of autonomous research bodies, including CSIC and the Nuclear Energy Board, will also be altered by the new law, principally so that they may more flexibly interchange staff.

Those who designed the new law feel proud of it; indeed they think the new structure could teach a thing or two to other countries, like the United Kingdom, which they see as very poor models for overall research planning. But it is much too early to say whether the Spanish system will succeed for, at the time of going to press, the commission will only have just had its first meeting. How quickly it will impose itself on the organizations it now commands remains to be seen.

Strangely, many in CSIC and the universities seem quite uninterested in the new law and doubt that it will bring about shifts in the direction of ongoing research. Perhaps more pertinent is the criticism

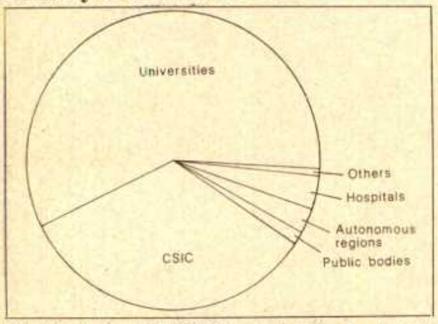
Sharing out the CAICYT cake

FOR the universities, CAICYT is the major source of research grants, although private foundations, industry and the Fondo de Investigaciones Sanitarias (FIS) of the Ministry of Health and Consumer Protection are important. The latter provides much support to medical faculties and hospitals. Those working in research council (CSIC) institutes also have grant applications assessed by CAICYT but their grants can be topped up from CSIC's own funds.

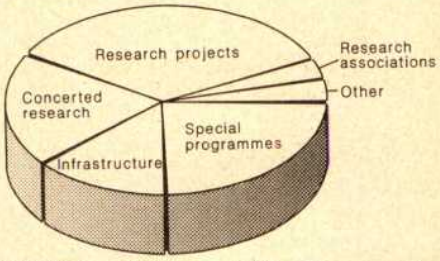
Supporting research projects uses up the largest slice of CAICYT's budget, but still accounts for less than half of total expenditure. Special programmes take a quarter of the funds. They come in two varieties, mobilizing programmes which aim at the general promotion of a whole field of science (current themes are high-energy physics and biotechnology), and national priority research and development programmes which also promote coordinated action across a whole field, but aim at a more concrete economic objective. Both involve all research organizations, particularly the institutes of CSIC. Four programmes have been launched in the latter category: biomass energy (which proved such a disaster that it was abandoned), aquaculture (which has stimulated the establishment of a new CSIC National Centre for Microelectronics with laboratories at the Autonomous University of Barcelona and the Polytechnic University of Madrid) and rail transportation.

Research in industry is promoted through concerted research programmes in which loans (up to 50 per cent of total cost) are given to private firms to cover their research costs. Part of the research may be totally funded if it is carried out at a government laboratory. If there are good prospects for development of a marketable product then help from CDTI (see p.324) is likely to come in the later stages.

An increasingly large slice of the budget goes to improve research infrastructure, working through the autonomous communities. Smaller sums go to aid industrial research associations, to encourage foreign scientists to take their sabbaticals in Spain and to support international cooperation, scientific publications and congresses. ☐



Distribution of CAICYT's project funds. A total of 3,826 million pesetas was given out in 1985.



CAICYT's total budget — 9,100 million pesetas in 1985, but 13,000 million next year — is widely spread.

Export market for advice

CAICYT is by and large a traditional research council: it assesses grant applications through the reports of external referees chosen by committees representing each subject area, it selects priority areas and arranges special grants to cover them and to aid cooperation with industry and the funding of research that might find application. All these activities and the other things it does (see opposite) are normal enough. What has made CAICYT a power in the land is that by all accounts it does its job very well and, more importantly, it was the first organization to bring an objective element into the assessment and planning of science. CAICYT's 300 or so referees have found themselves in demand. Grant proposals from both university and CSIC researchers normally pass before it (although if CAICYT chooses not to fund projects from CSIC researchers, they still have access to CSIC funds). And recently numerous other organizations have come to them for help, including some from abroad, like the Chilean research council.

The idea of making thorough analyses of the scientific situation really took off only recently. At the end of the Franco era one problem faced by both universities and the research council was that nobody really knew who was doing what or where and what equipment different laboratories had. Now CAICYT has a large computer and an enormous data base. A key word is sufficient to call up any scientist along with grant and publication record. Any piece of equipment can just as easily be located.

The data base has helped in putting forward realistic plans that Spain has the trained staff to meet, but CAICYT's concern for information sometimes appears to verge on the obsessional. The UNESCO coding system system (now, alas, out of date) is used and there is a joke in the laboratories that a researcher who cannot find a 6-digit category to fit his or her work will have a short career. ☐

that without a real commitment to spend more money (which the government has not made) no profound change can be expected. What is certainly clear is that the success of the new organization will depend largely on the quality of the advice it receives. Responsibility for that will rest heavily with a permanent expert commission set up to advise the Interministerial Commission. Fortunately, considerable experience is at hand in the form of a body that has already proven itself a driving force in the scientific scene — the Advisory Committee for Scientific and Technical Research (CAICYT) of the Ministry of Education. The new permanent commission will largely be the old CAICYT with a few additions and new name. ☐

The research council

Back on the road to recovery

THE Consejo Superior de Investigaciones Cientificas (CSIC), the nation's largest multidisciplinary research body, and its traditional source of scientific strength, is coming through a profound reorganization. At the end of the Franco era the CSIC had fallen so low that there was talk of abolishing it altogether. But instead it was reformed, more vigorously than the universities, and is reasserting itself both in basic and applied research.

The CSIC of the 1970s could provide a lesson in how not to run a research organization. The number of its institutes had grown to 170. Many of them were extremely small and had been set up for personal rather than scientific reasons; some contained just one person, for the old style Franco-era professor was a strong figure who found it hard to work under anyone else. Salaries were low and laboratories poorly equipped. The staff was growing older; by 1981 the average age was 48. But after the restoration of democracy things began to change and by the 1980s the pace had increased rapidly. Now just 76 institutes are left, some that vanished were closed down, but most were fused with others. That meant many former directors had, once more, to become subordinates or to leave.

Some were dispatched by lowering the age of compulsory retirement from 70 to 65. Not all went peacefully. Here and there in reorganized institutes there are autocrats who have hung onto large areas of laboratory space, despite the entreaties of their younger and more active colleagues. Elsewhere, quarrels over who was to gain power have left people no longer on speaking terms. And despite reorganization, integration of laboratories is sometimes proceeding in name only, but that perhaps requires only the passage of time to cure.

A flood of new appointments allowed young people to enter CSIC, or to move up its hierarchy. In 1981 there were 1,100 scientific staff; by the end of this year there will be 1,800. Over the same period the budget doubled and CSIC made efforts to open itself up to the universities and to industry. Fourteen joint centres have been set up in the universities, usually the university provides the building but all the laboratory equipment and around a third of the staff are provided by CSIC. Some 40 per cent of the Consejo's research projects also involve university researchers, for although they do not have direct access to CSIC's funds, they can make joint applications with CSIC researchers.

Industrial contracts are being signed at the rate of three a week. This year a little over a fifth of CSIC's total budget will come from industry. Industrial researchers can also come to CSIC laboratories for training — although it is not yet possible simply to send CSIC researchers to industry. CSIC's head, Enrique Trillas, is particularly proud of the successes of the Office for Evaluation and Technology Transfer and that industry is now coming to the CSIC without being asked.

RAMON y Cajal, who won the Nobel prize in 1906 along with Camille Golgi for establishing the neuron as the unit of the nervous system, signed, as its first president, the document that brought the Junta para Ampliacion de Estudiose Investigaciones Cientificas into existence in 1907. The Junta was to prove a liberal scientific institute sending many people abroad for training and leading a short scientific renaissance. Then the civil war came and in 1939 Franco suppressed the Junta. It was soon rebuilt as the CSIC; but not with the same people — some three-quarters of Spain's senior scientists had fled into exile. The new institution was given the quasi-religious goal of "rebuilding the unity of science broken by the philosophy of rationalism", but retained some liberal traditions; in the Franco regime's view, intellectuals were safer in the CSIC, where there were no students for them to teach, than in the universities.

Much then has been achieved. Even the Napoleonic style examination — the *oposcione* — has been altered, as it has in the universities (see p.320). Now, to get a first post within the research council, there is a public examination of the candidate's academic record and research speciality. But later promotion depends only on an assessment of the researcher's work. More important is that in both cases it is no longer a jury drawn from CSIC institutes only that makes the decision, but one containing professors from the universities and, increasingly, from abroad. In the past juries often came from the candidate's own institute, making the promotion of internal candidates and the exchange of favours a common feature of institute life. The rejuvenated CSIC institutes still span the whole of science: from history, through molecular biology to construction and cement.

For many in these laboratories, the greatest change has been that research proposals are now thoroughly assessed. In the old days a grant came with a permanent position. Now researchers receive a salary and basic infrastructure and must apply for grants, either from CAICYT and CSIC, private agencies or industry. And all scientific evaluations are made by CAICYT (see p.317) and its teams of referees, rather than CSIC itself, although an economic evaluation is first performed by a committee from CSIC.

CSIC's head Trillas.

The great changes made in CSIC do not mean, however, that its troubles are over. Although CSIC has better facilities for research than the universities and is the place where most research is done, it is still tiny, with less than 2,000 researchers, for a country the size of Spain. And more important, scientific traditions are not made overnight. The best institutes are at international levels. But they are few and far between compared to the run of the mill institutes that rarely produce a paper for an international journal. Moribund institutes still need infusions of talent, particularly of people trained abroad, but returnees face no easy task at institutes where excellence is not highly valued.

Most CSIC researchers, although happy to moan about the problems that remain, recognize the enormous improvements of the past ten years. If anything, what really needs to change is the attitudes of researchers themselves. One quote (delivered after a half hour of complaints about the bureaucracy) sums it up: "Our facilities are really no worse now than in the United Kingdom, and we have no lack of funds if we apply for them. It's up to us!"

Fundamental changes in attitude will come as talented young people take power within the institutes, coupled with increasing competition to gain grants. Then all that will be needed is a several-fold expansion of the system, before the research council begins to look like a ranking European scientific organization. □

Science evaluated

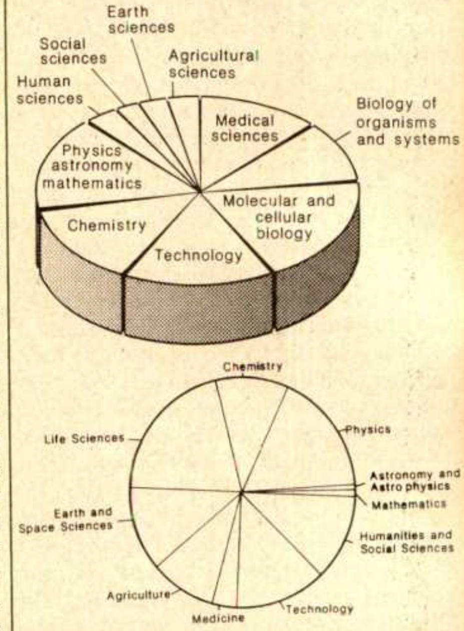
Still some catching up to do

It would be a mighty labour to try to give a complete and fair evaluation of the strengths and weakness of the different fields of science in Spain. Even in fields which are generally poorly developed there may still be outstanding characters making important international contributions: in ecology, for example, in which Spain produces few publications, there is Ramon Margalef at the University of Barcelona whose books have become standard works in quantitative ecology. Sweeping generalizations would not do such individuals justice. Something of Spain's record can, however, be read from the distribution of research grants of CAICYT and of research projects by CSIC coupled with the store of gossip available at every Spanish laboratory.

There is general agreement that molecular biology is strong (witness CBM, p. 319) and is attracting sizeable funding; "biochemists have had a powerful lobby for years" as one researcher put it. Physics has fared very much worse, with no large experimental facilities, and having seen people of the calibre of Blas Cabrera vanish into exile after the civil war. Only theoreticians managed to maintain standards. That should now change as a result of Spain rejoining CERN and an accompanying 'mobilization programme', in high-energy physics.

In nuclear physics there are some good Spanish scientists abroad but poor facilities within the country. European collaborations offer hope. Solid-state physics has also suffered from lack of equipment but this has already started to change.

Laser physics is the subject of a special CSIC mobilizing programme but a start is having to be made from almost nothing and standards are still low. In mathematics young returnees from foreign universities are just beginning to make things move and some specialized areas are already at international level. Astronomy appears to be a major disappointment. Despite access to the superb international facilities in the Canary Islands, very few Spanish papers appear in top journals. Atmospheric physics, earth sciences and whole organism biology remain very old-fashioned with only a few exceptions. But in geology, efforts are beginning to be made to link up with foreign researchers.



The share-out of research funds from CAICYT (top) and CSIC's project distribution.

Through English rags to scientific riches

Somewhat over half a century ago, Ramon Areces was working as a messenger boy in a little shop in Havana, Cuba. Now, through the foundation named after him, he is the biggest private source of support for scientific research in Spain. The path to philanthropy came through 'El Corte Ingles', a store he set up in Spain to make and sell suits with 'the English cut'. The name has stuck, although his department stores now sell everything from asparagus to zippers and it is impossible to find a city centre without one. And he is still selling suits — his factories producing ready-mades are the biggest in Europe. Overall, the group is one of Spain's biggest and parts of it have even gone into high technology — including electronics and biotechnology (see p. 325).

The foundation was set up ten years ago when Roman Areces, aged 72 and still a bachelor, decided to use part of his fortune to aid Spanish science. By international standards the foundation is not enormous but it is not so small either: In 1984–85, 147 million pesetas — close to a million dollars — were given out in grants along with double that amount for conferences, publications and to help equip research centres. Each year four research areas are chosen for support, and these replace (or are added to) the previously chosen areas. Anyone working in appropriate areas can apply for funding and grants are awarded on the decision of panels of referees. Research topics chosen recently range from robotics and solar energy to ocean sciences and cardiovascular disease. Individual grants are quite large — 23 million pesetas for a robot vision system, 13 million pesetas for molecular study of calcium channels in chromafin cells are examples. □

Centre for Molecular Biology

Long queues for laboratory space

"THE trouble with the Centro Biologia Molecular," said one research council administrator, "is that everyone wants to work there . . . but it's impossible". The 'CBM' has gained an international reputation for excellence and a national reputation for being far and away the best molecular biology research institute in Spain. Plus it has in residence Spain's Nobel prize winner Severo Ochoa. That has made it a popular place to be — a condition not without difficulties. Many at CBM are frustrated that they cannot accommodate all the researchers they would like while the research council would be happy to see some good scientists (particularly those returning from abroad) building good groups elsewhere rather than adding to CBM's lustre.

Among the main lines of research are virology; DNA regulation and protein synthesis; and molecular neurobiology, including the biochemistry of ageing and Alzheimer's disease. Perhaps best known (at least to readers of *Nature*) is the strong tradition in the developmental and molecular genetics of *Drosophila* begun by Antonio Garcia-Bellido on his return from Caltech and continued by Ginés Morata, Pedro Ripoll and Juan Modolell.

What makes the CBM interesting to the outsider is not just the science (of which there is plenty) but the way in which it has overcome some of the weaknesses in Spain's research system. It is the only major institute to have ended the traditional separation between CSIC institutes (specializing in research) and the universities (specializing in teaching). Under one roof (the university's) are the twin molecular biology institutes of the Autonomous University of Madrid and the CSIC.

The two sides share administration costs and elect their own representatives and a joint director. Those from the university side still have teaching duties while their CSIC colleagues have none, but that is the only difference and "we live in peace" as the director Jesus Avila put it. Both sides provide somewhat over 30 staff, and the CSIC over 60 'technical assistants'. Seventy-five research students complete the numbers. Fusion took place in 1975 before the need to bridge the gap between the universities and the research institutes was so widely recognized. But despite its success, the CBM has no imitators (only one institute has a similar structure). That might be because it took friends with political clout to set up the institute (among them Federico Mayor, then in high office). Their presence helps explain why there is no shortage of good equipment.

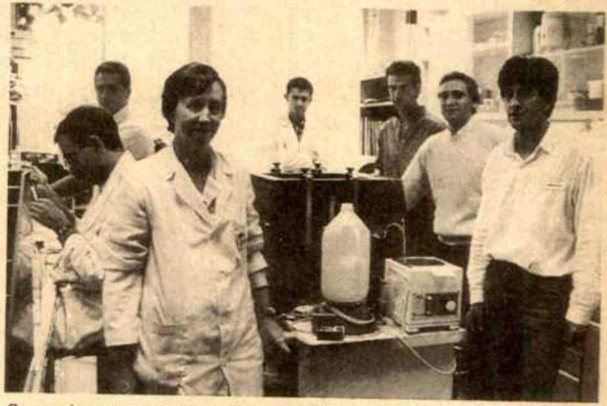
Severo Ochoa has now made his home at the CBM. He left Spain in 1936 and eventually became an American citizen working at the New York University College of Medicine. In 1959 he shared the Nobel prize with Arthur Kornberg for isolating enzymes that made it possible to synthesize RNA and DNA.

Organizational changes have helped overcome one common problem of the research institutes — a poor laboratory infrastructure (stores, animal rooms and the like). CBM researchers agree to apply jointly for a core grant as well as obtaining their own individual grants (although some researchers might end up with less this way) to maintain the research facilities. Elsewhere there is usually a levy on individual grants to provide common stocks but it rarely proves sufficient.

The core grant also enables them to tackle jointly one bizarre curse of CSIC laboratories: the technical staff belong to a large public service union and work from eight in the morning until three in the afternoon, so just when things are in full swing it is time to get the bus back to Madrid. Some extra money can be provided to keep some of them on later. And other problems, like keeping the heating on when the university switches it off (when classes are over) can be dealt with.

But despite these successes a gigantic problem remains to ire CBM researchers — the lack of space. There just is not room for everyone. "Asisnine" is how Dr Avila described the lack of coordination between the research council and the facility that has led to "at least eight people being employed who can't work here because they do not have space". A part of the problem is that space is not always distributed rationally. And that might be because, as a visiting advisory committee of foreign experts pointed out, the director has no real power. He or she is elected for two years which, according to Margarita Sallas, often seem "lost years from a scientific point of view, just a lot of administrative work". It is never easy to find someone to take on the job.

Without real power at the top, space cannot readily be allocated or projects terminated. Newcomers speak of having to bargain with territory holders to find a corner. As Juan Modolell put it "[space] is not dependent upon scientific accomplishment. I really have this laboratory because of historical circumstances, other people have half my space, or no space, and others several times more, but it has nothing to do with ability". That in turn, he says, reflects a more general problem, that "there is very little policy of promoting excellence".



Space is at a premium here in Margarita Sallas's laboratory as elsewhere in the CBM. The record seems to be ten people (and a few million fruit flies) in a room of just 49 square metres.

The director, Jesus Avila, does have plans to try to readjust laboratory space, if he is able (he was last seen by this correspondent wearily threatening to resign if promised administrative help did not materialize soon). What he wants to see is an institute with a potential for growth, that can let in young people. "Every institute has to grow or die, and we want this place to grow rationally", he says.

A more complete solution than readjustment can achieve might come with the new National Centre for Biotechnology to be constructed close by. There are doubts about just when it will be built (the decision was announced in 1984 but construction has not begun), but excellent molecular biologists are what it will need. There are many at the CBM who could do the job. A danger though is that the new institute will turn out to be just an annex to the CBM (or a place for some of its senior staff to retire to) instead of what it is meant to be — a laboratory working closely with industry. Those in industry who want something different from the CBM's strength in basic research complain that few people with industrial experience have been suggested for the board. For the researchers perhaps, as Juan Rojo, Secretary of State for the Universities and Research put if (very gently) "there may have to be a little shift of centre of gravity towards problems of interest to industry… a *Drosophila* group, if it's big, maybe some of them would shift a little to vaccines, agricultural products and so on." □

The universities

Worst problems overcome

Ask a group of professors about the state of the universities and you will hear a bewildering mixture of opinions. But after a little while a pattern emerges; praises come for the enormous improvements that have been wrought in the university system in the space of a few years but savage criticism is reserved for the defects that remain, often coupled with pessimism that they can ever be fully cured. Whether more criticism than praise is heard depends partly on the personality of the speakers, and very much on the amount of time spent abroad.

While perfection may be an impossible goal it would be too much to agree with the several cynics who said, "We were right at the bottom, so we could only get better". Planned reforms have had their effect and conditions for researchers are improving rapidly. The question is whether the reforms really went deep enough to give the momentum for the continued changes needed to bring Spanish universities up to the best international standard.

After the massive growth of the universities towards the end of Franco's rule real reform came with a new law for the universities — the *Ley de Reforma Universitaria*. Its overall aim was to remove the autocratic control exercised by central government over the universities, which made all universities equal and removed any spur to excellence.

Under the new law the universities were given power to write their own statutes, with the approval of the government, through the action of a University General Assembly (Claustro) freely elected by professors, students and administrative staff. Departments were rationalized. A huge number had been created under the old regime; many, it seems, to satisfy the personal ambitions of an individual professor or to separate those who had quarrelled. Resources are now concentrated in single departments for each subject area.

The enormous problem of untenured teachers was also tackled. The rapid rise in student numbers during the 1970s had made it impossible for the universities to appoint sufficient staff through the usual bureaucratic channels and many lecturers were appointed on short-term contracts. By the end of the boom there were more of them than there were tenured professors. Commissions were set up under the new law to decide who among the non-tenured staff should be taken on as professors; not surprisingly, perhaps, difficult choices were often avoided and the great majority were found suitable.

With their own charters written and

Research conditions still lagging behind

The University of Barcelona's School of Biological Science boasts an impressive piece of modern architecture, full of complex curves on the outside and with a huge central well inside, around which stairs zigzag upwards. But the building was planned in a more autocratic era and little consideration was given to the needs of those who were going to use it — with the peculiar result that corridors pass through the middle of research laboratories and libraries while unusable empty spaces abound.

Space is one thing the school is short of, for the study of biology attracts vast numbers of students; 3,000 in all. With numbers like that, some of the greatest difficulties faced by the university teaching system can be clearly seen at the school. There is no selection of students entering the school (biology is often a second option for those who wanted to study medicine, one of the few courses where numbers can be limited) and after one year only 800 of the 1,500 who entered are left — a drop-out ratio also seen in many other places.

At the end of the five-year course, half of the graduates will be unable to find a job, and only 10 per cent of them a job related to biology. With these prospects, it is not surprising that just half the students complete the course in five years; others retake courses they failed *en route* a few times — some stay on ten years and are well into their 30s. Only 10–20 per cent of the students have grants so the prospect of money running out does not provide a spur.

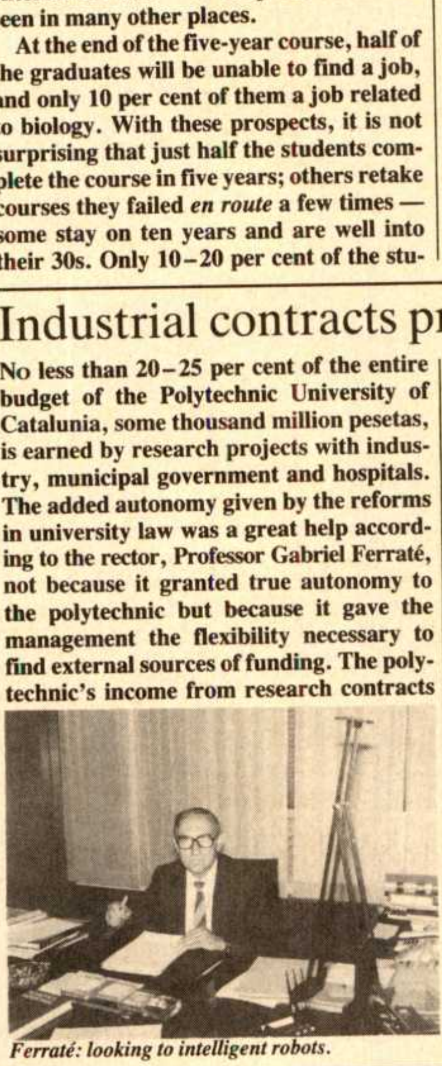
At the start, classes are big (more than a hundred students in each) and there is no chance of tutorials or seminars, nor much practical teaching — making the courses almost 'theoretical biology'. Only in the later years can groups of 20–30 students be dealt with. Given these factors, few students are highly motivated, and the long teaching hours make a real research effort from the staff difficult to attain. On top of that, back-up services are almost nonexistent.

Impressive architecture but does it work?

Professor Jaume Baguñá, who heads the Department of Genetics, has a dozen researchers and the same number of doctoral students without a single technician and only a part-time administrator. As Professor Baguñá says, "things have improved and change is coming, very slowly. But university research conditions are still very bad compared to the rest of Europe". □

Industrial contracts provide rich harvest

No less than 20–25 per cent of the entire budget of the Polytechnic University of Catalunia, some thousand million pesetas, is earned by research projects with industry, municipal government and hospitals. The added autonomy given by the reforms in university law was a great help according to the rector, Professor Gabriel Ferraté, not because it granted true autonomy to the polytechnic but because it gave the management the flexibility necessary to find external sources of funding. The polytechnic's income from research contracts is now increasing almost exponentially.



Ferraté: looking to intelligent robots.

The polytechnic was one of those in the camp opposed to keeping the status of teachers as civil servants, according to Professor Ferraté. But under the new law, winning contracts can also mean an increase in salary and that helps to provide motivation, which the polytechnic is taking full advantage of.

Research at the polytechnic has been buoyed up by contracts with young and energetic Catalan firms in the new technologies. Although the school of civil engineering has a high reputation, real glamour, as elsewhere, has passed to computer sciences, computer-assisted design and manufacturing and telecommunications: successful projects have been run on fast pattern recognition systems and automatic map-making from aerial photographs. Professor Ferraté himself founded a hybrid Institute of Cybernetics combining polytechnic and CSIC facilities. Its main thrust is "artificial intelligence applied to robotics", and several cooperative projects are running with US universities. □

approved what will happen to the universities? Will each university acquire its own distinct character rather than being one unit of a centralized bureaucracy? Will the best researchers (or teachers) find themselves in demand from competing universities? A glance at the law suggests that the answer will not be simple. It is a remarkably large document — some 59 articles and 22 pages. The autonomy given to the universities is of a form which it prescribes very exactly. All are now autonomous — but in the same way.

A key problem, not fully resolved, is that it is hard to reward directly those who are talented. There are only two full-time positions; the full professor (*Cathedraticos*) and assistant professors (*Profesores Titulares*). Salaries are fixed. There are no grades, and there are no easy means to increase a professor's salary (other than the fixed annual increment). This has meant there has been no means whatever to try to attract the brightest and best researchers, nor any reward for creating excellence. The result, over the years, has been an almighty indifference to the quality of research and teaching at a university; as one young researcher at the Barcelona Autonoma put it, "no-one really cares if their university is good or not. No-one ever fights to get the best man. They are happier with someone worse who won't provide any competition". And without any incentive to find good people the tendency has been for those already in place simply to rise through the ranks. The key step to a successful career has always been regarded as forming a close attachment to a powerful professor early on. The new law does allow researchers to double their salaries through contracts with industry, an incentive that many universities, particularly the polytechnics, are grasping with vigour. But the law provides little stimulus for basic research.

While autonomy may not have gone far enough in salaries, many say it has gone too far on appointments. The extra freedom given to the universities to decide on their staff has not always been wisely used — although it is still far from complete freedom.

All university staff are civil servants and in the past appointments were centrally controlled. Each required one of Spain's great official rituals — the *oposicione*. In a series of public examinations candidates had to prove their worth, sometimes in a direct debate with their competitors, before a tribunal of seven appointed by the government. The range of questions that might be asked was huge; it was not uncommon for candidates to be given a topic and be required to deliver a lecture on it the next morning. Nowadays, things are much simpler and the procedure is closer to a formal panel interview than a public ordeal. The examination comes in two parts; the first on the candidate's curricu-

Comfortable surroundings and a strong Jesuit teaching tradition make Comillas popular.

Comillas can set high entry standards

One advantage of being a private university is that you can select your students — and to enter the Universidad Pontificia Comillas, run by the Jesuits, is by no means easy. Exam grades have to be very high and are followed up by psychological tests and an interview. Part of the reason for the university's success is that its students almost always find jobs. "People trust our recommendation", says the university's rector Guillermo Rodriguez-Izquierdo. Many applicants are the children of graduates; it is apparently a painful process to turn away those of them that are not up to the mark academically.

The university, now in Madrid, began as a seminary set-up at the end of the last century and its degrees are recognized by the state following an agreement between the Holy See and the Spanish government. Business administration and economics are now the most sought-after courses for the university's 6,000 students, but there is a popular course in engineering and a unique system by which industry supports doctoral students.

The university is aiming to achieve a different style from the others. "We try to combine science with radical concern for human problems", says the rector. And perhaps just as important, "students come to the classes on time!" □

Getting basic research on the rails

The Autonomous University of Barcelona must be the only university in Spain to have its own purpose-built railway terminus. That is because the university was built, in 1968, 20 kilometres outside Barcelona with nowhere nearby for its 28,000 students to live. The university's newly elected rector, Professor Ramón Pasqual, readily admits that this has put the university at a disadvantage and that good students may choose to go elsewhere. But he is one of the optimists about the university system's future, and of the ability of his own university to offer something special. "Under the new law," he says, "the most important thing is that you can be different. In a few years there will be good and bad universities and the Ministry of Education will play differently with different universities. Some will go well, others will have problems".

New joint CSIC university institutes, including those for microelectronics and for materials are being set up on the campus and a science park is appearing across the road (Catalonia's 'Silicon Valley'). Links with industry are growing.

Pasqual is also optimistic about Spain's basic research effort. "Now every journal has a paper from a Spanish researcher", he says. And as a theoretical physicist he applauds the decision to join CERN and the European Synchrotron Radiation Facility which will provide completely new opportunities for experimentalists. The big problems that remain? "Universities are still very poor. We lack technicians and we need administrative support — departments here still have no secretaries". □

A 'campus university' in the true sense.

lum vitae, and the second on the field of research. The experience can still be harrowing, as much for the tribunal as for the candidate. When there are many applicants each has to pass through the same lengthy procedure and a tribunal can be busy for a month.

Where the university has gained control is in the selection of the tribunal. Two of the five members are provided by the university that has the vacancy; the remainder are chosen at random from among professors in the same field. At the same time the university may provide a clear 'profile' of the person they want to fill the job; the combined result is that it has become much easier for the universities to choose who they really want. And what it seems they have all too often wanted is simply to promote someone in the same department. Greater autonomy has, if anything, increased inbreeding rather than fluidity among researchers.

There are even stories that universities have connived to avoid a regulation that says no one should be appointed who has not spent at least some time at another university by making linked appointments in which professors apparently move but in fact stay where they are. And these problems come at a time when there has been a boom in new posts.

Just how bad an effect this has had is very much a matter of opinion; some go as far as to say that the net result of having to give many untenured teachers tenure, alongside misuse of the selection system, has filled the universities with mediocre young professors who will now dominate university life for thirty years. Others say these are just teething problems. And some politicians blame the rectors for the universities' problems. Rectors are elected under the new law and this makes them anxious to please their constituents rather than make strong decisions. Certainly, many in the political world now regret that rectors are not appointed.

Reform could have been carried much further by doing away with the automatic appointment of staff as civil servants with jobs for life. There were many, including very senior staff, who fought to replace lifetime tenure with long-term contracts to enable selection to be repeated at intervals. Curiously, the socialist government was of the same mind, before it faced the challenge of putting its ideas into practice.

One way of quickly raising standards of research is to send people off to the world's very best institutes for several years of doctoral or postdoctoral training. Spain has certainly not ignored this option and several exchange agreements and fellowship schemes exist. But those who go abroad say their problems begin when they try to come back. Foreign degrees are not automatically recognized, nor can a returning scientist expect an automatic right to the same amount of laboratory space and access to equipment as those who have built their territories at home. The administration is aware of the problem — and some who have returned successfully say that those who have not do protest too much. All want to work in the very top laboratories, ignoring the importance of establishing groups in the smaller universities.

One part of the university reform that seems to have had little impact is the decision to transfer responsibility for the universities to the autonomous regions. In practice this has not meant universities acquiring a strong regional flavour. All that has happened is that administration has been made somewhat easier, for not all requests have to go as far as Madrid. But Madrid still holds the budget strings and transfer has not been total. Half of the universities (including, naturally, those based in Madrid) have simply chosen to leave things as they are. And the grass always seeming greener on the other side of the fence, those universities that have been transferred protest that Madrid universities are able to collect more money, while the Madrid universities claim the others collect funds both from the central and the regional government. □

Complutense tackles the problems of scale

The Complutense in Madrid, with 118,000 students and 5,000 professors in 18 faculties, is one of the biggest universities in the world and by far the largest in Spain. One in five of all students are educated here. Managing a university on this scale is "often terrible; each small problem is multiplied by hundreds", says the vice-rector, Professor Angel Martin Municio.

In research, new measures are being taken to break down the barriers between disciplines and between the many small empires which have traditionally formed in the universities. The carrot being offered to persuade groups to get together is expensive technology: a world class nuclear magnetic resonance imaging centre is being set up to serve all researchers in the university, for example. Another success has been in bringing together all the relevant groups in the six hospitals attached to the medical school by providing funds for animals for use as disease models. This way the university also gains facilities good enough to allow participation in international programmes.

Headway also seems to be being made with the problem of student wastage; some departments in some universities lose half their students after one year. This year, within Madrid's three universities, students applied for a subject rather than a university. The result is that 80–90 per cent are studying what they want and motivation has been improved.

As elsewhere, the Complutense is actively pursuing contacts with industry. In five or six years, Professor Martin says, "Universities will be different according to their courage and effort". □

Professor Martin needs a helping hand.

Autonoma tops for molecular biology

The campus of the Autonoma in Madrid is instantly recognized as 1960s; bits of decaying abstract sculpture dot a park surrounding concrete buildings connected with tunnels, perforated by underpasses and decorated with murals symbolizing something that has long passed out of common knowledge. Just as at an airport you know what kind of place you are in — even if you are not sure of the continent (except here, perhaps, for the rare fragrance from the surrounding olive groves). And like an airport, the biggest facility is the car park; the campus is a half-hour ride from central Madrid and there seems to be an endless line of students trying to hitchhike a ride back there.

But being close to Madrid has helped the university attract some of the country's best researchers. The Centre for Molecular Biology is far and away the top institute in its field and there are strong groups in chemistry and in physics. The new Institute for Biotechnology is to find its home here. □

Molecular biology and sculpture predominate.

Science policy

The man in the hot seat

Professor Juan Rojo, a physicist, is Secretary of State for Universities and Research, which gives him overall responsibility for both the university system and CSIC. It is a job which he describes as "bad in the sense that I have to deal with personnel problems but good in that I can contribute to making stronger links between the universities and the research system". Professor Rojo's horizons will soon widen more than a little: once the new Interministerial Commission is running he will lead its advisory committee and that will give him a chance to look at the government's total 100 thousand million pesetas spent on science.

Professor Rojo seems optimistic about the universities' future. To those who believe that giving increased autonomy to the universities has actually increased their "inbred nature" he says. "Some, it is true, have used their autonomy to promote their own people but if you give autonomy you cannot control the universities at the same time. I believe autonomy will open the door for excellence." He is proud of another aspect of the law of university reform that is not widely commented on: the creation of the "Social Council", which contains 12 people from outside the university (including representatives of industry and the trade unions) and eight from inside. This "provides a counterbalance to autonomy", and he says "we have good evidence that it is fighting inbreeding". The council has powers "to increase the salaries of professors of special excellence, and to decide whether vacant chairs should be transferred to new areas . . . or, say into two lectureships".

Professor Juan Rojo want stronger links between universities and the research system.

Professor Rojo is also tackling another source of complaint: that Spanish researchers who have worked successfully abroad find bureaucratic obstacles prevent them returning easily. First task is to make a standard list of centres from which degrees will be recognized, "so that people don't have to waste time translating their theses" (for doctoral degrees and so on to be locally validated). And "second, we are trying to favour the kinetics of return. We are encouraging people to take their sabbatical leave here, as well as giving 2-year fellowships".

On a wider issue, work for the new Interministerial Commission has already begun. Themes under discussion for national programmes are information technology, biotechnology, new materials, engineering sciences and food technology.

Although many feel that Spain's total research expenditure is shockingly low at 0.6–0.7 per cent of gross national product. Professor Rojo points out that the rate of growth has been high, coming up from 0.4 per cent in the past five years. The top priority now is "investing in the training of people for the future. We now have 4,500 people at the postgraduate level which is reasonable". But there is still a serious gap to be filled in the training of technicians. "For people of 18 there is very little alternative to going to university, there are practically no technical colleges at all and we need to develop the level of technical training." ☐

Agricultural research

Molecular biology in the pig-pen

Agriculture is the only sector in which most research centres have been transferred to the autonomous communities. A precedent for a fuller devolution of research was not set, it seems, because agriculture is recognizably different. Each area has its own agricultural problems and needs its own research institutes to tackle them. Their activities are, however, closely coordinated from the centre by the National Institute for Agricultural Research (INIA).

Under the new Law of Science programmes for agriculture remain the responsibility of the Minister of Agriculture, but they are complemented by more wide-ranging interdisciplinary programmes that include other ministries and are parts of the national plan. Programmes are monitored by a commission from INIA containing referees from independent organizations.

One research institute, in Madrid, is directly attached to INIA (and takes its name from it) and is the home of most of agriculture's high-level basic research, including work on one of Spain's biggest agricultural problems, African swine fever. Spain and Portugal are the only countries in Europe where the disease is widespread. That means that although pigs are Spain's biggest agricultural earner (twelve million head a year are consumed), exports are almost entirely prohibited for the disease spreads easily, particularly in contaminated pork, and is usually fatal.

It was the rise of air travel that brought the disease to Iberia. Pigs kept near Lisbon airport, fed on swill from Angola, were the first to be infected. From there the disease spread into Spain in the early 1960s, before much was known about it. Mass slaughter of infected animals has proved the only method of control. When the disease reached the Dominican Republic in the 1970s the drastic decision was taken to slaughter all the pigs in the country. Small outbreaks in North Europe have been contained by the same means.

In Spain slaughter of infected animals and strict control of movement of stock mean that eradication may be possible in a few years. But now the infection has spread into the wild population, periodic re-infection is probable. The only answer, it seems, is an effective vaccine. But the search for such a vaccine has often seemed a hopeless task for the virus does not stimulate production of neutralizing antibody, a property shared by one rare mammalian virus; that causing Aleutian disease in mink.

Work at the institute now concentrates on understanding the basic molecular biology of the virus, immunological reactions to it, and its infectivity in pork products. Study of the virus genome does not encourage hopes that a vaccine can be produced easily. A variable region containing several gene families has been identified which suggests that the virus escapes the immune system by constantly changing. Now it is important to find out exactly what the genes code for.

The immunologists are a little more hopeful. Some pigs do recover from the disease and overall mortality has decreased over the years, suggesting that the immune system can do something. Some experiments suggest that the virus escapes from the host's immune system not because it is changing but because viral proteins are masked by host proteins. There are now hopes that there are some small virus-specific proteins that are not masked and against which antibodies can be produced. Serum from pigs that recovered from infection has already been found to inhibit infection by the virus *in vitro* tests. Can this encouraging result be built on in the future?

What the researchers now need ("worth their weight in gold", according to the institute's director Dr J. Sanchez-Vizcaino) is pigs that are serologically positive but healthy. That and another couple of years work will show if there is any hope of a vaccine. Research will soon be intensified with a move, 40km from Madrid, to a new Centre for Animal Infection, one of the largest in Europe. It will be perhaps the only one to have a large part of its floor space dedicated to pig-pens along with P3 and P4 laboratories. ☐

Industrial research

Companies need more science

SPAIN's entry into the EEC, on 1 January 1986, was the ultimate proof that the introspective Spain of the Franco era was dead. But enthusiasm for the wider horizons of Europe has to be balanced with the economic realities — Spain's industry now faces its biggest challenge for decades.

The key problem is that industry has not invested in research and development and that has left Spain with a pitifully small total research expenditure — just 0.6 per cent of gross national product, against the 2.4 per cent of Britain and the 2.7 per cent of West Germany — and largely low-tech industries. Boosting the research figures is now one of the government's top priorities.

Every research body is busy seeking out links with industry. The research council (CSIC) can boast that it is signing three contracts a week with industry on behalf of its institutes: and the polytechnic universities are doing particularly well with income from industry rising exponentially in some. Researchers are clearly under pressure to push industry, but is industry really prepared to pull? Dr Joan Majó, until a few months ago Minister of Industry and Energy and an electrical engineer, gives his views.

Former industry minister Joan Majó sees Spain as a major food-producer in years to come.

"There is not enough research in industry, that is clear. People simply blame the industrialists for this but it is more the fault of the circumstances. For years we have been living in a closed market, without external competition and there has been no need for R&D to make money. Some companies with external trade recognize the need and have reached good technological levels. But we do not have any very big multinationals that can support huge research efforts. Instead we have many medium-sized companies."

Can industry survive EEC entry and reach European levels? "We are joining at the best moment in the last ten years. Why? Because the opportunities are now greater than the dangers. Five years ago it was different. Industry had still not reacted to the industrial crisis of the 1970s and there was overproduction in Europe for which Spain could have provided a new outlet. Change began in the early 1980s and now we are able to compete. Productivity and investment have risen although some sectors, like iron and steel, have special problems."

Dr Majó believes that in any case Spain does not need to do all its own research. "The problems of the use and generation and technology are not the same. We have to accept that part of the technology we need is not generated here, or is developed by external firms. External firms should be encouraged where Spanish ones have no chance of success in the short term. The key is to be selective."

A range of familiar incentives — tax breaks, import restrictions and direct grants for research — are being used to stimulate industrial research. Some 35,000 million pesetas went in direct grants to electronics companies during Dr Majó's own period in office from 1982 to 1986. But there is still a lack of research infrastructure and trained personnel. One danger is "a possible collapse of the supply of technicians caused by the small scale of the technical universities. If major industries did all set up research laboratories they would exhaust the supply of trained personnel."

Top priorities are the same as elsewhere: electronics and biotechnology. "But Spain should become one of Europe's biggest food producers in the next few years and the biotechnology to be sought is to improve processes in food treatment rather than new pharmaceuticals".

Attempts are being made to build bridges between the universities, research institutes and industry, but how successful are they?" Efforts beyond the new Law of Science will be required. I have supported giving preference in grants to industry if they are collaborating with the universities, and to those who have joined multinational projects. And the technical universities need more resources". □

Industrial research

Looking for high-tech winners

THE basic research of yesterday is the applied research of today and the product of tomorrow. Most governments already realize that special mechanisms are needed to help speed the transformation of ideas into realities if they are not to be left behind in the international high-technology race. In Spain the need is perhaps more acute than elsewhere, for the banking and industrial communities are conservative and show little taste for risky ventures. So the government has provided the Centre for the Development of Industrial Technology (CDTI).

CDTI was set up back in 1977 but it seems to have only really got cracking after it was set free in 1982. It now has the status of a private company, although its budget and its board of directors are still provided by the government. Its director, Dr Jaime Sodupe, sees it as an "interface between industry and science" but talking more to the industry side as "there are already plenty of institutions to worry about science". Its activities carry on where CAICYT leaves off; support to help develop a small (or sometimes not so small) company's prototype so that it can enter the marketplace comes a stage after the applied research backed by CAICYT.

Some 600,000 million pesetas are now pumped by CDTI's 50 staff into its 100–200 projects each year. A part of the money is given out in venture capital repayable after two to six years. But the important point is that repayment is linked to commercial success; if the product fails CDTI can say goodbye to its money. Products already close to the market are often financed with an unsecured loan — without a need for guarantees the company's ability to borrow further from the banks is not affected. So far CDTI has had more than 60 per cent of its money returned safely which makes the director wonder if they are being sufficiently daring; similar organizations elsewhere in Europe often obtain only 30 per cent return.

Somewhat unusual is CDTI's role in international affairs. It is responsible for managing Spain's annual contribution to CERN (2,000 million pesetas), the European Space Agency (5,000 million pesetas) and soon the Airbus. And it also tries to find ways to get companies into European programmes. There have been successes. At the Eureka meeting in London in June, 67 projects were involved; 14 of them involving Spain, six of these with Spain as chief partner. CDTI's staff is optimistic, "each month is easier than the last, we don't have to convince managers anymore", said one of them. One remaining problem is that a big part of CDTI's job is also to collect and distribute information, and make industry aware of the opportunities and the latest world-wide trends (as well as organizing promotion of Spanish industry at fairs and the like). But Spain's embassies abroad are still living in the past — they have no science attachés. □

Industry: biotechnology

A sunny spot for entrepreneurs

SPAIN has not been immune from the world-wide rush towards the commercial exploitation of the advances of molecular biology. As elsewhere, the United States has provided the inspiration for scientists to turn entrepreneur — often directly, for the staff of the new biotechnology companies mostly have excellent American accents acquired at top US universities. The risk capital behind them, though, is Spanish: often it is CDTI (opposite) that is playing fairy godmother.

Five small companies are in the market for diagnostic kits using monoclonal antibodies. Among them are the well-established Biokit, now participating in a Eureka project to develop a gonorrhoea diagnosis kit, and the newer Invesgen which among other things is looking for a test for heroin consumption (proving between them that there is money for molecular biology in moral decay).

Biokit, described by a competitor as "a very pushy lot", can boast that the average age of their staff is just 30 years. They were the first to manufacture diagnostic kits in Spain, with a test they produced for rheumatoid factor back in 1976, just two years after setting up their company with ten people in a "120 square metre space". World-wide marketing agreements with foreign companies followed for this and for their next product, a syphillis diagnostic. With financial help from CDTI, chlamydia, rubella and hepatitis diagnostics came next. The philosophy of Biokit when aiming at a new product is "we must have contact with everyone in the world with knowledge in that field". What this means in practice is that despite being based in Barcelona, Biokit scientists go out to the United States knocking on people's doors until they are known and trusted and it is understood that the little company from Spain should be taken seriously.

The future now looks bright. Many of the products under research will be launched in the next year or two and there is hope that sales will reach the 1,000 million peseta mark and Biokit be a world leader in sexual disease diagnostic kits. But still the major input of expertise is likely to be US not Spanish universities. For the distant future (which is more than three years ahead in this business) there is hope from the Eureka project. But the race to develop a quick test for gonorrhea is not going to be an easy one to win.

Invesgen has not had to work so hard in building links to the United States as its key personnel came from Massachusetts Institute of Technology (MIT). Indeed, Invesgen probably only exists because the government decided back in 1974 to send thirty graduates to MIT to study for their doctorates. On their return some were involved in a project to set up Spain's own miniature MIT — an idea that eventually proved to be ahead of its time. Two years ago, four of the original MIT students got together with a fifth researcher to found Invesgen, at first within a division of a huge company of the El Corte Inglés group and soon after as an independent company in the suburbs of Madrid.

A start in setting up a sales network came through an agreement to market the Pasteur Institute's products; and a push for new products came with finance from CDTI. The company has grown to employ ten postdoctoral researchers plus technicians and sales staff. Closest to the market is a kit to quantify simply factors related to rheumatic disease (C-reactive protein, streptolysin, and rheumatoid factor). Selling Spanish products to hospitals in Spain is not going to be easy for there is still a feeling that foreign products are better. But the company's research director, Dr Julio Coll Morales, quotes the adage "no-one profits in his own land" and says that progress will come through selling in the United States. Distance from the world's scientific giants does make progress harder; at the most direct level there can be very long waits for reagents, sometimes so long that "people forget why they ordered them by the time they arrive".

And Dr Coll Morales admits that they are "a little lonely" working in a small group far from the universities. There is still some predjudice against the "fellow from industry". Hopes are that the new Centre for Biotechnology will make a difference. □

Ports safe in a storm

PROFESSOR Felipe Martínez and Dr Manuel Pastor of the Research Centre for Public Works (CEDEX) stand in front of Bilbao harbour. Not the real thing, but a massive model set up in a gigantic building complete with wave-making machines. Under the same roof are the harbours of Valencia, Las Palmas, and part of Barcelona beach needing restoring before the Olympics. The Centre for the Study of Ports and Coasts, where Professor Martinez is director, looks at all kinds of problems in coastal defence and harbour construction: particularly important as Spain has one of the world's largest fishing fleets, much of it operating from small ports. At Bilbao the problems are for big ships: a peculiar resonance in the harbour at times amplifies long-period waves (of four minute period and unknown origin) and makes unloading of ships at one quay difficult. Dr Pastor's finite element model and the physical model itself both produce the same effect and suggest a cure — opening an extra narrow channel between two basins. □

Patent success for pharmaceutical group

FERRER International is an exception to the rule that Spain's companies do not invest in research and technology. The company is not among Spain's 200 biggest enterprises — but when it comes to total research and development expenditure it ranks twelfth. And its researchers boast more patents than anyone else in the private sector. Its business is pharmaceuticals.

Change in the company's thinking — a determination to make new rather than derivative products — came in the 1970s alongside the nation's political liberalization. An effort was made to bring research up to best European levels and now over 10 per cent of Ferrer's 1,000 employees work in its Barcelona research centre.

For the centre's director, there is no choice for Spain but to try to increase its technological level, "it's either technology or colonization", he says. But the path ahead is by no means easy; there are plenty of giants in the pharmaceutical business and Ferrer International is just medium-sized, with annual sales worth some 15,000 million pesetas. To succeed, the company will have to rely on "agility" and sticking to fields where they have good ideas, mainly analgesics, antidepressants, Ca^{2+} antagonists, H_2 histamine receptor blockers and antifungal drugs.

Their approach is conventional: studying physiology and the structure of chemicals known to have physiological effects modifying and testing them and improving routes of chemical synthesis. Collaborations with universities are common: "universities are changing", says the director, "but we must be realistic. It is difficult for them. They often do not have the best apparatus and they must think of how many publications they can produce. Industrial interest is not yet sufficient to resolve their problems." □

The Basque Country

A mountain of problems to tackle

THE Basque Country suffered from cruel neglect under the Franco regime. Its heartland, the provinces of Guipuzcoa and Biscay (which contains the town of Guernica), had fought on the side of the Republic during the civil war and been granted autonomy by it. With Franco's victory autonomy ended; the region was 'punished' and use of the Basque language was banned. Despite the region's enormous industrial importance the central government refused to establish a university or research institute there — just a school of engineering. Now the technological backup to help replace the region's declining heavy industry is just being developed. And out of hardship there has grown a unique Basque response in indigenous cooperatives that link industries, research institutes and a bank.

Parts of Bilbao, where heavy industry was most concentrated, are palpably dying. The town grew rich in the First World War when Spain was neutral and both sides were desperate to buy its iron and steel. Several of its biggest works are now bankrupt but the city, trapped in a narrow valley, still spends half its time blanketed in smog. Signs of decay are everywhere; the unemployed crowd street corners and the walls are covered with slogans, both political (in Basque) and the more desperate "*Heroina Assassasina*". The worst blows, occasioned by entry into the EEC following on a world recession, are thought to be over. The contraction in the steel- and ship-yards is coming to a halt but a large number of small and medium-sized manufacturing businesses remain that have never had the money to invest in research and whose equipment is out of date. And in a story familiar from Sunderland to Pittsburgh, the race is on to add value: control and automation, computer-assisted design and manufacturing, robotics and flexible manufacturing are the key words.

There is only one area that is taboo: nuclear power. Construction of a nuclear power plant was begun but abandoned after the project manager, and then his successor, were assassinated by Basque Nationalists. Although nationalist sentiments have lessened with regional autonomy, terrorism has still to be taken very seriously.

The regional government is doing what it can for science and technology within its limited means. It has taken over responsibility for several research centres intended to raise industry's capabilities. Typical of them is Labeine in Bilbao. Set up in 1955, when research was more a "desire than a reality", it has expanded at a cracking pace (40 per cent a year) since the local government gained responsibility in 1980. Its budget is now 600 million pesetas (£3 million), still peanuts by international standards; and its staff 130, half of them scientists. The intention is not to do basic research but help industry; both at the level of testing and pollution control and the introduction of high technology. Among their projects are those for developing an expert system to diagnose faults in electric power stations and to establish a unit for the supply of customized integrated circuits.

A new university has been established, scattered over the region but with most of its departments in Bilbao and San Sebastian. It began life in 1968 as the University of Bilbao; addition of other centres turned it into the University of the Basque Country, now with a little over 40,000 students. The quality of the university remains very uneven and it proves hard to recruit good people in those areas, like computing and engineering, where they are most needed, for industry can always offer better pay. A massive shortfall of qualified people in these areas is forecast for the end of the century, not so much through lack of students but through lack of competent teachers.

Basic science is being provided for in scholarship schemes that are unique to the Basque region, but which the central government could do well to emulate. One hundred and fifty predoctoral and twenty postdoctoral grants are being given (held for two years in Spain, or three years in a foreign country) to help raise young researchers' standards. About half the grant holders stay in the country; for the rest France, the United Kingdom and then the United States are favourite destinations (and cost the government only a little over a million pesetas a year). Attempts are also being made to bring the university up to international level by providing money for re-equipping laboratories. Four hundred million pesetas were spent in this way last year, but applications were for four times that amount and the search is on for new sources of funds. Industry is more directly supported through spending 1,000 million pesetas a year on projects in the regions' five industrial research centres (including Labein and Ikerlan described here) to develop 'generic technologies' to the level where industry can come in for specific applications.

All this support comes from local taxes, quite separately from payments made to the central government for 'national' services — which still includes science and technology. Some of the money comes back in grants from CAICYT but 70 per cent of the nation's research institutes are found in Madrid. Not surprisingly there are local politicians who strongly feel that the contribution for the science budget should be handed back to the Basque government to spend as it wishes in its own area.

The difference of opinion stems from the failure of the constitution to be crystal clear on the dividing line between the competence of the autonomous regions and the central government. Does the power of the government to coordinate research mean that it also says how the money is to be spent? The new law of science, which increases central control, raises hackles in the Basque Country and many declare it unconstitutional. More rumblings of discontent from them (and from Catalan politicians) are bound to follow but it would take a narrowly won election, with nationalist parties holding the balance, to persuade the central government, whatever the constitution may say. □

Mondragon, amid mountains in the heart of the Basque Country, is packed with industrial cooperatives.

The Basque Country

Cooperatives provide a solution

ANYONE who thinks that cooperatives, in which workers own their workplaces, could never be more than an idealist's dream should visit Mondragon in the Basque Country. Britain's Minister of Employment, Kenneth Clark, made the effort last month and apparently came away impressed. Mondragon's industrial cooperatives now have 19,000 employees (or employers, depending on which way you look at it) and their export sales are booming. Alongside them are agricultural, education, consumer, housing and services cooperatives which can provide everything from technical education to part-time jobs for women with children. And the industrial cooperatives *en masse* have felt the need to raise their technological standards sufficient to establish Ikerlan — a unique cooperative research institute.

The cooperative movement grew in the special conditions of the Basque Country from the vision of one extraordinary man, Father Don José María Arizmendiarrieta. During the civil war he worked as a Basque Army journalist and at its end he narrowly escaped execution. He came to Mondragon, a small town in the mountains south of Bilbao, and in 1943 set up a small technical training school with the aim of aiding the reconstruction of his country. Those enrolled not only studied but raised money from the community to keep the school going. As it turned out, the graduates of the school were later to become the managers and technicians of the cooperatives. The first was established in 1956, after a vain attempt to persuade local industry to allow worker participation in ownership. It consisted of just five men making paraffin heaters. Within a year there were five more cooperatives. They were a success; perhaps partly because the Basque Country has a long history of communal labour on its farms. Then the problem became how to raise capital for further expansion. The answer: set up a cooperative bank. More than twenty years later the Caja Laboral Popular (the working people's savings bank) has over 120,000 million pesetas (£600 million) on deposit and provides financial management, export advice and banking services to the region's 160 plus cooperatives. Its funds have come from the local community, who knew their money would be invested in cooperatives, and from the profits of the cooperatives themselves.

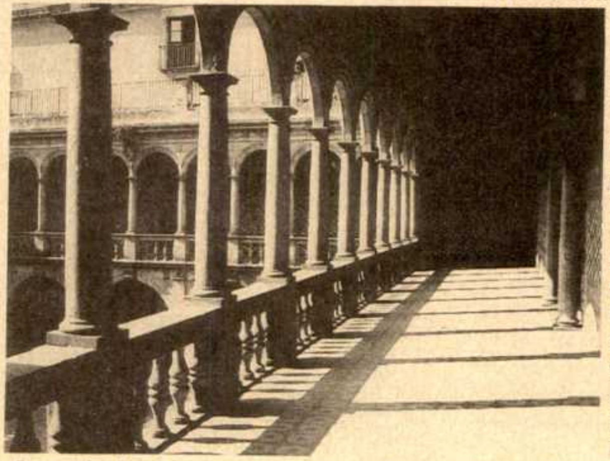
Each 'primary' cooperative is based on the simple principle that all who work there must be shareholders, and no one can be a shareholder who does not work there: the "indissoluble combination of worker and employer". The board of directors is elected and the highest-paid can earn no more than three times the salary of the lowest paid. The bank, is a 'secondary' cooperative, it provides services to all cooperatives, and has its management elected both by its own 1,000-plus workers and by the other cooperatives. The research institute, Ikerlan, set up in 1977, is another secondary cooperative.

The word 'cooperative' might conjure up an image of low-tech — of bearded idealists making handicrafts in pastoral surroundings — but that is not what Ikerlan is about (although the pastoral surroundings are there). Its aim is to develop the technology to make the cooperatives internationally competitive. Its laboratories are packed with computers, robots, experimental flexible manufacturing systems, and even a miniature 'robotized transportation vehicle'. It differs little from any small advanced technology institute from Tokyo to San Francisco.

Technological support is given to every cooperative (and other business) that solicits its services. Well over a hundred projects aimed at improving someone's product have been completed in its 12-year history. The research always involves members of the organization that requested it in order that training and technology transfer can be combined with product development — a philosophy that "was at first hard to get over to the government" which now provides for part of the running costs of Ikerlan. It is recognized that specific product development alone will not suffice to keep local industry competitive; half of Ikerlan's 70 scientists' time is now spent on generic research — basic work likely to later find specific application. In the computer sciences, for example, there are research programmes on geometric modelling, automatic programming of numerically-controlled machines and interactive computer-aided drawing. Just as elsewhere the aim is to provide a computer environment which helps an engineer to go from drawings for a specific product generated with the help of a computer to instructions for its computer-controlled creation. It is to the implementation of such research that small industries, producing say complex gears, look for their long-term health. ☐

Can there be a real 'Catalan science'

THE seventeenth century cloister shown here provides the entrance way to the Institute of Catalan Studies, maintained in rooms originally built as the house of convalescence to the fourteenth century hospital alongside. The institute is not as old as that, having been set up in 1907 on the crest of a revival in Catalan culture to aid "high scientific research" in the region.



Within a few years the institute had a structure rather like that of the old academies, with four sections: philology (mainly the study of the Catalan language), history and archaeology, science, and philosophy and social science. But its fortunes were thereafter to change with the political seasons, for any organization that might foster regional autonomy was suspect. Under the military dictatorship of Primo de Rivera (1923–30) it was suppressed, with the arrival of the Second Republic (1931–39) it flourished, and then when Franco came to power it had to continue its work of publishing scientific books in Catalan underground. Since 1976 things have returned to normality and the institute has returned to its original headquarters.

A large computer now hums away under the gothic arches in the basement helping to prepare a new dictionary of contemporary Catalan. For scientists, its principal importance is that all the local scientific societies are affiliated to it and rely upon it to help organize conferences and prepare publications. It has set up a Centre for Mathematical Research in the Autonomous University of Barcelona and is running joint projects; with the University of St Louis on the microseismicity of the Pyrenees, and with a Europe-wide group on the mapping of bryophytes.

The institute's president, Professor Enric Casassas i Simó, would like to see the institute expand further into a true interdisciplinary research centre. But there are others who see the institute's involvement in science as an anachronism. they argue that there is no place for "Catalan science" in the international age and particularly deride attempts to find Catalan equivalents for new scientific terms. ☐

Catalonia

Plenty of energy in Barcelona

THE really big news in Barcelona of course is not science but the Olympics. The choice of Barcelona as the site for the Olympic Games in 1992 sent Catalonia wild and will do much to heighten regional pride. It will also do something for science: a new biomedical institute is certain to be created for toxicological tests on the athletes and will live on after the games. And an Olympic village is going to be necessary and might afterwards provide much needed halls of residence for the universities (pessimists say the village will simply swallow up funds previously earmarked for the universities).

Like the Basque Country, Catalonia has a long history of independence and its own language and culture. But emotional appeals for independence are rarely heard, perhaps because Catalonia is recognizably prosperous and contains many of Spain's high-tech industries (as well as the Costa Brava). And it now has three excellent universities. In the Franco era the region was neglected. Despite the intellectual eminence of Barcelona, Spain's most cosmopolitan city with a population second only to Madrid, just four of CSIC's 78 institutes were located here: those for fisheries, humanities, geology and the Centre for Research and Development. New institutes are now springing up for microelectronics, materials science and economic analysis.

The region has its own commission for science and technology (CIRIT) and more than a few academics who would like to see Catalonia fully responsible for disbursing its own contribution to the central science budget. But until the unlikely day when Madrid relinquishes this power, CIRIT will have to make do with funds the Catalan government can raise to supplement central government allocations. All agree it cannot raise enough. Around 100 million pesetas goes each year in sending people abroad for training, and a further 200 million in research grants. Other funds are available for research in specific sectors, such as agriculture, but overall there is insufficient money for any large, specific project.

Of the CSIC institutes only the Centre for Research and Development is of any real size. As elsewhere, the institute has been through a painful process of reorganization. Just last year the five-storied building contained five institutes, with five directors, five libraries, and five administrators, all run separately. Now one institute, it brings together all the research groups in Barcelona working on pharmacology, organic chemistry and molecular biology. Changing the structure was clearly not easy: a bitter dispute over the election of laboratory heads has left one floor of the building with a crowd of researchers at one of its ends and two empty laboratories stripped of equipment, with one professor, formerly an institute chief, at the other. It is now up to the courts to decide whether the elections were held properly, and what belongs to who.

Sir Alexander Fleming is much fêted in Spain with streets or squares named after him in several cities. Above is a famous statue situated in a small square at the edge of the Barcelona red-light district. It is said that its inhabitants often leave flowers here in gratitude for his discovery of penicillin.

Overall director of the institute is Professor Joan Albaigés Riera. He sees the key advantage of the reorganization as creating groups of above critical size (at least 3 or 4 people in each, plus research students and technicians) and bringing related groups together to promote interaction. His speciality is environmental chemistry and entry into the EEC has greatly helped extend international connections and thus raise the level of research. The institute will be taking part in both the EUROTRAC and EUROMAR programmes to monitor air and sea pollution. □

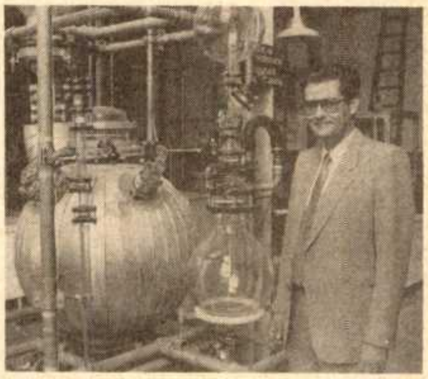
An education that pays for itself

IN an era of rapid change it is perhaps no surprise to find the occasional survivor from another age. Such is the Instituto Quimico de Sarria, set up in 1916, which can be summed as a "private Jesuit university with only one faculty — that for chemical engineering". State schools of engineering turned into polytechnics in the 1970s, and are now, if anything, more prestigious than the universities. Sarria continues as a single-subject university — but that does not mean it has lost prestige.

The institute, in an old suburb at the edge of Barcelona, shows its origins. At its centre are high-ceilinged laboratories, elegantly tiled in the fashion of the 1920s; across the corridor is a dimly-lit chapel entered by carved wooden doors.

But the institute is no fossil — courses are now well tailored to the needs of industry. A survey of its graduates finds 31 per cent of them working as directors in industry and another 42 per cent as technical executives. The institute's director, Dr Miguel Gassiot Matas, reckons there are two to three jobs available in industry for each graduate. The ability to guarantee their students a job seems a hallmark of all the Jesuit universities.

Part of the reason for the institute's success is its belief that it is not possible to teach well without doing research; a view that has only recently become fashionable in the state universities. Indeed the institute has to do research in order to survive; its costs are not met by the state and even with the high fees (around 300,000 pesetas, £1,500 a year) paid by its 600 students, it cannot make ends meet.



The director of the Institute Quimico de Sarria, Dr Miguel Gassiot Matas, in his teaching laboratory. The apparatus is not all just for demonstrating industrial processes; the students also help manufacture pharamaceutical caffeine which adds to the institute's income.

Almost a third of the institute's income stems from contract work, performed for industry and government. Much of the work is analysis of food, chemicals and pharmaceuticals but forensic science is also important. It was to the institute that the government turned during the outbreak of toxic oil syndrome, although it was a laboratory in London that discovered anilides in the oil a few days before them.

What of the future? The institute's director is well aware that each branch of science grows ever-more dependent on its neighbours; he looks to construct curricula connected with different fields to create "a small polytechnic school centred around chemical engineering". And with a look back to the political past he says, "an option to the state system is necessary; it is the most important guarantee of liberty". □

Portugal: political change

Dictatorship out with a whimper

JUST twelve years ago Portugal lacked a democratic government and was fighting wars in its African colonies of Mozambique, Guinea and Angola which had dragged on for a decade. A quarter of its male population of military age was in the armed forces. Now democracy is firmly established and of the colonies only Macao remains (until China takes it back).

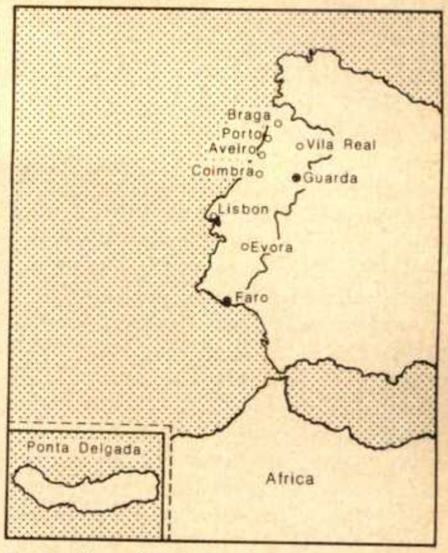
Although change has been rapid the recent relationship with the colonies still colours life more than in any other European nation. Almost a twelfth of the population has lived in Africa for when the military struggle was finally abandoned some 750,000 settlers came home. But as the Empire that stretched all the way east to Timor is becoming a memory, Portugal is turning to enthusiastically embrace Europe.

The series of political changes that led to the restoration of democracy, beginning with the 'revolution' in 1974, were triggered by weariness with the colonial wars. The dictator Antonio Salazar, who had ruled Portugal for 40 years, was already long out of office, having been paralysed by a stroke in 1968. But his successor, Marcelo Caetano, proved unable to modernize the country. Elections were held in 1969 but barely 20 per cent of the population were permitted to vote and opposition parties strictly supervised. The unsurprising result was a landslide victory for the ruling party.

Just how fragile the real power of the government had become was demonstrated on 25 April 1974. A group of army officers led a coup in which, with only a few shots and no casualties, over 40 years of dictatorial rule was brought to an end. Under the new rulers of the Armed Forces Movement power was placed in the hands of the Junta of National Salvation. At first, it took a moderate line but within a few months it lurched leftwards.

A Supreme Revolutionary Council was formed and began to implement radical policies whose effects are still apparent in Portuguese economic life. Large parts of the economy were nationalized, including banking, insurance, shipbuilding and transportation. In the south of the country, in the Alentejo, large private farms were seized by their workers and divided up. And the colonies were granted independence. But a massive turnout for the election of 1975 (to choose an Assembly to draw up a new constitution) gave support to the socialists, not the communists.

An unstable period followed, with attacks by communist sympathizers on the parliament, culminating in an attempt at a coup by left-wing military officers in 1975. Its failure proved the beginning of true democracy in Portugal. In the elections that followed the approval of the new constitution in 1976, the socialists formed the first freely-elected government. Since then the constitution has been revised giving Portugal an elected President, who appoints a Prime Minister, and an elected unicameral legislature, the Assembly of the Republic.



Portugal's twelve state universities: Azores (at Ponta Delgada), Algarve (at Faro), Aveiro, Coimbra, Évora, Lisboa (Lisbon), Nova de Lisboa, Técnica de Lisboa, Minho (at Braga), Porto, Beira Interior (at Guarda) and Trás-os-Montes e Alto Douro (at Vila Real). There are also a number of small private universities and a large Catholic University in Lisbon. The universities at Vila Real, Evora, and Faro are very new and are intended to act as poles of development in the inner regions of the country. Here conditions are backward and there is enormous scope for improvement in agriculture. Portugal has an illiteracy rate of 19 per cent and is still in desperate need of training schemes in basic technology. 90,000 students are now in higher education. A network of polytechnics is being set up to complement the universities.

To date no party has ever been able to gain an absolute majority and changes of government have been embarrassingly frequent. The Social Democrats have now overtaken the socialists as the largest group, although they are in turn easily outnumbered by the combined opposition (or by just the socialists and communists). There has been a general trend rightwards (the Supreme Revolutionary Council, which persisted as an advisory board was abolished in 1982) but the massive state holdings acquired earlier remain. Their status is highly controversial: they have performed poorly and the banks have proved unable to match the performance of smaller foreign entrants.

The lands seized in the Alentejo are gradually being returned to private hands as mistaken agricultural policies (including the replacement of the traditional cork trees by wheat) have failed. But the strength of the left prevents any rapid reversal of former policies. Key issues now are the need to raise the general educational standards (the illiteracy rate is the highest in Europe) and to improve agricultural practices in the poorer regions as barriers protecting Portugal from full exposure to EEC competition are gradually removed.

Pattern of research planning explained

THE Junta Nacional Investigaçáo Cientifica e Technologia (JNICT) is growing into the major body for the planning, promotion and coordination of Portugal's scientific and technological research. The overall control of JNICT goes to the Secretary of State for Science who operates under the jurisdiction of the Minister of Planning. Much of the research within the universities is carried out in centres that belong to the Instituto Nacional de Investigaçáo Cientifica (INIC), a funding agency operating under the Ministry of Education and Culture. Besides the twelve universities, one remarkable research institute, the Instituto de Investigaçáo Cientifica Tropical (IICT) is controlled by the education ministry. Other ministries control research institutes for agriculture, fisheries, health, meteorology and geophysics, and hydrographics. Best known are the Laborotório Nacional de Engenharia e Tecnologia Industrial (LNETI) and the Laborotório Nacional de Engenharia Civil (LNEC). □

Science policy

A support system in evolution

Portugal is on the verge of taking scientific research seriously. Somewhere in its research organization exist bodies to monitor international trends and identify national priorities, evaluate fairly project proposals, coordinate different sectors, and encourage interaction between industry and academia — all the things a modern nation needs. And it has a supply of well-trained researchers. The problem is that the various parts are not all the right size.

Portuguese scientists are themselves well aware of the problems — even enthusiastic about tackling them. Change has begun. In the scenario now developing two organizations will certainly be important: the National Board for Scientific and Technological Research (JNICT) and the National Institute for Scientific Research (INIC). The former's star is on the rise while the latter, even by the admission of those who run it, could profitably be reformed in a more sophisticated organization.

JNICT

As the Minister of Education, Professor João de Deus Pinheiro, put it, "JNICT was the turning point". When it was set up in 1967 it was the first organization to evaluate projects using independent referees, including foreigners, and to follow up and assess how well projects were running. Now JNICT appears as the one national body planning, coordinating and funding scientific and technological research in all sectors of activity. But it is still not the real scientific power in the land it could be, despite its 20 year history.

Two things have held JNICT back: frequent changes in its position in the administration (it is now in the Ministry of Planning, under a Secretary of State for Scientific Research, but this is its sixth resting place) and, more important, the failure of the government to give it sufficient funds. The total science budget now runs close to 13,000 million escudos (65 per cent of which is government expenditure, most of the remainder coming from industry) but last year JNICT received only 200 million escudos (1.5 per cent of the total).

The future looks brighter. This year the budget rose to 1,000 million escudos and next year it should go 2,500 million escudos (19.2 per cent of the total), for the first time putting it ahead both of INIC and the largest public research institute, the National Laboratory of Engineering and Industrial Technology (LNETI).

JNICT's grant can flow anywhere within the research and development system — to universities and their research centres, to state laboratories, to industry, and to non-profit research organizations. It is thus well placed to ensure that national priorities are met and gaps filled. In the words of the JNICT president, Professor José Mariano Gago, "the strongest indication of a trend to increase overall coordination is the amount of money being put here." A more powerful JNICT with what Professor Pinheiro called a dual policy of backing "both the best researchers and the areas that give an advantage to Portugal" could be just what the country needs. With its bigger budget its plans will grow. Next year the largest slice will go on contract research, concentrated in four priority areas: material science, marine science, biotechnology and electronics. Part of the remainder will go to encouraging industrial applications of research but a sizeable portion will be reserved for "encouraging excellence": ten to fifteen groups of real international standing will be supported whatever their field of study might be.

One problem that JNICT is trying to cure is that of "small-scale groups who can never achieve good results in time". Attempts are being made to create new networks of researchers. Membership of CERN is providing some opportunities for at first the annual contribution will be spent in Portugal building up resources. A Lisbon group specializing in microcomputers and optical communication will link up to a Coinbra group with expertise in nuclear detectors and instrumentation to form a new 'institute'. The share out of funds is entirely decided by an international committee. A similar scheme will create a new institute of biotechnology.

INIC

For the universities the Ministry of Education's own grant body, INIC, is of prime importance in supporting research. That support does not, however, go directly to the universities but mostly to those in INIC's own 126 research centres within the universities. The 3,500 researchers in the centres are almost all university professors so their salaries come from a separate source but they have fewer teaching and administrative duties that staff outside the centres. That leaves both INIC and the universities in a curious position; INIC has a large number of quite small research centres whose staff's promotion is decided by the university, while the universities have no real control over the research activities of their own staff. Worse still is that research centres covering the full range of disciplines have to be maintained and that means INIC is under obligation to continue funding them all by block grants. Projects assessment is included in the complicated formula used to calculate each centre's annual budget but there is no strong sense of competition for research funds and, in any case, INIC's referees are not noted for their critical powers.

Originally, this system made sense in that central distribution helped overcome the universities' own problems in sharing out their budgets. But as the universities have matured and a Law of University Autonomy looms on the horizon there seems little point in the present system. INIC officials are themselves proposing change. Many of the centres, they say, could be handed over to the universities and instead some twenty or so larger interdisciplinary institutes be created. The new organizations springing up to serve high-energy physics and biotechnology could provide a model. The problem is that changes of this kind have been suggested for some years, without much happening. The President of INIC, Alberto José Correia Ralha, a very patient man, says "sometimes even I think I am going to get angry". ☐

Portugal's Minister of Education, Professor João de Deus Pinheiro has been in his job two years "an almost unimaginably long time" given the frequency with which governments change. Total expenditure on research he sees as low although it is probably double the official figure of 0.4 per cent of GNP because "salaries are not included". But change is going to involve more than just increasing budgets. "For the fifty years of authoritarian government a good student was one who could repeat the text book or the teacher's words. Creativity and criticism were words absent from our education system" he says. A massive review of the education system is now under way in which priority will go to improving science teaching in the schools through teacher retraining. To improve the research system help is being sought from the World Bank for institutes in biotechnology and agriculture, water resources, and materials. An institute for marine science is also planned. Improving links with industry is a priority. Interministerial coordination is still poor and relations with the Ministry of Industry have "not always been good".

Young Portuguese, the minister says, might learn something from thinking afresh about history. Rather than viewing the fifteenth century voyages as an outcome of the desire to spread Christianity they can be seen as stemming from wise technological policy. Portugal's breakthroughs in ship design and organization created the equivalent of "today's space rockets" and made exploration possible. ☐

Tropical research

Everything under the Sun

The only way to describe Lisbon's remarkable Instituto de Investigação Científica Tropical is a 'horizontal institute'. Rather than specializing in one field, it covers almost everything provided it can be related to the tropics. Geology, archaeology, zoology, ethnology, geodesy, veterinary medicine, history, ancient maps, soil science and anthropology are studied among other things, and there is a botanical garden.

There is a historical explanation for the institute's structure. It began life just over a hundred years ago as a Commission for Cartography to map the new colonies and, as the colonies grew, so it expanded to offer them a complete range of scientific services. And if it had not been for the British, the colonies would probably have been a lot bigger. Maps produced early this century show everything between Angola and Mozambique painted the 'rose colour' of Portuguese territory. But the British sternly warned that their north-south expansion was not going to be halted by a Portuguese east-west connection. The resulting crisis and threats that gunboats were to be dispatched brought down the government of the day.

After the colonies were given up, twelve years ago, there was a series of upheavals (along with changes of name from 'Junta' to 'Laboratorio' to 'Instituto') leaving the institute in the care of the Ministry of Education with the aim of aiding scientific research in the tropics (in 40 countries, not just the former colonies) and training specialized personnel. The government budget is 800 million escudos a year but further help comes from international organizations; the United Nations, UNESCO and the African Development Bank among them. The different specialities are not housed under one roof but in independent centres and each is connected to relevant university departments: the directors are also university professors.

For the international community perhaps the most important centre is that for the Investigação das Ferrugens do Cafeeiro (CIFC), a world centre for studying coffee rusts — fungal diseases. Coffee may be only a drink but it is of tremendous economic importance: second only to petroleum in the value of its world trade.

Rusts are important because of what they could do to the industry. The major commercial species of coffee is *Coffea arabica*. But *arabica* is highly susceptible to coffee leaf rust, which quickly destroys the plant. In the first major outbreak, towards the end of the nineteenth century, Ceylon's coffee industry was utterly destroyed. Little natural resistance has been found among varieties of *arabica*. And to make matters worse, it appears that all the coffee plantations in Central and South America, where 65 per cent of the world supply is grown, were established from the progeny of a single plant, taken from Java to the botanical garden in Amsterdam in 1706.

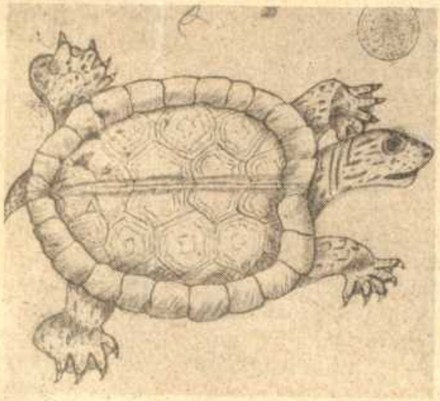
Angola, Portugal's biggest African colony, was the world's third-greatest coffee producer. But the coffee rust research centre in 1955 owes less to this link than to US worries about what an outbreak of coffee rust could do to the economic stability of Latin American countries dependent on coffee crops. In 1952 two US scientists set out on a world-wide tour to look at the disease and, after encountering a Portuguese researcher, decided Lisbon would be the ideal place for a centre — no coffee was grown in Portugal and rusts from around the world could be studied safely there.

Coffee is big business and a fungus, coffee rust, a big threat to it. Here just a few of the tens of thousands of coffee plants that pass before the Centro de Investigação das Ferrugens do Cafeeiro director C.J. Rodrigues Jr for testing each year.

In those days, the fungus had not reached the Americas. But in 1970 the first outbreak occurred in Brazil, and within a few years the rust had spread all over the country. Spores are probably carried by the wind for they have been found 2,000 metres up in the air. By 1983 rust had crossed the Andes into Columbia and also appeared in Central America.

In the intervening years the centre had accumulated some 33 different races of the fungus and a vast collection of coffee varieties that had enabled them to classify plants according to their resistance spectrum. With this standardization done they could begin work on the genetics of resistance. And they had discovered in another of their colonies, Portuguese Timor, a hybrid between *C. arabica* and *C. canephora* that seemed totally resistant to almost all fungal races. Furthermore, like *arabica* it was tetraploid and self-fertile. Luckily the resistance genes were dominant. A programme of crossing and backcrossing and resistance testing then began to introduce them into an *arabica* background.

Altogether nine genes for rust resistance have now been identified. The centre is cooperating with researchers all around the world to help develop resistant strains, with the 'Timor hybrid' still at the centre. Breeders send tens of thousands of coffee plants by air every year for resistance testing in the centre's greenhouses — for many growing regions the choice may soon become resistant strains or crippling bills for fungicides. Plans are now afoot to use cryogenic techniques to preserve spores and to develop tissue culture methods so that known lines of coffee plants can be propagated quickly. □



Given its long history and colonial links it is not surprising that the Institute for Tropical Science has amassed some treasures. Above is an illustration showing a turtle from one of the earliest works on the natural history of Brazil, the *História dos Animals e Arvores do Maranhão*, by Father Cristóvão de Lisboa who was resident in Maranhão in 1627. The monograph is on display at the Archives of Overseas History which now houses the records of the old Overseas Territories Office as well as other collections.

Another treasure house, too little known outside Portugal, is in the Centre for Ethnology. For years it has put its collections on public view only rarely but now it is rigorously pursuing an open policy. An astonishing collection of African sculpture is now on view (all, alas, the product of cultures already destroyed) and in the basement store-room glass fronts are being added to crowded storage shelves so that the public will be able to see everything the museum has. □

Portugal's university research

Adding a little more flexibility

Research funds from both INIC and JNICT are available to university researchers. But according to a group of scientists drawn from the New University of Lisbon's Faculty of Science and Engineering, the total does not necessarily add up to much: "Just a little from each, only occasionally a jackpot". In fact, in a good year there are around 120 million escudos (£600,000) to support the research of the 70 staff, including money from industrial sources.

This university is now trying, with a lead provided by Professor Leopoldo Guimarães, to create an alternative in UNINOVA, an institute bringing together the universities and industry. Industry has not been totally neglected in the past. The faculty's Department of Environmental Sciences real research is paid for by contracts — a bimass-from-wine production effluents project paid for by a German company, and environmental assessements projects from the Ministry of Industry and the local municipality. UNINOVA — the Institute for the Development of New Technology — is intended to be on a different scale. Some 16 companies, including ICI, Sperry and Digital, are taking shares in the institute. The idea is that the involvement of Portugal's biggest (and often foreign) companies in electronics, computers and biotechnology will power research in those areas as well as providing funds. The institute is not intended to perform research directly for the companies involved.

A simialar organization has already proved a success at the Technical University of Lisbon, and the vice-rector there, Professor Anotónio Simões Lopes, is particularly proud of it. It also has the Institute for Systems and Computer Engineering set up jointly by the university, the University of Porto and the three telecommunication operators. Just six years old it already provides for 300 researchers.

Such institutes will add new flexibility to the university system. It has not proved easy in the past to add numbers where they are most needed, partly because PhD students are virtually guaranteed jobs in the same university so there are limits on how many of them can be taken in.

Despite these difficulties it would be wholly wrong to think of university staff as demoralized. Up to the late 1970s many people were sent abroad for doctoral training, particularly to Britain, and have provided Portugal with a distinctive core of enthusiastic young (under 40) researchers. Every well-established university has a group of international standing. Recent successes (in international collaborations) include the isolation of LAV II virus (with Luc Montagnier of the Institute Pasteur) and the controversial proof of Poincare's conjecture (with Colin Rourke of the University of Warwick). And Coinbra's nuclear detector group has even attracted a doctoral student from Japan. ☐

Industry

No shift from ivory towers

Professor Clemente Pedro Nunes, Director General of Higher Education, is new to his job and bursting with energy. He is a chemical engineer, with a doctorate from the University of Birmingham, and plenty of experience of working in industry. The great problem he wants to tackle is the failure of the universities and industry to interact. One statistic sums it up: there are now over 2,000 holders of doctoral degrees in Portugal but less than 10 are working in industry. And there are no signs of a trend to move into the industrial sectors, except in computer software.

Much of the blame must lie with industry for failing to invest in research and development. "Most of all what is needed", says Professor Nunes, "is managers in industry who can discuss science and technology; even in big companies there are very very few." But the universities are also at fault as the progression from a masters degree through a doctoral degree to lifetime tenure is almost assured. There is no pressure to leave and "naturally every professor wants new blood in the department and knows every trick in the book to force extra vacancies. The bill, of course, comes to us (the Ministry of Education). And university salaries are not much different from those in industry."

Professor Nunes wants more scientists in industry.

Fierce words, perhaps, but how can industry be persuaded that research and development is in its best interests? Tax incentives and perhaps "a sabbatical year in industry paid by the state" suggests Professor Nunes. Part of the problem is that "industry is undercapitalized. Nationalization in the mid 1970s broke the back of many structures and they have not yet recovered". Encouraging signs are coming from the joint university–industry research institutes set up within universities. Polytechnic universities also hold out promise for raising industry and agriculture's level of sophistication. There are now 16 in existence, but not all are complete and last year they could take in only 1,000 students. But this year is to be the "big year for their launch". ☐

Oiling the wheels

"It's difficult to imagine what Portuguese intellectual life would be without the Gulbenkian Foundation" said Ernesto Veiga de Oliveira, ex-director of Lisbon's Museum of Ethnology; a comment that well summed up what many other researchers had said about the foundation.

The foundation gives away more than seven thousand million escudos each year and even though science is the least of its benificiaries (receiving 12.6 per cent of the total; after education, arts and social welfare) its impact is clearly felt in the research community. But just why is the Gulbenkian Foundation based in Portugal?

It is a complicated tale. Calouste Gulbenkian was born in Istanbul but took British nationality and was a graduate of Imperial College, London. There he gained a knowledge of mining engineering that helped him realize the potential importance of Middle East oil. By the time he died in 1955 he owned 5 per cent of Iraq's oil reserves. In between he made his home in Paris but, in 1942, after the German invasion, he moved to Portugal, which remained neutral (although favouring the Allies) during the Second World War. He hired a hotel (now the Sheraton), brought in a couple of Rolls-Royces and, finding Portugal to his taste, continued to live there after the war. Along the way he collected the paintings, furniture, ceramics and silver that now form the collections of Lisbon's biggest museums.

The foundation played a key role in Portugal's scientific development. Starting in the mid-1960s, when the universities were at a low ebb, hundreds of scientists were given grants to study abroad. Many now occupy important positions in the universities and government. An institute of science was also established but as the universities developed, the need for it has lessened and it is gradually being closed down. Fields of strategic importance (informatics is now the centre of attention), are helped with special equipment grants. Translations of technical works are made so that inexpensive editions can be published alongside books from Portuguese authors. And links with other Portuguese-speaking countries are kept up through special cooperation agreements. ☐

Superfluid ^{3}He in rotation

V. P. Mineev*, M. M. Salomaa† & O. V. Lounasmaa†

* L. D. Landau Institute for Theoretical Physics, USSR Academy of Sciences, 117334, Moscow, USSR
† Low Temperature Laboratory, Helsinki University of Technology, SF-02150 Espoo, Finland

Experiments on vortices in rotating superfluid ^{3}He have revealed phenomena which have not been observed in any other quantum liquid and have implications in fields beyond low-temperature physics. In ^{3}He-A, vorticity may be supported by a continuous winding of the order parameter which gives rise to the observed continuous coreless vortices with two flow quanta. Exotic vortices with half-integer circulation quanta may also exist in this phase. In ^{3}He-B, an abrupt change in the vortex-core structure has been explained theoretically as a topological phase transition involving half-quantum vortices. NMR experiments on rotating ^{3}He-B have revealed that the cores of vortices observed possess spontaneously broken parity, manifested by their ferromagnetic superfluid cores.

QUANTIZED vortices in rotating superfluid ^{3}He display novel structures that make them interesting objects in condensed-matter physics. This can be attributed to their anisotropic nature and rich internal structure of ordering: unlike superfluid ^{4}He (He II), the superfluid phases of liquid ^{3}He are not only superfluids but also liquid crystals, magnets, and spin liquid crystals; a few, or all of these different aspects of ordering may contribute to the properties of inhomogeneous states, such as quantized vortices.

Superfluidity and superconductivity are observed in liquids whose macroscopic behaviour is governed by quantum statistics; the latter becomes important at low temperatures when the thermal de Broglie wavelength of the particles in the medium exceeds the interatomic spacing. Superfluids can flow without friction through narrow gaps and tubes. Only two liquids, ^{4}He and ^{3}He, are known to exhibit this property. Superconductivity, the loss of electrical resistance, is observed in many metals below a critical temperature T_c that varies from one substance to another. In superconductors, superfluidity is manifested by the conduction electrons.

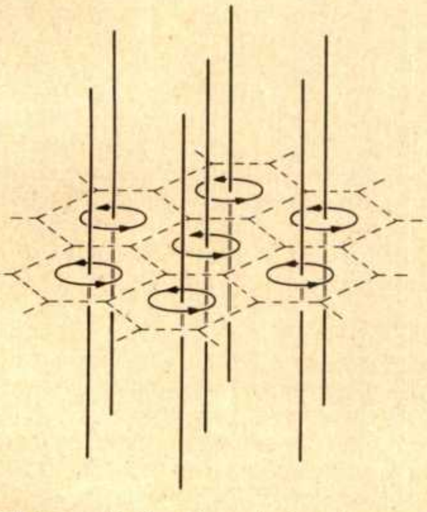


Fig. 1 The hexagonal lattice of quantized vortices, as seen by an observer co-rotating with the superfluid. The rotation axis is parallel to the array of vertical lines depicting vortex cores at the centre of each primitive lattice cell; lines with arrows illustrate streamlines of superflow. Dashed lines indicate the hexagonal vortex-lattice cell boundaries, along which the superfluid is at rest in relation to the rotating container. On average, the lattice of quantized vortices mimics solid-body rotation with a parabolic meniscus. Rotating superfluid ^{4}He has been studied since the 1940s[1], first by Andronikashvili[2] extensive measurements have been conducted recently by Glaberson, by Packard, by Reppy, by Rudnick, and by Tsakadze and their co-workers.

Phenomenologically, a superfluid can be considered a liquid with two components: the normal fraction has density ρ_n and the superfluid fraction has density ρ_s. The superfluid behaves like a single macroscopic particle with a quantum-mechanical wavefunction $\Psi(\mathbf{r})$, usually called the order parameter. Physical properties of particular interest in superfluids are those in which the quantum character of the liquid manifests itself on a macroscopic scale. The most interesting of these are phenomena that appear in superfluid ^{4}He and ^{3}He under rotation. Due to their quantum nature, unlike classical liquids, superfluids cannot rotate as a whole. Instead, circulation perforates them in quanta of individual vortex lines[1,2] (Fig. 1).

In 1972, Osheroff, Richardson, and Lee found the superfluid A and B phases of ^{3}He below 3 mK; the P/T (pressure/temperature) diagram is illustrated in Fig. 2. This discovery opened a new and exciting era in ultralow-temperature physics. In 1981, vortices in rotating superfluid ^{3}He were first investigated experimentally at the Helsinki University of Technology[3].

During the past five years, intensive studies with the nuclear magnetic resonance (NMR) technique, persistent-current measurements, ion-mobility investigations, and hydrodynamic experiments have all revealed several new, unprecedented and often unexpected phenomena associated with vorticity in anisotropic superfluids. Space permits only a brief discussion of persistent-current experiments and a more detailed description of the pioneering NMR results; the latter have provided most of the fundamental information on vortices in superfluid ^{3}He. For example, in ^{3}He-A, continuous distribution of vorticity has been observed, as in a classical liquid—accompanied, however, by a liquid-crystal-like texture. In ^{3}He-B, new superfluid phases nucleate inside the cores of the quantized vortex lines—as revealed by the spontaneous vortex-core magnetization and the first-order vortex-core phase transition[3] (see Fig. 2).

Vortices in classical superfluids

In ^{4}He, which has a nuclear spin $S=0$ and which obeys Bose–Einstein statistics, superfluidity is understood as the Bose condensation of individual atoms into the zero-momentum state[4,5]. The Bose condensate may be described by a macroscopic wavefunction $\Psi(\mathbf{r})=C(\mathbf{r})e^{i\Phi(\mathbf{r})}$, whose amplitude squared, $C^2(\mathbf{r})$, is the density, $\rho_s(\mathbf{r})$, of the superfluid component. The

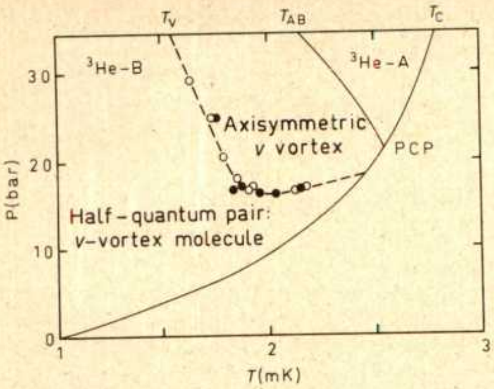

Fig. 2 Phase diagram of liquid ^{3}He. On rotating ^{3}He-B in an open-volume NMR cell, a transition is observed[3] on crossing the dashed line T_v in the P,T-plane[15]. The intersection of the T_{AB} and T_c curves is the polycritical point, PCP. ○, NMR experiments at $H = 284$ G; ●, $H = 568$ G. This vortex-core transition is a topological change between two inequivalent ways to accommodate vorticity[48,49]; see Fig. 8.

gradient of the phase, $\nabla\Phi(\mathbf{r})$, gives the superflow velocity:

$$\mathbf{v}_s = \frac{\hbar}{m_4}\nabla\Phi(\mathbf{r}) \tag{1}$$

Being the gradient of a scalar, superflow is potential, curl-free: $\nabla \times \mathbf{v}_s = 0$. Experiments show that this is true everywhere, except along special vortex lines at which $\nabla\Phi$ is singular; the flow velocity diverges as $v_s \propto 1/r$ where r is the distance from the vortex core. The integral $\oint \mathbf{v}_s\, d\mathbf{r}$ along any closed path around a vortex is proportional to the change in phase $\Delta\Phi$, which—to keep the wavefunction single-valued—must equal an integral multiple of 2π. Hence the circulation of superflow is quantized in He II:

$$\oint \mathbf{v}_s\, d\mathbf{r} = m\frac{h}{m_4} \tag{2}$$

in quanta of $h/m_4 = 0.997 \times 10^{-3}$ cm^2 s^{-1}; m_4 is the mass of a ^{4}He atom and m is an integer. Equation (2) resembles the Bohr–Sommerfeld quantization condition: the angular momentum per particle is quantized in units of $\hbar$.

Viscous fluids in a container rotating at the angular velocity $\boldsymbol{\Omega}$ behave like a solid body, that is $\mathbf{v} = \boldsymbol{\Omega} \times \mathbf{r}$ and $\nabla \times \mathbf{v} = 2\boldsymbol{\Omega}$. This is not possible for a superfluid, but because rotational motion is energetically more favourable than the stationary nonrotating situation, a vortex lattice (Fig. 1), is created.

Each vortex normally carries only one quantum of circulation, because the energy of two vortex lines is smaller than the energy of a single one with two circulation quanta. Repelling each other, vortices form a hexagonal two-dimensional lattice. On average, such an arrangement imitates solid-body rotation. Consequently, the total number of singly quantized vortex lines in a vessel of cross-sectional area A is

$$N = \frac{2\Omega A m_4}{h} \tag{3}$$

and this corresponds to $N/A \simeq 2{,}000$ vortices cm^{-2} at $\Omega = 1$ rad s^{-1}.

Vortex lines in superfluid ^{4}He have no particular internal structure: the superfluid density tends to zero on the vortex axis, where the fluid is normal. Hence the kinetic-energy density of the rotating superfluid component, $\frac{1}{2}\rho_s v_s^2$, remains finite everywhere, in spite of the $1/r$-singularity of $\mathbf{v}_s$ on the vortex axis. The characteristic scale for spatial changes in the order parameter, determining the radius of the vortex core, is the so-called coherence length, $\xi = 0.1$–0.2 nm in ^{4}He; this is of the same order as the interatomic distance.

Superfluid phases of ^{3}He

Like electrons, ^{3}He atoms having a half-integer (nuclear) spin $S = \frac{1}{2}$ are governed by Fermi-Dirac statistics. Strong mutual interactions renormalize the ^{3}He atoms into quasiparticles but do not change the nature of the quantum statistics. According to the BCS theory of Bardeen, Cooper and Schrieffer, Fermi systems undergo a transition into a macroscopically coherent new superfluid ground state in the presence of an arbitrarily weak attraction between the quasiparticles. The long-range order may be viewed as being due to the formation of mutually overlapping giant molecules, called Cooper pairs.

In superconductors[6], as a consequence of the isotropy of interactions between the conduction electrons, these pairs have angular momentum $L = 0$ (s-wave pairing) and total spin $S = 0$ (singlet). In superfluid ^{3}He, the Cooper-pair states[7] have $L = 1$ (p-wave pairing) and $S = 1$ (triplet). The order parameter $\Psi(\mathbf{r})$ for a p-wave paired superfluid can be written as a linear combination of spherical harmonics χ_{S_μ} and $Y_{L\nu}$, respectively, for the states with different projections $S_\zeta = \pm 1, 0$ ($\chi_{1\mu}$ with $\mu = \pm 1, 0$) and $L_z = \pm 1, 0$ ($Y_{1\nu}$ with $\nu = \pm 1, 0$) on directions of the quantization axes, $\hat{\zeta}$ and $\hat{z}$:

$$\Psi(\mathbf{r}) = \sum_{\mu\nu} a_{\mu\nu}\chi_{1\mu}Y_{1\nu} \tag{4}$$

In ^{3}He-A, all pairs are in the state with $L_z = 1$ and $S_\zeta = 0$, that is, there is only one component, $a_{0+} \neq 0$. In ^{3}He-B, with $L + S = J = 0$, states with $L_z = \pm 1, 0$ and $S_\zeta = \pm 1, 0$ are equally populated, and there are three equal components of the order parameter: $a_{+-} = a_{00} = a_{-+}$.

In both the A and B phases[8,9], the average value of the spin, namely the spontaneous Cooper-pair magnetization, is zero. In ^{3}He-B, the average of the angular momentum is also zero; hence this liquid is completely isotropic in the absence of inhomogeneities. In contrast, all Cooper pairs in ^{3}He-A share the same direction of $\mathbf{L}$, which determines the orbital anisotropy axis $\mathbf{l}(\|\hat{\mathbf{z}})$. Therefore, many properties of ^{3}He-A, for example viscosity, are different in directions parallel or perpendicular to $\mathbf{l}$. Hence ^{3}He-A is an anisotropic superfluid liquid crystal. In addition to the orbital anisotropy, there is a magnetic anisotropy in the A phase, described by the vector $\mathbf{d}$ which defines the spin quantization axis $\hat{\zeta}$; the Cooper-pair spin $\mathbf{S}$ is perpendicular to $\mathbf{d}$. Because of this anisotropy, the paramagnetic susceptibility of the A phase is a uniaxial tensor.

Superfluidity in ^{3}He-A is not necessarily associated with curl-free flow because $\nabla \times \mathbf{v}_s$ may be different from zero. In fact, the A phase can support nonsingular vorticity in the presence of an inhomogeneous distribution of the anisotropy axis $\mathbf{l}$. Previously, curl-free flow was considered an essential property inherent to every superfluid. Thus it has become necessary to revise many theoretical concepts of quantum liquids, especially their behaviour under rotation.

Rotating cryostat

All NMR measurements—and most of the other types of experiments—on superfluid ^{3}He in the rotating equilibrium state have been made in the ROTA cryostat at Helsinki[10,11]. This apparatus incorporates a copper nuclear stage, a dilution refrigerator, an activated charcoal cryoadsorption pump, radial and axial air bearings, and computerized measurement electronics. The apparatus can be rotated at angular velocities Ω up to 3.0 rad s^{-1}. The copper nuclear stage, weighing 4.0 kg, is first precooled to 20 mK, with the 8-T magnet on, by means of a dilution refrigerator. The nuclear stage is then thermally isolated by operating a superconducting heat switch and demagnetized in 10 h to 150 mT, whereby it cools to 0.4 mK. Next, the charcoal adsorption pump is switched on and the external pumping lines are disconnected, allowing the cryostat to be rotated.

The ^{3}He sample cell is on top of the nuclear stage and thermally connected to it. For NMR measurements the cell was a cylinder, 5 mm in diameter and 30 mm long. Its geometry is thus clearly defined, and the NMR response of stationary ^{3}He in this configuration is well known. The measurements were made at three fixed frequencies; 1,845, 920 and 460 kHz. The magnetic field was usually oriented along the rotation axis but could be tilted sideways when required. The field was swept linearly in 2–3 min over the resonance at 56.9, 28.4 or 14.2 mT. For persistent-flow measurements, the experimental cell was a 50-mm-diameter torus, 6-mm thick; the flow path was filled with 20-μm plastic powder to enhance v_c, the critical velocity for superflow.

Persistent currents in ^{3}He

One of the characteristic properties of superfluids is their persistent-flow capability: in He II the flow of the superfluid component around a closed path persists as long as the liquid is kept under its transition temperature, $T_\lambda = 2.17$ K. Experiments for observing persistent currents in the superfluid phases of ^{3}He have been carried out by groups at Cornell University[12,13] and in Helsinki[14,15]. In both laboratories, an a.c. gyroscopic technique was used. Figure 3 illustrates the gyroscope employed in the Cornell experiments. The principle of the measurement is: when the ring is driven about the y-axis at the resonant frequency of the ω-mode, a sinusoidal response around the x-axis results, provided that there is an angular momentum in the ring which is caused by superfluid flow.

In the gyroscopic experiments, the sample was first cooled well below the superfluid transition temperature at rest. The cryostat was then rotated around the z axis at an angular velocity Ω and stopped, and the vibrational amplitude in the ω-direction was recorded. An angular momentum was detected in the torus only if the speed of rotation had exceeded a critical value Ω_c. In such conditions, an irreversible creation of superflow occurs which persists even after the cryostat has been brought to rest. In ^{3}He-B, no decay of superflow was observed in Helsinki[14] during 48 h, implying an effective viscosity at least 12 orders of magnitude less than that in the normal Fermi liquid at the same temperature: thus ^{3}He-B shares properties with 'classical' superfluids. In the Helsinki experiments no observable current was found to persist in ^{3}He-A. However, the Cornell group[13], exploiting a method with a higher quality factor near T_c, also detected persistent currents in ^{3}He-A. A discontinuous change in the critical flow velocity, attributed to a vortex transition in ^{3}He-B was seen in the Helsinki experiments[15].

Vortices in ^{3}He-A

Before any experiments had been conducted on rotating ^{3}He-A, it had been recognized on theoretical grounds that this phase should possess curious superflow properties[16–18]. In particular, the possible existence of continuous vortices—which were subsequently found in Helsinki—had first been predicted by Chechetkin[19] and also discussed by Anderson and Toulouse[20]. In addition, half-quantum vortices had been suggested by Volovik and Mineev[21] and subsequently by Cross and Brinkman[22] on the basis of the Cooper-pair structure in ^{3}He-A.

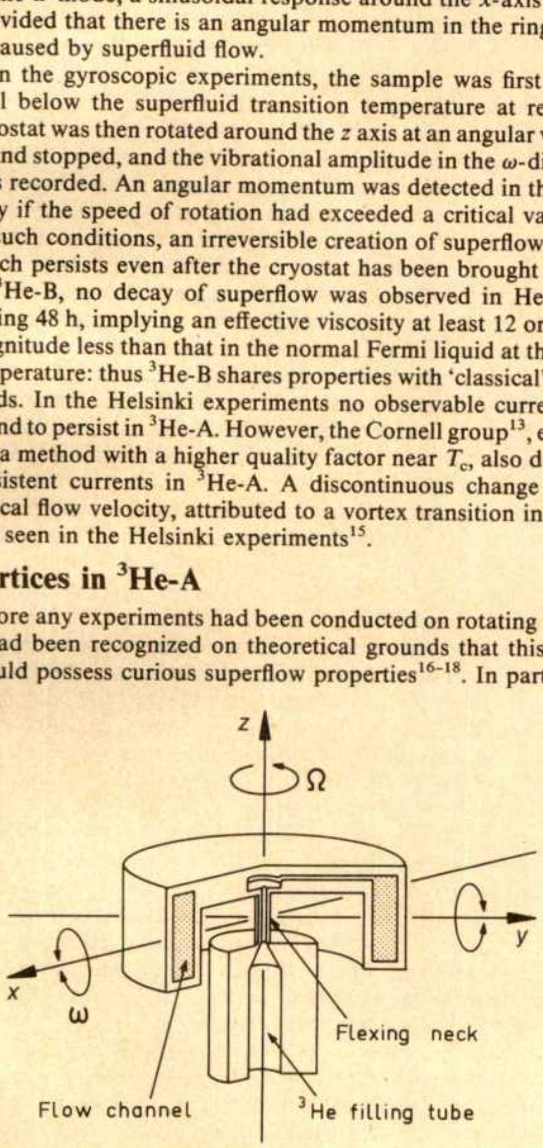

Fig. 3 Schematic diagram of the a.c. gyroscope employed in the Cornell experiments[12]. To immobilize the normal fluid, the toroidal flow channel is filled with fibrous material; the resulting average open volumes have linear dimensions of the order of 0.1 mm. For operating details, see text.

Superfluidity of ^{3}He-A

The p-wave pairing state of ^{3}He-A was discussed above: each Cooper pair in this liquid is under rotational motion with the projection $L_z = 1$ of the angular momentum on the direction of the quantization axis $\mathbf{l}$. This internal motion is mixed with the macroscopic Cooper-pair centre-of-mass motion. Because of this, the nature of superflow in ^{3}He-A is very peculiar: rotational motion can follow from the presence of spatially inhomogeneous distributions of the $\mathbf{l}$ vector[17]. These textures unbalance the internal Cooper-pair motion, producing a nonpotential net superflow without the formation of singularities.

The spatial structure of the order parameter is determined by competition among several forces. The elastic stiffness of the $\mathbf{l}$ and $\mathbf{d}$ fields tends to make them uniform; this gives ^{3}He its liquid-crystal-like behaviour. The dipolar interaction tries to lock $\mathbf{l}$ and $\mathbf{d}$ parallel or antiparallel to each other. At cell boundaries, $\mathbf{l}$ is perpendicular to the walls[16]. In the presence of superfluid flow, $\mathbf{l}$ tends to orient parallel to $\mathbf{v}_s$. An external magnetic field tries to lock $\mathbf{d}$ into the plane perpendicular to $\mathbf{H}$ ($\mathbf{d} \perp \mathbf{S} \parallel \mathbf{H}$).

The actual texture of the liquid depends on the interplay between these effects, with the configuration of lowest free energy prevailing. As the textures of $\mathbf{l}$ can create rotational superflow in ^{3}He-A, the circulation of superflow velocity in the A phase need not be quantized. At first sight, the possibility of nonpotential superflow seems to admit purely solid-body rotational motion. However, the energetics of the $\mathbf{l}$ texture require that even in ^{3}He-A under rotation, a periodicity in the order-parameter texture appears.

Vortex structures

Every elementary vortex-lattice cell contains a vortex line with m quanta of circulation. The value of the circulation quantum in superfluid ^{3}He, $h/2m_3 = 0.662 \times 10^{-3}$ cm^2 s^{-1}, differs from that in superfluid ^{4}He [see equation (2)] not only due to the different isotopic mass, but also owing to the factor 2, caused by Cooper pairing.

The possibility of rotational superflow means that a singular vortex line can be transformed into another one with continuous coreless distribution of vorticity. However, due to topological constraints[23], the elimination of the singularity in $\mathbf{v}_s$ on vortex lines with odd number of circulation quanta is accompanied by the appearance of a singularity in the $\mathbf{l}$ texture ($\nabla \mathbf{l} \to \infty$ on the axis). However, vortices with an even m can be transformed into vortices with a continuous distribution of vorticity, while maintaining a nonsingular distribution of the $\mathbf{l}$ texture. Hence, vortices with odd m are always singular, but the singularity in vortices with even m can be continuously dissolved.

The singular singly quantized vortex has two different cores, the hard core with radius of the order of the coherence length, $\xi \simeq 10$ nm, inside which the order parameter deviates from its bulk ^{3}He-A value, and the soft core, with a radius of the order of $\xi_D \simeq 6$ μm, the dipolar healing length outside which the dipolar force is greater than the elastic forces. Beyond the soft core, $\mathbf{l}$ is practically uniform; all vorticity in the liquid is thus localized inside the soft core. The continuous vortices have no singular core; however, depending on the external conditions, they may acquire a soft core with localized vorticity. The coherence length in ^{3}He is about two orders of magnitude longer than that in ^{4}He.

A very different type of singular vortex is possible if one takes into account that the total wavefunction for Cooper pairs in

^{3}He-A is the pure product of the orbital and spin parts: $\Psi(\mathbf{r}) = a_{0+}\chi_{10}Y_{1+}$ [see equation (4)], where the dependence on the coordinate **r** of the centre of Cooper-pair mass arises from the **r**-dependencies of the quantization axes: $\mathbf{l}(\mathbf{r})$ and $\mathbf{d}(\mathbf{r})$. The quantization of circulation in 'classical' superfluids is simply a reflection of the fact that the phase of the order parameter, upon circling a closed contour in the superfluid, can only change by $\pm 2\pi m$ because the wavefunction must be single-valued, thus $\Psi(\mathbf{r}) \rightarrow \Psi(\mathbf{r})e^{\pm i2\pi m} = \Psi(\mathbf{r})$. But in ^{3}He-A, we may have for the orbital part of $\Psi(\mathbf{r})$: $Y_{1+}(\mathbf{r}) \rightarrow Y_{1+}(\mathbf{r})e^{\pm i\pi}$, while for the spin part: $\chi_{10}(\mathbf{r}) \rightarrow \chi_{10}(\mathbf{r})e^{\pm i\pi}[\mathbf{d}(\mathbf{r}) \rightarrow -\mathbf{d}(\mathbf{r})]$, resulting in: $\Psi(\mathbf{r}) \rightarrow \Psi(\mathbf{r})e^{\pm 2i\pi} = \Psi(\mathbf{r})$. Hence, half-quantum vortices are possible. However, a half-quantum singularity in the orbital part of $\Psi(\mathbf{r})$ is not separable from a simultaneous singularity in the spin part. Thus in ^{3}He-A we may have an example of topological confinement of singularities that is closely related to similar phenomena in Grand Unified Theories.

Therefore, three topologically different types of vortices[23] can exist in superfluid ^{3}He-A: (1) singular vortices with an odd quantum of circulation, and with topological charge 1; (2) continuous coreless vortices with even integer quanta of circulation, and with topological charge 0; and (3) singular vortices with a half-integer quantum of circulation, and topological charges $\frac{1}{2}$ and $-\frac{1}{2}$. The topological summation laws are: $\frac{1}{2}+\frac{1}{2}=1$, $1+1=0$, and $\frac{1}{2}+1=-\frac{1}{2}$. This means, in particular, that two singular singly quantized vortices can combine to produce a doubly quantized continuous vortex—with consequent annihilation of the singularity.

In ^{3}He-A under rotation, a vortex lattice and a corresponding periodic **l**-vector texture[24] is present: there is a great difference in the quantization conditions for ^{3}He-A and for superfluids with traditional properties. In the latter case, circulation along any closed contour around the vortex is an integer in terms of the circulation quantum. For the vorticity in ^{3}He-A, this is valid only along the boundary of a primitive cell. From energy considerations alone, at angular velocities of the order of 1–3 rad s^{-1}, it follows that, in the so far experimentally relevant magnetic fields of 15–60 mT, the most advantageous structure in the rotating bulk ^{3}He-A is a lattice of singular singly quantized vortices.

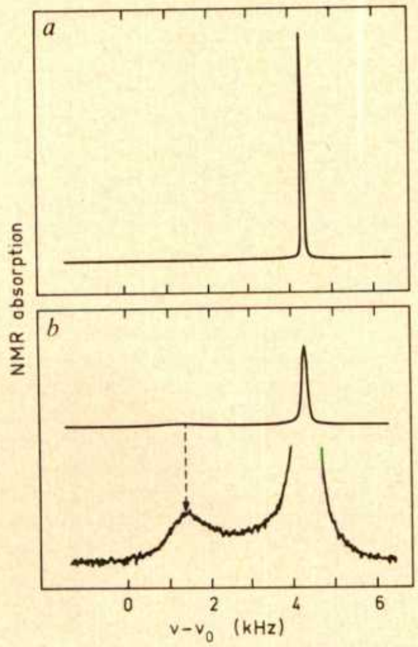

Fig. 4 NMR spectra[11] of stationary and rotating ^{3}He-A. Additional broadening of the main peak, due to rotation, is apparent; the shift of this peak towards higher frequencies by 4.6 kHz from ν_0 is related to the spin-orbit coupling. Arrow points to the satellite absorption peak which appears in the NMR signal during rotation. It is caused by the excitation of spin waves trapped by the continuous vortex texture. Lowest curve is vertically magnified ×50. *a*, $\Omega = 0$; *b*, $\Omega = 1.21$ rad s^{-1}.

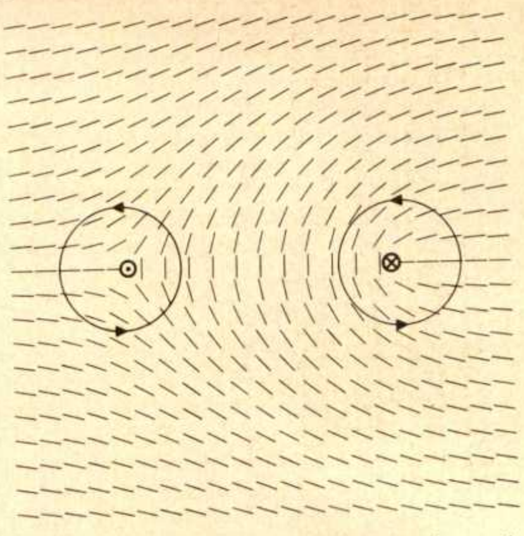

Fig. 5 Texture of the magnetic anisotropy vector **d** around a pair of vortices with half-quantum circulation[28] in ^{3}He-A. Energy of the local disturbance ('soliton') in the uniform **d** texture between the half-quantum pair is proportional to their separation; the pair is thus glued together by the soliton string, as in quark confinement; see Fig. 8*b*. The liquid-crystal-like **d** texture displays defects with opposite Frank indices at the half-quantum vortices: **d** rotates by $+\pi$ and by $-\pi$ on circling the two singular points (⊙ and ⊗).

NMR on vortices

How does one detect and investigate the physical properties of individual vortex lines in ^{3}He? The most versatile tool used so far is the NMR technique, based on the resonance absorption of electromagnetic radiation at the Larmor frequency $\nu_L = \gamma H_0$, corresponding to the precession of nuclear magnetization in the liquid under a constant field H_0; γ is the gyromagnetic ratio of ^{3}He. Note that NMR cannot be used on ^{4}He because the nuclear spin $S = 0$ for this isotope.

Precession of the nuclear spins **S** in an anisotropic superfluid is not free: the directions of the **l** and **d** vectors tend to be locked by the spin-orbit coupling. This produces an additional torque on the spins of the Cooper pairs, and because of this a shift in the NMR absorption line away from γH_0 occurs, see Fig. 4.

In a strong magnetic field, the doubly quantized vortex texture is modified: If **H** is applied parallel to the axis of the rotating vessel, the **d** vector is in the plane perpendicular to $\mathbf{H} \| \mathbf{\Omega}$ because of magnetic anisotropy. Due to the spin-orbit coupling, **l** tends to be parallel to **d**, thus $\mathbf{l} \perp \mathbf{H}$. This results in the broken axisymmetry of the ^{3}He-A vortices in a magnetic field. The distribution of the **l** vector deviates from the homogeneous situation $\mathbf{l} \| \mathbf{d}$ only in the central part of every elementary vortex-lattice cell inside the soft core, where the energy of the inhomogeneity is larger than that due to the spin-orbit coupling. Thus the soft cores, which contain the vorticity, are well separated: at the typical rotational speed of 1 rad s^{-1}, the spacing between the vortices is ~0.3 mm and thus more than an order of magnitude larger than the diameter of the soft core.

The regions of inhomogeneous distribution of **l** act as potential wells for localized standing spin waves. Therefore, a periodic **l**-vector texture leads to the appearance of an additional satellite NMR peak in the absorption spectrum at the frequency of the local vortex mode (Fig. 4). The intensity of this peak is proportional to the number density of vortices, that is to the angular velocity of rotation [see equation (3)]. The calculated intensity of the vortex peak for a lattice of continuous vortices[25–27], each with two circulation quanta, is ~10 times smaller than that for a singular vortex lattice and is in fair agreement with the experi-

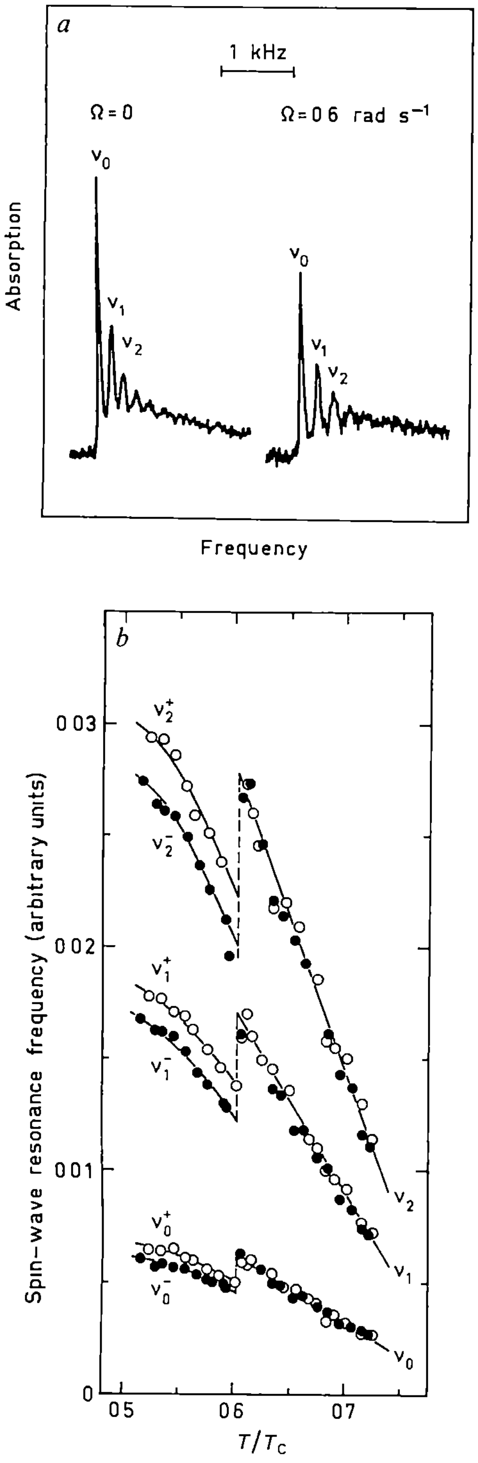

Fig. 6 *a*, Measured NMR absorption spectra[11], at 29.3-bar pressure, for ^{3}He-B as functions of frequency in the stationary case and at $\Omega = 0.6$ rad s^{-1}. The envelope of the observed oscillatory curve corresponds to the 'flare-out' texture[31,32]. The series of almost evenly spaced spin-wave satellites results from the coherent nuclear motion of the Cooper pairs. Separation between the resonant peaks at ν_0, ν_1, ν_2, is larger during rotation than in the stationary liquid. *b*, The spin-wave resonance frequencies ν_0, ν_1, and ν_2, of Fig. 6*a* at $\Omega = 0.6$ rad s^{-1}, as functions of reduced temperature. The data illustrate a gyromagnetic effect[35] due to the magnetic moment of the vortex cores[36,37]: the resonance frequency measured during rotation with **Ω** parallel to the magnetic field **H** (○) differs from that for **Ω** antiparallel to **H** (●). The effect is large at $T < 0.6T_c$ but hardly observed for $T > 0.6T_c$, the vortices below and above this transition temperature at $T_v = 0.6T_c$ have different core structures and, therefore, different intrinsic magnetic moments.

mentally observed NMR satellite intensity[11]. This supports the existence of continuous vortices in ^{3}He-A, instead of the energetically slightly more advantageous singular singly quantized vortices. A possible explanation for this is that in the creation of a singular vortex a high potential barrier has to be overcome. Therefore, we may conjecture that continuous vortices are formed first under rotation and that once they exist in metastable states it becomes difficult to transform one continuous vortex into two singular ones for creating a singular vortex array.

Half-quantum vortices have not been seen experimentally in ^{3}He-A (see, however, below and Figs 2 and 8*b*). These singularities may be observed in the A phase only when the spin and orbital variables can be considered independent. Such a situation exists in narrow gaps between parallel plates, where the energy of the inhomogeneity is larger than the spin-orbit coupling[22,28]. Because of the peculiar topology, the doubly (±) valued **d**-vector field changes sign (∓) on circling a half-quantum vortex line, see Fig. 5. This produces an interesting consequence[29]: the equation for the spin wavefunction bound by the inhomogeneous **d**-vector texture is analogous to the Schrodinger equation for a charged particle in a 'magnetic field', concentrated in the vortex-core tube. This analogue of the Aharonov-Bohm effect also generates spin wave scattering, which should result in significant additional broadening of the main NMR line, possibly providing an experimental signature allowing identification of half-quantum vortices.

Vortices in ^{3}He-B

In 1978, when the decision was made to build a rotating ^{3}He cryostat in Helsinki, it was believed that the vortex lines in superfluid ^{3}He-B would be just like those in superfluid ^{4}He, with no internal structure. In the first NMR experiments[3], however, a spontaneous phase transition in the core was discovered. This immediately implied a complicated vortex core, it is appreciated that vortices in superfluid (^{3}He-A and) ^{3}He-B provide a beautiful application for the concept of broken symmetry[30] in condensed-matter physics. The vortex-core transition has been established to involve a change in the topology of the vortex-core matter between two distinct ways that vorticity can flare out from real to momentum space.

NMR spectroscopy

In ^{3}He-B, the mutual orientation of the quantization axes of L and S is arbitrary in the absence of spin-orbit coupling, the superfluid is thus degenerate with respect to rotations of the spin axis $\hat{\boldsymbol{\zeta}}$ about the orbital axis $\hat{\mathbf{z}}$. Any three-dimensional rotation may be represented by an angle θ around some axis specified by a unit vector $\hat{\mathbf{n}}$. The B-phase states are degenerate with respect to directions of $\hat{\mathbf{n}}$ and, in the absence of spin-orbit coupling, to the value of θ. Moreover, as in superfluid ^{4}He, the ^{3}He-B states are also degenerate with respect to the value of the overall phase Φ of the order parameter. This means that the energy of the homogeneous liquid does not depend on $\hat{\mathbf{n}}$, θ or Φ. In inhomogeneous ^{3}He-B, for example, when vortices are present, the energy depends on the gradients of $\hat{\mathbf{n}}$, θ and Φ.

As in ^{4}He, the superflow velocity in ^{3}He-B is determined by the gradient of the phase $\mathbf{v}_s = (\hbar/2m_3)\nabla\Phi$ and the circulation of superflow is quantized. Therefore, there are no coreless vortices in ^{3}He-B and the superfluidity of this phase is in several respects analogous with the properties of superfluid ^{4}He. In particular, a two-dimensional lattice of singly quantized vortices is formed under rotation.

In ^{3}He-B, the order parameter and the texture are fully determined by the $\hat{\mathbf{n}}$ vector, which is analogous to the directrix vector describing the orientation of molecules in liquid crystals. Because the orientational force exerted by an external magnetic field on the nearly isotropic ^{3}He-B is so small, the magnetic healing length ξ_H is long, effects due to walls are thus very important in ^{3}He-B and they give rise to $\hat{\mathbf{n}}$ textures[31,32]. Inside the vortex cores, however, the magnetic anisotropy energy is of

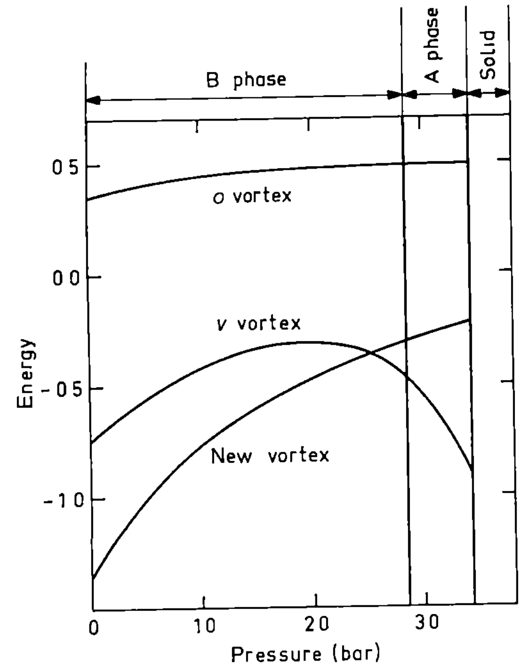

Fig. 7 Energies of the axisymmetric *o* and *v* vortices, and the nonaxisymmetric new vortex, as functions of pressure according to numerical calculations[41]. Pressures are given on a theoretical scale: for example, the tricritical point (see Fig. 2), actually at 21 bar, is at 28.5 bar.

the same order of magnitude as in ^{3}He-A, therefore, vortices have a strong influence on the $\hat{\mathbf{n}}$ texture. The $\mathbf{v}_s$ field around the vortex also has an orientating effect on $\mathbf{n}$ (ref. 33).

The most powerful experimental tool for observing vortices in ^{3}He-B is the NMR technique, as in ^{3}He-A. The precessing motion of the nuclear spins is coupled with the order-parameter distribution, determined by the spatial variations of $\hat{\mathbf{n}}$, θ and Φ. The energy minimum for spin-orbit coupling fixes θ to the 'magic' angle $\theta_0 = 104°$. Another consequence of the coupling is the appearance of a small anisotropy, caused by the magnetic energy term which orients $\hat{\mathbf{n}}$ along $\mathbf{H}$. In the presence of an axial magnetic field, as a result of boundary conditions on $\hat{\mathbf{n}}$ and the magnetic anisotropy, the equilibrium orientation only occurs in the bulk liquid at distances $> \xi_H[\mathrm{cm}] \simeq 4(1 - T/T_c)/H[\mathrm{mT}]$ from the walls.

In a cylindrical container, with an axially oriented $\mathbf{H}$, a spiral-like 'flare-out' texture results[31,32]. As in ^{3}He-A, the $\hat{\mathbf{n}}$-texture gives rise to observable localized standing spin waves. These stationary coherent nuclear spin modes are confined by the flare-out texture (Fig. 6*a*). The frequencies of these modes depend on the spatial variation of $\hat{\mathbf{n}}$. With the use of NMR it is thus possible to register changes in $\hat{\mathbf{n}}$. Consequently, if the texture of the liquid is altered by rotation, this can be observed. The influence of rotation on $\hat{\mathbf{n}}$ is due to those vortex-core regions where the balance between the equal-weight projections of $S_\zeta = \pm 1, 0$ and $L_z = \pm 1, 0$ is broken. Because of this, the cores of vortices in ^{3}He-B possess an anisotropic magnetic susceptibility[33], which depends on the orientation of $\hat{\mathbf{n}}$ and on the direction of $\mathbf{\Omega}$.

The appearance of an additional energy of magnetic anisotropy due to the vortex cores suggests the possibility of studying the vortices by the measurement of the Ω dependence of the frequencies of the spin-wave modes in the flare-out texture, see Fig. 6. The signature of vortices is also in the shift of the NMR signal[34] in a field $\mathbf{H}$ tilted with respect to the direction of the axis of rotation: the shift is zero without the vortices. In addition, a gyromagnetic effect[35] has been observed, which was manifested by the fact that the cores of the ^{3}He-B vortices possess a magnetic moment[36-39], for further discussion, see Fig. 6*b* and below.

Vortex structures

In superfluid ^{3}He, the hard vortex-core size is in the Ginzburg-Landau (GL) regime near T_c of the order of several coherence lengths, $\xi_{GL} \simeq 10\ (1 - T/T_c)^{-1/2}$ nm, which is the temperature-dependent Cooper-pair extent. Because of the large size of vortices and the complicated nature of ordering it is not necessary to have normal liquid inside the vortex cores in ^{3}He-B, instead, other combinations of different p-wave pairing states may nucleate. The structure of the core can be determined by numerical minimization of the vortex energy.

In the cylindrical coordinate frame[36], the order-parameter amplitudes $a_{\mu\nu}(\mathbf{r})$ in equation (4) may be written for a singly quantized vortex as

$$a_{\mu\nu}(\mathbf{r}) = \begin{matrix} C_{++}\,e^{-i\phi} & C_{+0} & C_{+-}\,e^{i\phi} \\ C_{0+} & C_{00}\,e^{i\phi} & C_{0-}\,e^{2i\phi} \\ C_{-+}\,e^{i\phi} & C_{-0}\,e^{2i\phi} & C_{--}\,e^{3i\phi} \end{matrix} \qquad (5)$$

For an axisymmetric vortex, the above amplitudes $C_{\mu\nu}$ are only functions of the radial distance r from the vortex axis and independent of the azimuthal angle ϕ. The core structures have been classified using symmetry arguments[37,38]: it was found that an axisymmetric vortex in ^{3}He-B, with unit quantum of circulation, may be in five different states, distinguished by the internal discrete symmetry of the vortex core. These states are labelled *o*, *u*, *v*, *w* and *uvw*, in all of them the vortex core possesses a magnetic moment. The most symmetric *o* vortex, first discussed by Ohmi *et al.*[36], has a normal core with superfluidity destroyed on the axis, as in ^{4}He. In the *u*, *v* and *w* vortices the internal symmetry is partially destroyed, whereas in the *uvw* vortex it is completely broken.

Energetically the most favourable of the different possible axisymmetric vortices is the *v* vortex with broken parity[37,38], in this case, all the nine functions $C_{\mu\nu}$ in equation (5) are real. Although the B-phase pairing amplitudes C_{+-}, C_{00}, and C_{-+} also in this vortex must tend to zero on the vortex axis, because of broken parity, this vortex, nevertheless, has a superfluid core: the two components without phase factors in equation (5), the *A* phase C_{0+} and a ferromagnetic so-called β phase C_{+0}, are not prohibited by any centrifugal barrier at the vortex axis. This results in the core which practically consists of the A phase, as it is energetically more favourable than the β phase. These results were later independently confirmed by other workers[39-41].

Because of the ferromagnetic superfluid in the core, a large spontaneous vortex magnetization $\mathbf{M}$ results, its direction is determined by the directions of $\mathbf{\Omega}$ and $\hat{\mathbf{n}}$. This vortex magnetization, created by rotation, gives rise to a new free-energy term, $-\mathbf{H}\cdot\mathbf{M}$, which is odd in both $\mathbf{\Omega}$ and $\mathbf{H}$ and which explains the gyromagnetic effect shown in Fig. 6*b*. A change in the sense of rotation or in the direction of the magnetic field changes the texture of the liquid. Therefore, $\mathbf{M}$ could be measured[35] directly by NMR spectroscopy even though its value in ^{3}He-B rotating at $\Omega = 1$ rad s^{-1} is tiny: only of the order of 10^{-11} nuclear Bohr magnetons per ^{3}He atom.

The *v* vortex possesses a spontaneous electric polarization, also caused by the violation of parity in the core[38]. The *w* vortex would also show striking properties: it has a complex superfluid core and it displays spontaneous superflow along the vortex axis. The *uvw* vortex shares the properties of both the *v* and *w* vortices.

Vortex-core transition in ^{3}He-B

Perhaps the most interesting feature signalling a nontrivial vortex-core structure in ^{3}He-B is the phase change, which takes place when crossing a transition line while the liquid is rotating, see Fig. 2. This was observed experimentally as abrupt discontinuities in the spacing of standing spin waves[3] and as a jump in the vortex-core magnetization[35] (Fig. 6*b*) and as a jump in the critical flow velocity[14,15]. These changes are independent of the angular velocity of rotation, that is, the density of vortices,

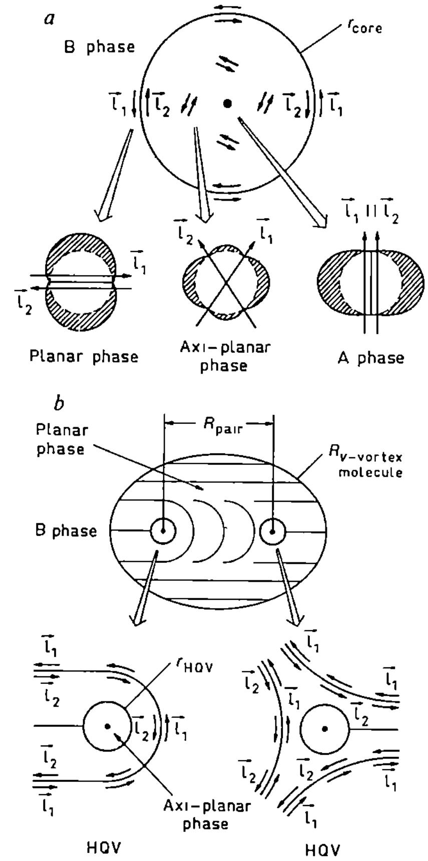

Fig 8 Topology of the energy gap (hatched areas) on the Fermi sphere in the cross-sectional plane of *v* vortices in ³He-B at high and low pressures (see Fig 2) *a*, In the axisymmetric *v* vortex[38], point vortices first appear in the 'planar-like' phase at $r = r_{core}$ For $r < r_{core}$ vorticity is supported by continuous winding, in the 'axi-planar-like' phase, of the nodes for quasiparticles with spin up ($\mathbf{l}_1$) and down ($\mathbf{l}_2$), changing from antiparallel at $r = r_{core}$ to parallel at $r = 0$ with 'A-phase-like' core *b*, The nonaxisymmetric *v*-vortex 'molecule' The two centres are both a half-quantum vortex[49] (HQV) confined in the core (see Fig 5) Each HQV is accompanied by a disclination in the l-vector field with half-integer winding number, reversing $\mathbf{l}_1$ into $\mathbf{l}_2$ on circling either HQV The nodes lie in the cross-sectional plane ('planar-like' phase), except inside inner cores of radius r_{HQV} where they flare out of the plane and deviate from each other (in the 'axi-planar-like' phase) This 'bag' model of the core 'molecule' resembles hadrons with the HQVs corresponding to quarks

implying that the transition is not affected by interactions between vortices Rather, the transition is attributed to a change in the core of isolated vortex lines

Much work has been devoted to identifying the vortices associated with this unexpected transition First, it was contemplated[37,42] that one might understand the transition to be one between two of the five axisymmetric vortices It was found, however, that the *v* vortex provides the absolute energy minimum among the axisymmetric vortices[38] Also, it is stable against small nonaxial perturbations[43] Salomaa and Volovik[44] suggested that the mechanism of the vortex-core transition in ³He-B is breaking of axisymmetry Nonaxisymmetric vortex structures were also considered by Theodorakis and Fetter[45]

Recently, it has been reported[41,46,47] that a nonaxisymmetric vortex has a lower energy than the axisymmetric *v* vortex at low pressures Thuneberg[41] was the first to perform the full two-dimensional energy minimization by solving numerically the Ginzburg-Landau differential equations, his results are illustrated in Fig 7, whereas Volovik and Salomaa[46,47] only carried out investigations within sectors of definite symmetry At all pressures the energy of the axisymmetric *o* vortex is clearly higher than the energies of the axisymmetric *v* vortex[37] or the nonaxisymmetric 'double core' new vortex with two points of local maxima in the energy density At low pressures, the new vortex has the lowest energy With an increase of pressure, the energy difference between the new vortex and the axisymmetric *v* vortex decreases and their energies are equal at ~3 bar below the tricritical pressure, this is in excellent agreement with the experimental data of Fig 2 Thuneberg's calculations show that the axisymmetric *v* vortex becomes stable at higher pressures

Volovik and Salomaa[46,47], on the basis of their systematic study[38] of all the discrete broken symmetries, confirmed Thuneberg's[41] calculation and identified the new vortex as the nonaxisymmetric *v* vortex of their classification scheme At present it seems that in ³He-B the nonaxisymmetric *v* vortex is stable at low pressures and the axisymmetric *v* vortex at high pressures (Figs 2 and 7) Volovik and Salomaa find that the mechanism of restructuring the superfluid core in the vortex transition is independent of any model-dependent details the first-order vortex-core transition is triggered by the proximity of the *A* phase alone, and driven by the broken parity of the *v* vortex, combined with superfluid condensation-energy considerations

Point vortices on the Fermi surface

What is the actual physical meaning of the vortex-core transition what happens to superfluid vorticity? To answer these questions, it is crucial to appreciate that vortices in ³He can couple the real **r** and the momentum **p** spaces superfluid-core vortices can escape the real-space singularity on the vortex axis by flaring out into the momentum space, this process is associated with nodes in the energy gap on the Fermi surface within the vortex core[48] We denote by $\mathbf{l}_1$ and $\mathbf{l}_2$ the directions of the nodes for the two energy gaps, $\Delta_1(\hat{\mathbf{p}})$ and $\Delta_2(\hat{\mathbf{p}})$, for the two possible ³He spin projections In both *v* vortices, there appear two pairs of such nodes These objects are topologically interesting point vortices ('boojums') in the **p**-space, around which the phase Φ_i of $\Delta_i = |\Delta_i(\hat{\mathbf{p}})|\, e^{i\Phi_i(\hat{\mathbf{p}})}$ (for $i = 1, 2$) changes by $\pm 2\pi$, therefore, the singularity ($v_s \propto 1/r$) can be resolved without breaking superfluidity on the vortex axis

Volovik and Mineev[48] were the first to propose that the core transition in ³He-B involves a change in the topology of the vortex-core matter, however, the transition proved more interesting[49] than that originally suggested To escape the singularity in the axisymmetric *v* vortex[38] (Fig 8*a*), $\mathbf{l}_1$ and $\mathbf{l}_2$ each cover half the Fermi sphere unwinding unit quantum of circulation thus results according to $m = \frac{1}{2} + \frac{1}{2} = 1$, this is associated with the simultaneous spatial variation of each orbital anisotropy axis, $\mathbf{l}_1$ and $\mathbf{l}_2$, just like vorticity can be supported by the continuous winding of the order parameter in the **l** textures of ³He-A

For the nonaxisymmetric *v* vortex, the topological scenario for flaring-out of the singularity is essentially different[49] The composite core 'molecule' is illustrated in Fig 8*b* It contains two half-quantum vortices, 'quarks'[47], coupled by 'strings' disclinations in both $\mathbf{l}_1$ and $\mathbf{l}_2$, closely resembling the **d**-field disclination in Fig 5 One may here verify that each point vortex covers one quarter of the Fermi surface in both of the half-quantum vortices $m = (\frac{1}{4} + \frac{1}{4}) + (\frac{1}{4} + \frac{1}{4})$, hence the two 'quarks' do represent objects with fractional topological charge Consequently, Fig 2 identifies the vortices involved in the core transition, whose first-order character signals the topological bifurcation in the distribution of vorticity into the momentum space

Conclusions

The varied vortex-core structures in the superfluid phases of ³He lead to the possibility of several phase transitions inside the cores These can occur in the hard vortex core, but also in the much more extended soft-core region In ³He-B, so far only one of many possible transitions has been found in the NMR spectra[3,15,35], the nature of this vortex-core transition is understood theoretically[49] The search and study of these new physical phenomena will be the subject of future theoretical and experimental investigations

To date, these studies, principally with use of the NMR technique, have concentrated on the static properties of vortices In the future, problems related to the dynamics of vortices need to be tackled nucleation, the mechanisms for transitions—possibly involving monopoles—to lower-energy states, and the formation and properties of vortex rings In this research, ions[50] have already been used and experiments involving ultrasound are being planned

The physics of vortex phenomena in ^{3}He is interesting from a much broader point of view, owing to the different mechanisms for topological confinement, exemplified by the generation of the **d**-vector soliton (string) that glues together the pairs of half-quantum vortex disclinations in ^{3}He-A, as in quarks There are many conceptual connections to quantum field theories, and close analogies with defects in liquid crystals[51] The structure of the vortex core in the B phase is intimately related to the topology of the point vortices on the Fermi surface[48] The novel dimerization mechanism in flaring-out of vorticity for the non-axisymmetric v vortex molecule suggests the identity of the vortex-core transition in ^{3}He-B the nonaxisymmetric v vortices are topologically confined pairs of half-quantum vortices, analogous to quarks inside nucleons Provided that experiments will confirm this identification[49], vortices with half-integer circulation have first been found in rotating superfluid ^{3}He-B

It is commonly believed that the neutron mass in pulsars undergoes a BCS-type transition to form a superfluid Fermi liquid in a $^3P_2$ state[52] Normal-core vortices with spontaneous magnetization have been discussed for neutron stars[53,54], and the analogue experiments on the superfluidity of pulsars[55] have been conducted on rotating superfluid ^{4}He Being a Fermi liquid, also paired in a p-wave state, superfluid ^{3}He should provide a better substance for such model experiments It is likely that, just as in superfluid ^{3}He, vortices in pulsars also display a superfluid core This possibility could introduce a substantial revision in present understanding of heat transport in neutron stars and thereby in our picture of the latter stages of supernovae

An interesting experiment was recently suggested by Zurek[56], the proposal is to carry out a rapid isothermal expansion of liquid ^{4}He through the superfluid transition, whereby vorticity should be generated at the interfaces of the superfluid condensation fronts Such vortex lines are proposed to be analogous to the cosmic strings[57,58] that are believed to have nucleated in the phase transitions of the early Universe An analogue model experiment on superfluid ^{3}He (here presumably by a rapid isothermal compression through the superfluid transition) would be more difficult to carry out However, this is potentially more interesting because the 'vacuum' states of superfluid ^{3}He, with the most complicated known broken symmetry in condensed matter, provide a more relevant analogue system for Grand Unified Theories Here the vortex density can also be directly measured by the NMR technique This idea has also been proposed for liquid crystals (M Yu Khlopov and S Obukhov, unpublished data), where the creation of disclination lines at the phase transition may be seen directly with a microscope

Vortices in heavy-fermion superconductors remain largely unexplored Provided that these materials[59] do exemplify p-wave or other unconventional pairing, it is possible that some of the conceptual generalizations which have been necessary to make progress in understanding experimental results on vortices in superfluid ^{3}He will also prove useful in the context of heavy-fermion superconductors

In conclusion, vortices in superfluid ^{3}He, although highly interesting for their own sake also seem to be important in a broader context beyond low-temperature physics, for more detailed expositions of the topic, see refs 34, 43 and 60 (review)

Electrophoresis of ribonucleoproteins reveals an ordered assembly pathway of yeast splicing complexes

Claudio W. Pikielny*, Brian C. Rymond† & Michael Rosbash†

* Department of Biochemistry and † Department of Biology, Brandeis University, Waltham, Massachusetts 02254, USA

Three splicing complexes formed with a yeast pre-messenger RNA during in vitro *splicing can be resolved by non-denaturing gel electrophoresis after incubation in the presence of non-specific competitor RNA The time course of the appearance of these complexes and their composition suggest that they represent an ordered pathway of splicing complex assembly*

THE detailed analysis of RNAs generated during pre-mRNA splicing *in vitro*[1-5] and *in vivo*[6-8] has led to the definition of a two-step splicing pathway in mammalian systems as well as in the yeast *Saccharomyces cerevisiae* (for recent reviews see refs 9, 10) In the first step, the 5′ splice junction is cleaved, generating two molecules, the exon 1, and the intron-exon 2, in a lariat configuration, due to a 2′-5′ linkage between the 5′ end of the intron and the 2′-OH of an adenosine in the intron (which in *Saccharomyces cerevisiae* is the last A of the TACTAAC box) In the second step the two exons are ligated and the intron is excised as a lariat The two-step pathway appears similar for *S cerevisiae* and mammalian systems but differences in the *cis*-acting signals and the effects of mutations in these *cis*-acting sequences, indicate that some aspects of pre-mRNA splicing are different[11-13]

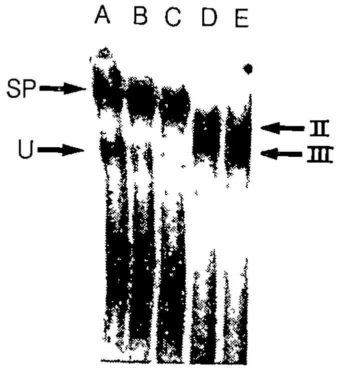

Fig. 1 Effect of non-specific competitor RNA on the electrophoretic resolution of splicing complexes A splicing reaction was carried out as described[4,5,11] with recombinant plasmids transcribed *in vitro* with SP6 polymerase[29] and containing rp51A sequences[13] The reaction was incubated for 20 min at 25 °C, stopped by the addition of Q buffer (400 mM KCl, 2 mM $Mg(OAc)_2$, 20 mM EDTA and 100 mM hydroxyethyl piperazine ethane sulphonic acid HEPES-NH_4OH (pH 7 5)), and separated into 10 μl aliquots which were analysed by electrophoresis on a non-denaturing agarose-acrylamide composite gel[13] Just before loading, each 10 μl sample was incubated on ice for 10 min in the presence of a preparation of total yeast RNA[30] at a concentration of lane A, 0 μg μl^{-1}, B, 0 1 μg μl^{-1}, C, 0 2 μg μl^{-1}, D, 0 4 μg μl^{-1}, E, 1 μg μl^{-1} The optimal concentration of non-specific RNA is ~1 μg μl^{-1}, higher concentrations did not improve the resolution but caused streaking and aggregation (not shown) Other nucleic acids have been tested as competitors, but neither transfer RNA nor DNA improve the resolution of splicing complexes *Xenopus laevis* total RNA was just as effective as was *Saccharomyces cerevisiae* total RNA The complexes observed, in the different lanes, labelled SP, U, II and III

Splicing occurs in very large RNP (ribonucleoprotein) complexes[14-16] In mammalian systems these splicing complexes, also called spliceosomes, contain snRNPs (small nuclear ribonucleoproteins[15,17]) which are required for the splicing reaction[9,10] Point mutations in either of the two sequences essential for the splicing of yeast pre-mRNAs (the 5′ splice junction and the TACTAAC box) inhibit spliceosome formation[14,18] It has only recently been possible to show that specific trimethyl-capped RNAs (for a review of small nuclear RNAs, see ref 19) are present in yeast spliceosomes[13] and that at least some of these are essential for the splicing reaction[19]

We recently used non-denaturing polyacrylamide gels to analyse yeast RNPs formed during *in vitro* splicing[13] Of the two RNPs visible, the first (called SP for spliceosome) shows all the characteristics of a splicing complex or spliceosome its formation is dependent on (1) time, (2) ATP and (3) an intact TACTAAC box and 5′ splice junction, it also contains the products of the first step of the splicing reaction (exon 1 and intron-exon 2 lariat intermediate) and a product of the second step, the excised intron in a lariat configuration SP band formation precedes any detectable cleavage or ligation events, reaching a maximal level shortly after the addition of ATP The second complex (named U for unspecific) behaves as a nonspecific RNP by all the above criteria These data imply that only the SP complex is a spliceosome and that its formation is an early and probably essential step in the splicing of pre-mRNA

Competitor RNA improves resolution

The addition of non-specific competitor RNA to a splicing reaction before electrophoresis increases the mobility of both the SP and the U complexes, presumably because loosely bound factors are lost (Fig 1) The U band is readily dissociated with increasing concentrations of competitor RNA, as expected of a nonspecific complex The SP band is less affected, implying that some interactions in this complex are resistant to the addition of competitor RNA The SP band was resolved into two major bands of higher mobility, suggesting that in the absence of competitor RNA the SP band is heterogeneous and contains at least two different splicing complexes The two bands visible in this experiment are bands II and III, the only ones normally detectable after a 20 min incubation (Fig 1)

Three splicing complexes

A time course shows that three distinct complexes, called I, II and III in order of increasing electrophoretic mobility, are formed (Fig 2, w t) In this typical experiment, substantial amounts of bands I and III were visible after 2 min of incubation, the concentrations were maximal at 5 min and decreased thereafter Substantial amounts of bands I and III are formed after 30 s of incubation (data not shown), well before the formation of splicing intermediates and products can be detected (see ref 13, for example) Band II is not visible until 5 min of incubation after which it continues to increase in intensity The first appearance of band II coincides with that of the intermediates of the reaction The order of appearance of the three complexes suggests that two early complexes (bands I and III) may be intermediates in a pathway leading to the formation of the late complex (band II)

Complex formation with point mutant

Analysis of a strong point mutation at the TACTAAC box (the 3'-III mutation, TACTACC[21]) supports and extends this idea As expected from *in vivo* studies[21], incubation of an RNA substrate containing this mutation in an *in vitro* splicing reaction, results in no detectable intermediates or products (data not shown) Surprisingly, however, there was a substantial accumulation of band III (Fig 2, 3'-III, note that this portion of the gel reads right to left), which formed more slowly than with a wild-type substrate RNA No band I or band II was detected The data suggest that the 3'-III mutant is blocked after formation of the early complex (band III) and hence that band III is the initial complex and leads to the subsequent formation of bands I and II with a wild-type substrate

Distribution of labelled RNAs

To characterize these splicing complexes further, we analysed the RNA distribution across RNP gels (Fig 3) Precursor RNA has a broad distribution with a clear maximum which coincides with band III and extends into band II and the region corresponding to band I (band I is indistinct at incubation times of 20 min) The products of the first step, the intron-exon 2 lariat and exon 1, are found almost exclusively in the band II fractions The intron produced in the second step is distributed over bands II and III, in Fig 3 it is more prominent in the band III region A very low level of the exon 1-exon 2 RNA is detectable in band II

We used a smaller RNA to determine the influence of substrate size on the migration of the different splicing complexes and to improve resolution The rp51A δ2 RNA is only 247 nucleotides (nt) long (as opposed to 800 nt for rp51A) but is spliced accurately and efficiently *in vivo*[22] and *in vitro*[11] The smaller substrate gives rise to a similar pattern of bands, the early forming complexes are designated bands III and I and the later complex is named band II (Fig 4*a*) All three of these complexes show much higher mobility than the corresponding complexes formed with the larger substrate There is also a fourth complex of higher mobility, not visible at early times (band IV) The RNAs present in each band from the 20 min time point were analysed on a denaturing polyacrylamide-urea gel (Fig 4*b*), the distribution of radioactive RNA species between the bands is similar to that found for the larger transcripts (Fig 4*b* and data not shown), confirming the correspondence of the complexes formed with the two transcripts Band I contains mostly pre-mRNA and band III contains only pre-mRNA, whereas band II contains substantial amounts of both products of the first step, the intron-exon 2 lariat and exon 1 Bands I and II are not completely separated, but it can be seen that band I contains mostly pre-mRNA and that the products of the first step contribute >50% of the radioactivity in band II Band IV contains mostly intron-exon 2 lariat, some excised intron and pre-mRNA, but no detectable exon 1 (compare lanes II and IV) It probably results from the partial dissociation of band II and cannot be an active complex because it lacks exon 1

snRNAs associated with each complex

We have recently shown through partial purification of *in vitro* generated splicing complexes (or spliceosomes) by two different methods (non-denaturing electrophoresis and oligo(dT)-cellulose chromatography of spliceosomes formed on a polyadenylated substrate) that at least three different trimethyl cap-bearing snRNAs, 160, 185 and 215 nt long are associated with

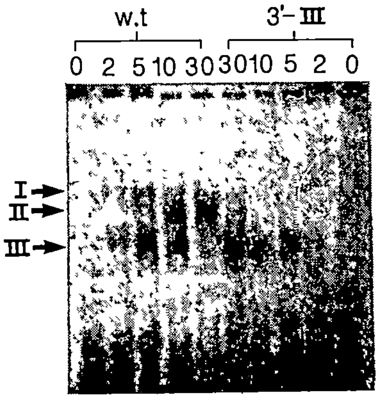

Fig 2 Time course of formation of splicing complexes Splicing reactions were carried out for the times indicated above each lane (in minutes), quenched and incubated in the presence of 1 μg μl^{-1} of total yeast RNA for 10 min on ice just before loading as in Fig 1 (Note that, for the mutant transcript, the time points read from right to left) w t, splicing complexes formed with the wild-type rp51A transcript 3'-III, splicing complexes formed with a transcript indentical to the one in *a* except for an A to C transversion at the last A of the TACTAAC box[21] The different bands observed are labelled I, II and III

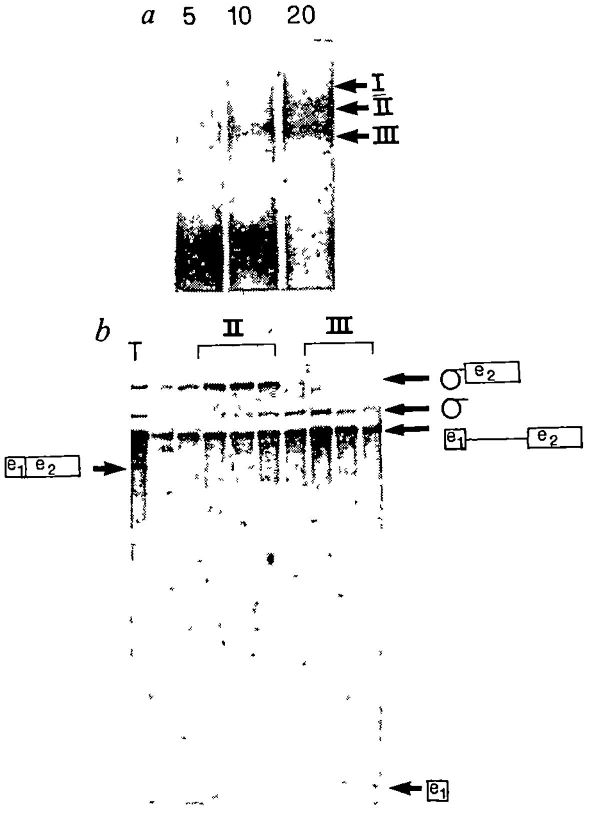

Fig 3 Distribution of pre-mRNA, intermediates and products among splicing complexes formed with a long substrate *a*, Splicing reactions with saturating amounts of substrate (1 ng μl^{-1}) were incubated for 5, 10 and 20 min as indicated and resolved on a non-denaturing gel after incubation with total yeast RNA The gel was then electroblotted to a DEAE membrane, which was then autoradiographed[13] *b*, The lane corresponding to the 20-min time point was cut into 2-mm slices, the RNA eluted from each slice and analysed on a 5% polyacrylamide, 8 M urea gel[13] The regions corresponding to bands II and III (as visible in *a*) are indicated, the lane between bands II and III which has the least amount of radioactivity and the two lanes corresponding to the two fractions above band II were not assigned to either band T, unfractionated reaction The structure of the different RNAs, as deduced from their electrophoretic mobility on this and other gels of different polyacrylamide concentrations, is shown at the side

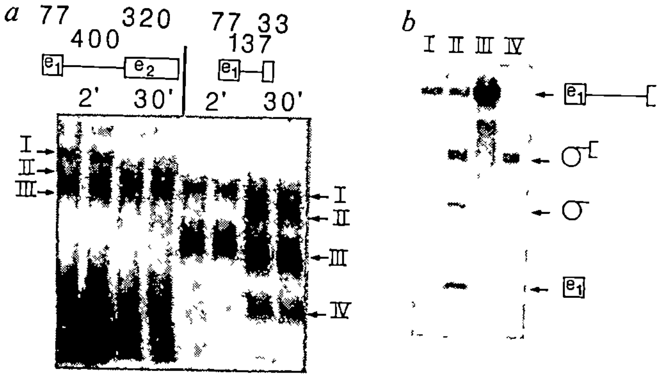

Fig. 4 Distribution of pre-mRNA, intermediates and products among splicing complexes formed with a short substrate. *a*, Preparative, non-denaturing gel showing the analysis of splicing complexes formed in the presence of a full-length (rp51A, 800 nt long) or short (rp51A $\delta 2/DdeI$, 247 nt long) RNA substrate after 2-min or 20-min incubations in a splicing reaction (each reaction was loaded on two lanes). An autoradiogram obtained after electroblotting the gel onto a DEAE membrane[13] is shown. The structure of the transcripts is shown above the lanes. *b*, The RNAs were extracted from each band and analysed on a 5% polyacrylamide, 8 M urea gel[13]. The structure of the different RNAs as determined by their electrophoretic mobility is shown on the right.

yeast spliceosomes[13]. Comparison of our patterns of immunoprecipitated snRNAs with those in a recently reported study[23] suggests that these three species are those known as snR14 (160 nt), $snR7_S$ (185 nt) and $snR7_L$ (215 nt). The latter two are transcripts from the SNR7 gene and vary in the lengths of their 3' ends[23].

An additional, unusually large, trimethyl-capped species (1,100–1,200 nt) also appeared to be associated with complexes formed on a polyadenylated substrate, but not with spliceosomes purified by gel electrophoresis, probably because of a high background level in that region of the gel[13]. In the presence of carrier RNA the splicing complexes migrate in a region of the gel showing less background, allowing us to confirm that this RNA is also part of the spliceosome. Based on its molecular weight, it is almost certain that this large RNA corresponds to a recently discovered essential RNA species, lsr1 (large spliceosomal RNA1), the product of the LSR1 gene, which has extensive sequence homology to the mammalian U2 snRNA[24]. Comparison of gel patterns suggests that this species is identical to snR20[23]. Although these comparisons are not yet definitive, we will refer to these RNAs as LSR1, $snR7_L$, $snR7_S$ and snR14.

We analysed the distribution of these RNAs among the different splicing complexes, comparing their level in each complex with the background level in the absence of *in vitro* assembled complexes (see Fig. 5 and ref. 13). By this criterion, each complex contains a specific complement of trimethyl-capped RNA species. lsr1 is clearly present in all three complexes, band III appears to contain only this species, as determined by this assay. Band I also contains the three other RNAs previously shown to be associated with spliceosomes, ($snR7_S$, $snR7_L$ and snR14). Band II contains lsr1, $snR7_S$ and $snR7_L$ but is missing snR14. Thus, we can account for all the species described previously and the three complexes show different snRNA compositions (Fig. 6).

Pathway of complex formation

The addition of high concentrations of competitor RNA before electrophoresis greatly improves the resolution of splicing complexes over our previously reported method[13] and allows a more detailed description than has been possible with the more conventional technique of sedimentation analysis[14–17]. The competitor RNA presumably removes non-specific or relatively loosely-associated factors, reducing the size and increasing the electrophoretic mobility of the splicing complexes. The relative

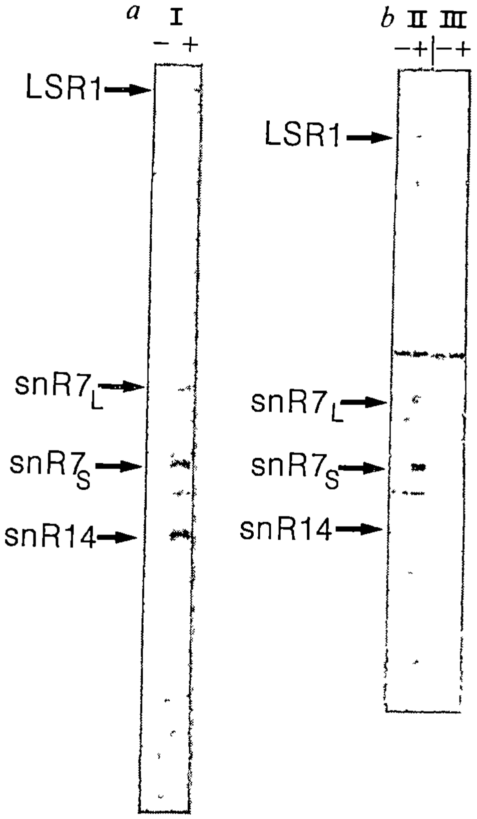

Fig. 5 Trimethyl-capped RNAs in the three splicing complexes. snRNAs present in bands I, II and III. Preparative reactions in the presence of the short substrate (rp51A $\delta 2/DdeI$) were incubated for 2 and 30 min at 25 °C and run on gels similar to those shown in Figs 3 and 4, after incubation for 10 min on ice in the presence of 1 μg μl^{-1} of periodate-treated *Xenopus laevis* RNA (see below). The gels were then electroblotted onto DEAE membranes and the RNAs present in band I (panel *a*) or bands II and III (panel *b*) were eluted from each lane, ethanol-precipitated in the presence of 5 μg of salmon sperm DNA (see below), end-labelled with pCp and RNA ligase (as described[31] with the modifications described in ref. 13), immunoprecipitated with anti-trimethyl-cap rabbit antibody (as described[32], with the modifications described in ref. 13) and analysed on a 7% polyacrylamide 8 M urea gel. To ensure that the capped RNA species are specifically associated with *in vitro* assembled complexes, a reaction containing no exogenously-added substrate was processed in parallel[13]. The lanes containing complexes I, II and III are indicated. + and − denote the presence or absence of exogenously-added substrate in the splicing reaction. The sizes of the various RNAs were determined (on this and other gels) by comparison with 5S RNA, 5.8S RNA, the rp51A $\delta 2/DdeI$ transcript (247 nt), the rp51A transcript (800 nt) and 18S RNA. Two modifications were introduced in these experiments to ensure that the snRNAs observed were present in splicing complexes and not artefactual. First, *Xenopus laevis* RNA that had been oxidized with periodate (to make it unavailable for end-labelling with pCp and RNA ligase[31]) was used as competitor instead of total yeast RNA. The protocol for periodate treatment was provided by M. Green. Briefly, 200–500 μg of total *Xenopus laevis* RNA were resuspended in 1 ml of 0.3 M NaOAc *p*H 5.3, 1 ml of (4 mM $NaIO_4$, 10 mM NaOAc *p*H 5.3) was added and the mixture was incubated in the dark at 4 °C for 1 h, then at room temperature for 1 h. The reaction was quenched by adding 0.2 ml of propylene glycol (1,2-propanediol) and incubated at room temperature for an additional 10 min. The RNA was then phenol-extracted, ethanol-precipitated and washed extensively. Second, instead of tRNA as carrier in the ethanol precipitations after elution from the DEAE membrane, we used salmon sperm DNA which had been previously freed of any contaminating RNA by overnight incubation in 0.3M NaOH and ethanol precipitation in the presence of 2.5 M NH_4Ac, because we found that salmon sperm DNA was not (or only very poorly) labelled in a standard pCp end-labelling reaction.

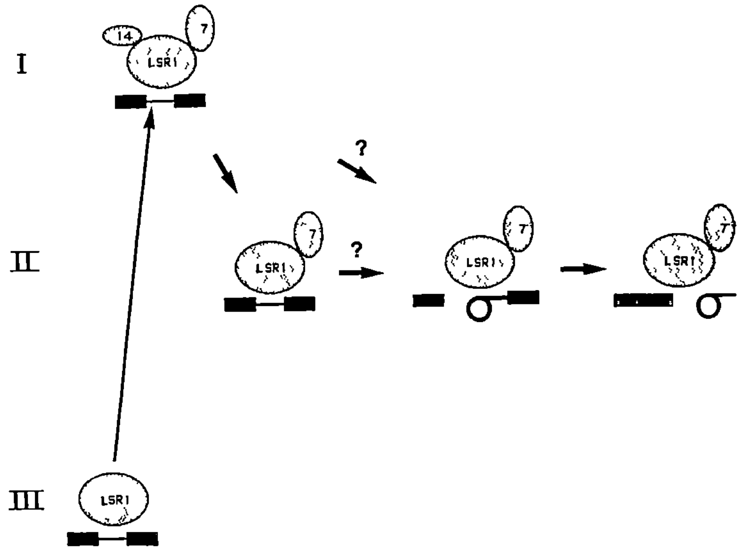

Fig 6 Schematic summary of the data corresponding to the complexes formed on the pre-mRNA and those containing the products of the first and second step Each band (I, II and III) is indicated with the complex(es) it contains The composition in snRNAs is based on the assumption that a given band is homogeneous, which may not be the case The arrows indicate transformation of one complex into another, which might involve other undetected intermediate complexes The question marks reflect the fact that it is not clear which complex is the site of the first step

mobility of the three major complexes is inversely related to the number of snRNAs found associated with each of them It is not clear whether this is a causal relationship as the snRNA characterization includes a number of uncertainties There may be additional snRNAs, undetected in this and our previous analysis (see discussion on this point in ref 13) and differences in protein composition and/or conformation between the three complexes

We suggest that the three complexes form in an ordered manner III→I→II To demonstrate such a pathway rigorously, one would have to show that it is possible to 'chase' pre-mRNA through the different complexes This has not yet been possible but three lines of evidence, taken together, suggest that this interpretation is correct

First, the kinetics of appearance of the various complexes show clearly that bands I and III appear early in the reaction, preceding any covalent modification of the substrate Band II appears subsequently, as the products of the first step, 5′ exon and lariat intermediate, first become detectable Although the precise kinetics depend on the extract used, temperature and other details of the individual experiment, the two early bands (III and I) always appear together under normal conditions In addition, both bands usually decrease substantially as band II intensifies (Fig 2*a*) In several experiments in which the substrate pre-mRNA was saturating, band III accumulated to high levels and did not decrease (Figs 3*a* and 4a), even after long incubations (data not shown) In contrast, band I is only easily detectable at early times of incubation Second, an examination of assembly under non-optimal conditions indicates that only band III is formed This is true with a substrate containing a single point mutation at the branchpoint (Fig 2*b*) as well as with defective extracts obtained, for example, by diluting a normal extract (data not shown) The III→I→II sequence explain the data most simply but a model where either III or I can lead to II is also possible Analysis of the snRNAs associated with each complex suggests that III is the initial complex as it contains lsr1 but not snR7 (S or L) or snR14 Band I is then formed with the binding of these two other snRNAs, and band II follows with the loss of snR14

Sites of the two steps of splicing

The complex in which the first step occurs is expected to contain pre-mRNA and the products of this reaction Both bands I and II are candidates for this active complex since we cannot resolve the two complexes clearly, they both appear to contain the two types of molecules (The products of the first step are much more abundant in band II than band I, however) If band I is the site of the first step, 5′ cleavage and lariat formation are accompanied or rapidly followed by the loss of snR14 and the transition to band II, which then more slowly undergoes the second step If band II is the site of the first step, the presence of pre-mRNA in band II may be due to the fact that, at least *in vitro*, this active complex can also be formed (for example, band I can lose snR14) without undergoing the first step We therefore cannot determine whether the loss of snR14 and the concomitant band I→band II transition occur before or after the first step of the reaction

The site of the second step of the reaction, 3′ cleavage and exon ligation, can be assigned more easily to band II The products of the first step (intron-exon 2 lariat and exon 1), which are the substrates for the second step, are found in highest concentration in band II The distribution of the products of the second step is also compatible with this view In contrast to the lariat intron, almost none of the exon 1-exon 2 RNA is found associated with the large splicing complexes[13,14,16,17] In Fig 3 a low level of exon 1-exon 2 RNA is detected and coincides with band II A similarly low level of excised intron is also present in the band II fractions, larger amounts of this molecule are in faster migrating complexes which may be derived from band II simply by loss of the exon 1-exon 2 RNA

This description does not relate the complexes observed to the *in vivo* complexes, or even to the complexes formed in *in vitro* splicing, from which bands I-III are derived The treatment involved is particularly severe, including high salt, the addition of EDTA and, notably, incubation with non-specific competitor RNA (see Fig 1) and can be expected to disrupt all but the strongest interactions Thus the RNP gels show a 'core' splicing complex This may affect the interpretation of the proposed assembly pathway As an extreme possibility, there may exist a preformed spliceosome containing all the different snRNPs that will bind to the pre-mRNA, the interactions between the different snRNPs and/or between certain snRNPs and a given part of the pre-mRNA substrate might then become stronger or weaker as the splicing reaction proceeds The different complexes observed here would then reflect different levels of interaction rather than the step by step association or disassociation of snRNPs with a complex containing the pre-mRNA substrate Further studies may lead to an understanding of the interactions which produce stable complexes and the active splicing complexes, and the identification of the factors which recognize the conserved sequence elements in yeast introns

This study was supported by grant GM23549 from the NIH to M R C W P was supported by a Dretzin predoctoral fellowship and B C R by a post-doctoral fellowship from the NIH We thank A Jacquier and M Green for helpful discussions, D Torrey for technical assistance, R Luhrmann for anti-TMG antibodies, and T Tishman for typing the manuscript

An accretion event in the Seyfert galaxy NGC 5548

B. M. Peterson & G. J. Ferland

Department of Astronomy, The Ohio State University, 174 West 18th Avenue, Columbus, Ohio 43210, USA

Accretion on to a massive collapsed central object is now commonly thought to power active galactic nuclei (AGN)[1–3]. If this is indeed so, then changes in luminosity of the system should correspond to changes in accretion rate, or, equivalently, the mass flux at regions a few Schwarzschild radii from the putative black hole. The observational consequences of such a change in accretion rate may not be pronounced, as gas near the central source of radiation is expected to be very highly ionized and difficult to observe outside the X-ray band. Here we draw attention to a remarkable change which occurred in the spectrum of the low-luminosity, optically variable, Seyfert galaxy NGC 5548. An increase in optical luminosity was accompanied by the appearance of a strong, abnormally broad He II 4,686-Å emission line. The appearance of this line indicates the presence of a component of highly ionized gas that did not contribute to the optical spectrum before the increase in luminosity. The greater line width suggests that the gas producing the He II emission is much closer to the central object than the broad region (BLR). This observation may be the first direct evidence of the accretion onto a central object.

We have been observing the low-luminosity Seyfert 1 galaxy NGC 5548 for some time[4] Optical spectra have been obtained at regular intervals A major goal of this work was to determine time lags between continuum activity and the response of the emission-line region The time delay, which establishes the separation between the central engine and the BLR, is found to be around 31 days, corresponding to $r \simeq 7\ 9\times10^{16}$ cm (ref 5) If the BLR gas is bound in the potential well of the central object then the corresponding virial mass is $\sim 3\times10^{7}\ M_{\odot}$

During the course of these observations, the optical continuum increased by around 66% (see Fig 1, in which the flux density of the continuum near 5,500 Å is shown, after removal of the underlying galaxy continuum) Details of the observational procedure and reduction techniques are discussed elsewhere[4] This increase in visual brightness was accompanied by a similar increase in the extreme ultraviolet (EUV, that is $\lambda <$ 912 Å) because the flux in the Balmer lines also increased (when the 31 day time-lag is taken into account) The fact that the increase in brightness in the continuum and Balmer lines increased together suggests that the luminosity of the EUV and optical continua are well correlated

The surprising feature of these observations is the unexpectedly large increase in the strength of the He I 4,686-Å line (see Fig 1) This phenomenon has not been reported before, although it is only within the last few years that Seyfert galaxies have been spectroscopically monitored with sufficient frequency to make such detection possible Whereas the continuum increased by a factor of ~1 7, the He II line increased more than tenfold The most likely explanation for this change was the addition of a new gaseous component He II lines are formed by recombination in active nuclei[6] the luminosity of a recombination line will remain constant if the gas is fully ionized and the mass and density of the emitting gas remain constant In a radiation-bounded geometry, one in which the majority of the ionizing radiation striking a BLR cloud is absorbed by the emitting gas, the equivalent width of an emission line should remain constant, and the He II line should increase in phase with the continuum Our observations rule out both these simple pictures

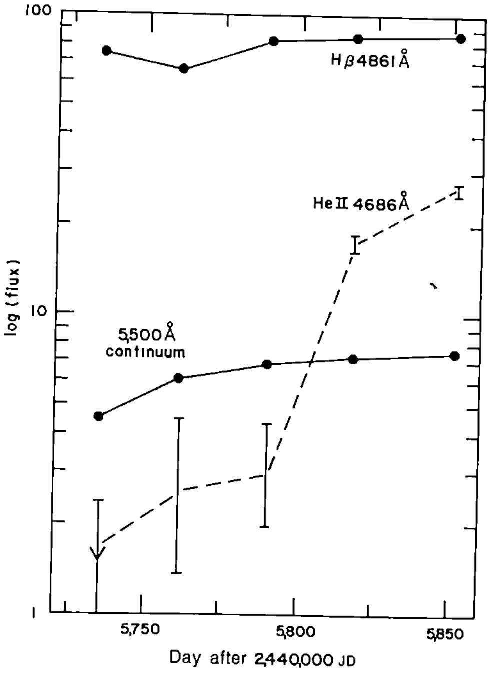

Fig 1 The flux in Hβ, He II 4,686 Å and the 5,500 Å continuum, over the course of our observations Line fluxes are in units of 10^{-14} erg s^{-1} cm^{-2} and continuum fluxes are in units of 10^{-15} erg s^{-1} cm^{-2} Å^{-1}

It is possible to argue that the dramatic increase at 4,686 Å is caused by a flattening of the continuum, thereby increasing the number of helium-ionizing photons relative to the optical continuum We reject such an explanation because our data show no evidence for continuum shape change at lower energies, based on ultraviolet and optical observations Moreover, the

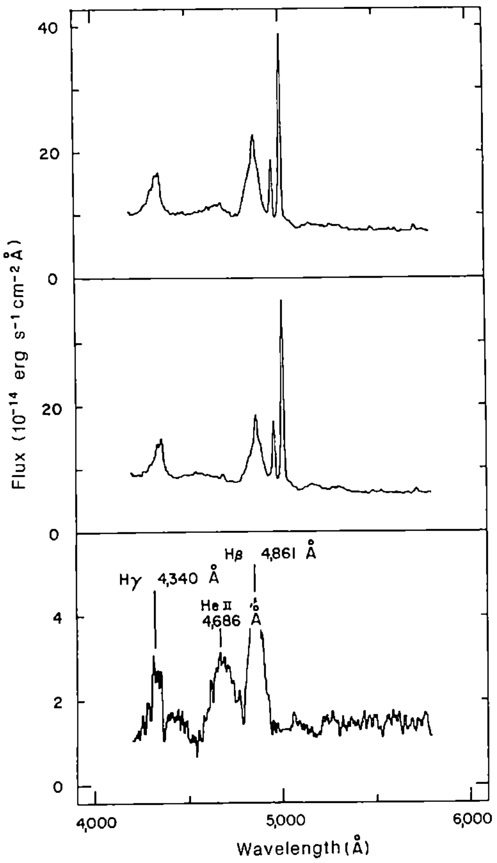

Fig 2 The top two panels show the optical spectrum near the Hβ and He II 4,686 Å lines during the high and low states The bottom panel is a difference spectrum, with the strongest emission lines marked The high-state spectrum was obtained on 1-2 June 1984 UT (2,445,852-3 JD) and the low-state spectrum was obtained on 2-3 March 1984 UT (2,445,761-2 JD)

Balmer lines and the He I 5,876-Å line, which are sensitive to the radiation field in the range 1-4 Ryd, did not increase by as large a fraction as the optical continuum if the increase at 4,686 Å is attributable to an increase in the density of ionizing photons, the increase in flux would have to be confined to energies in excess of 4 Ryd We therefore believe that the increase in the I(4,686 Å)/I(Hβ) ratio was caused by the appearance of a new component of gas

The He II 4,686-Å line profile confirms that a new component of gas is present, that this gas is not associated with the classical BLR, and that the gas is probably closer to the central object that the BLR Figure 2 shows a difference spectrum, obtained by subtracting a low-state spectrum (when He II emission is weak) from one obtained in the high state, when the anomalous He II emission was present The increased Hβ line is apparent, along with Hγ near the blueward limit of the spectrum The Hβ profile is similar to that seen in low-state spectra, and is an indication of the width of broad emission lines in this object Surprisingly, the new He II emission line has a width ~75% greater than the neighbouring Hβ Although there is some tendency for He II lines to be slightly broader than hydrogen lines[7], the difference seen here is much greater than has ever been seen before The greatly enhanced He II emission can be attributed to gas moving with much greater velocity than BLR clouds If the gas is confined within the potential well of the central object, we can infer that the He II-emitting material lies at roughly one-third of the BLR radius from the central object, or at roughly 3×10^{16} cm We thus conclude that the increase in luminosity of the central object in NGC 5548 was accompanied by the appearance of a new component of gas much closer to the central object than previously detected The coincidence further suggests that the newly present very-broad-line-region (VBLR) gas may be associated with the increase in accretion rate that must occur in the standard picture

At first sight, it seems surprising that the VBLR is detected only in He II The lack of a correspondingly spectacular change in Hβ, or He I 5,876 Å is convincing evidence that the gas is fully ionized, namely, He is doubly ionized throughout the VBLR If so, then the I(4,686 Å)/I(Hβ) intensity ratio would be near its case B value of ~1 for a solar composition Strong VBLR Hβ emission is not expected Although Hβ appears much sharper than He II 4,686 Å, tests show that a fairly substantial component of very broad Hβ could exist in the observed profile Line profile synthesis shows that the I(4,686 Å)/I(Hβ) ratio in the VBLR lies between 1 and 2 If both lines radiate with case B emissivities then this ratio sets the limits $0\,1 \leq \text{He/H} \leq 0\,2$, that is, the material does not seem to be highly processed

A simple argument suggests that the new component of gas nearly covers the continuum source completely For conditions in the BLR, where the gas is optically thick to ionizing radiation, the equivalent width of Ly-α is related to the mean optical-X-ray continuum slope by $W(\text{Ly-}\alpha) = (1{,}216/\alpha)(912/1{,}215)^{\alpha}(\Omega/4\pi)$, where α is the spectral index and $\Omega/4\pi$ is the covering factor of absorbing gas This assumes that each ionizing photon eventually produces one Ly-α The spectral index is[8] $\alpha_{\text{ox}} \simeq 1\,1$, corresponding to a BLR covering factor of ~15% This value is fairly typical of AGN The He II I(4,686 Å)/I(Hβ) ratio before the increase in luminosity was also fairly typical of active nuclei (see Fig 1) If we take the pre-increase 4,686-Å flux as typical of gas with a 15% covering factor, then the roughly sevenfold increase in equivalent width at 4,686 Å corresponds to an increase in the covering factor to 50-100% The increased equivalent width further suggests that the VBLR gas absorbs the majority of the He$^+$-ionizing radiation ($\lambda \leq 228$ Å) This fact, together with the large covering factor, suggests that it is this ephemeral VBLR that may account for the variable low-energy X-ray absorption characteristic of low-luminosity Seyfert galaxies[9] The fact that the VBLR does not contribute He I lines (He I lines are present in our spectra, but have widths similar to the Balmer lines) shows that the VBLR is not, however, optically thick to He$^+$-ionizing radiation

Simple calculations allow estimation of the column density and mass of the VBLR gas For an assumed distance of 70 Mpc the 4,686-Å flux at maximum light is $\sim1\,0\times10^{41}$ erg s^{-1} This corresponds to an emission measure of $N^2V = 8\times10^{66}$ cm^{-3}, assuming a temperature of 10^5 K and He/H = 0 1, where N is the hydrogen density and V the emitting volume There is no reliable density indicator in the VBLR spectrum that we observe, but if we assume a density of 10^{10} cm^{-3} (a typical BLR density) and full coverage at a distance of 3×10^{16} cm then the VBLR gas has a column density of $\sim7\times10^{22}$ cm^{-2}, typical of X-ray absorbing gas The geometry of this gas is unclear because unpublished photoionization calculations show that such clouds would be unstable to disruption by radiation pressure The emission measure also corresponds to a mass of 0 8 $M_{\odot}$, assuming a solar composition An obvious possibility is that the rapid appearance of the VBLR was the result of the disruption of a star Such conjectures are beyond the scope of this report, but a possibility is that a star was disrupted in the inner regions of the system when the optical continuum began to rise, but that the newly added gas only became spectroscopically active in the optical region when debris was ejected to nearly the BLR radius

We have shown that a new emission-line region, not previously detected in the optical spectrum, appeared when the non-thermal continuum in NGC 5548 increased in luminosity If current ideas about the energy source in AGN are correct, then such an increase in luminosity can only be caused by an increase in the accretion rate in the innermost regions of the nucleus We believe that we have actually observed such an accretion event in progress

Large-amplitude semidiurnal temperature variations in the polar mesopause: evidence of a pseudotide

R. L. Walterscheid*, G. G. Sivjee*, G. Schubert* & R. M. Hamwey†

† Department of Physics and Astronomy, Dartmouth College, Hanover, New Hampshire 03755, USA

Current atmospheric tidal models[1,2] predict an amplitude of ≲2 K for the solar semidiurnal temperature variations in the polar mesopause (~85 km altitude) during the winter solstice period. In contrast, here we report an amplitude of about 13 K for the 12-h variations in the mesopause temperature at Longyearbyen, Spitsbergen (78.2° N) on UT day 359 in 1984. The kinetic temperature of the mesopause was deduced from the thermalized rotational distribution of the mesopause airglow OH(8,3) vibrational–rotational band emission in the near-infrared spectral region. A semidiurnal 'pseudotide' is proposed as the source of the observed large-amplitude 12-h temperature variation. This pseudotide is generated by gravity-wave momentum fluxes modulated by the true semidiurnal tide[3]. The semidiurnal pseudotide is very efficiently excited at very high latitudes. Based on conservative values of gravity-wave amplitudes, we estimate a temperature amplitude of ~10 K.

Certain exothermic chemical reactions among mesopause constituents, particularly the interaction of O_3 with H, produce OH in vibrationally and rotationally excited states The radiative lifetime of these radicals is ~1 ms, whereas the collision frequency in the mesopause is $\sim 10^4 \, s^{-1}$ Consequently the OH radicals undergo ~10 collisions, on average, before shedding their excess energy, and their distribution among the rotational states is thermalized to the ambient kinetic temperature Measurements of the relative intensities of the airglow OH rotational-line emissions can therefore provide a measure of the mesopause kinetic temperature

Spectroscopic observations of the OH rotational lines in the P_1 and P_2 branches of the (8,3) and the (6,2) vibrational–rotational bands were made in Longyearbyen, Spitsbergen, in December 1984 The high latitude of the observatory (78 2° N) permitted continuous 24-h observations of the wintertime polar airglow On UT day 359 in 1984 the spectroscopic observations around 7,300 and 8,500 Å showed no auroral band emissions or O II 7,320-Å line emission, and only a weak O I 8,446-Å line emission The absence of a significant level of any auroral optical emission indicates that there were no particle precipitation events during this period energetic enough to have had any effect on the thermodynamics of the mesopause The local solar shadow height above the Longyearbyen observatory was >150 km over the entire observing period

We analysed the relative intensities of the spectrally resolved OH rotational lines, using Mies's[4] transition probabilities and Kvifte's[5] as well as Coxon and Foster's[6] rotational-term values and emission wavelengths, to derive the mesopause temperature, T The average temperature, $\bar{T}$, of the mesopause over the 24-h period on UT day 359 in 1984 was 219±2 K For comparison with other reports of mesopause temperature variations (albeit of shorter period, see, for example, Krassovsky[7]), we have analysed the normalized changes in temperature, that is, $(T-\bar{T})/\bar{T}$ Figure 1 shows the time history of this quantity for the 24-h period on UT day 359 in 1984, and also the 12-h component of the temporal spectrum calculated by Fourier analysis of the temperature-data set The major mode of the wave-like structure in the time history of $(T-\bar{T})/\bar{T}$ is clearly the semi-diurnal wave with an amplitude of 0 0574, which corresponds to $T-\bar{T} \simeq 13$ K

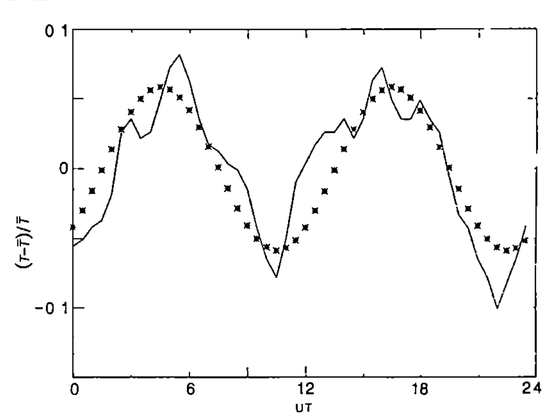

Fig 1 Time history of normalized changes in mesopause temperature, that is, $(T-\bar{T})/\bar{T}$, for a 24-h period on UT day 359 in 1984 (continuous curve) The contribution attributable to the 12-h Fourier component (*) is also shown

Forbes's[2] model calculations of the semi-diurnal components of the solar and lunar atmospheric tides predict amplitudes of 2 0 and 0 4 K at 87 km height in the polar region (78° N) during the December solstice period Our calculations, using the model described in ref 1, predict even smaller amplitudes (<1 K) This model includes a large number (8) of the conventional zonal wavenumber 2 semidiurnal modes Clearly, the normal tidal oscillations of the atmosphere do not account for the order-of-magnitude larger amplitude of the observed semidiurnal temperature oscillations The observed temperature oscillations also cannot be due to very-high-order solar-driven modes, which potentially have significant amplitudes at high latitudes, because these modes are only weakly excited by global solar forcing, and local solar forcing is lacking in winter The observed temperature oscillations might be due to the viscous distortion of the principal solar-driven modes This distortion can broaden the latitude region having significant amplitude However, such strong broadening has not been seen at emission altitudes in a model that includes this effect[2]

The occurrence of semidiurnal oscillations in polar-latitude mesopause temperatures is not an unusual event Myrabø[8] co-added 19 days of airglow data from Spitsbergen for the period 9-27 December 1982 and found a semidiurnal temperature amplitude of ~3 K, but no diurnal variation Viereck *et al* (R A Viereck, C H Deehr, G G Sivjee and G J Romick, manuscript to be submitted to *Planet Space Sci*, hereafter referred to as VDSR) report that semidiurnal oscillations are seen in more than half the OH airglow data obtained from Spitsbergen during the winters of 1984-85 and 1985-86 In some of the data the semidiurnal oscillations are quite large, the co-addition of five consecutive days of data gave a predominantly semidiurnal variation with a peak-to-peak amplitude of ~16 K Forbes[2], on the other hand, predicts a predominantly diurnal variation at the latitude of Spitsbergen VDSR do report the presence of diurnal variations in their inferred mesopause temperatures

The above considerations suggest the possibility of a high-latitude source for the oscillations such as Joule and particle heating in the lower thermosphere However, conventional semidiurnal modes are not good candidates for exhibiting the effects of high-latitude forcing because, even though extremely high-order modes can potentially have appreciable amplitude at high latitude, they are strongly absorbed by dissipative processes in the lower thermosphere and, moreover, are only weakly excited by high-latitude heating Because these modes are not confined to high latitude, but are global in extent, high-latitude heating does not project well onto these modes In fact, the totality of conventional semidiurnal modes (denoted gravitational modes by Flattery[9]) are not able to resolve very-high-latitude thermal forcing Gravitational modes alone are not complete, and another set of modes called rotational modes[9] are required when $\lambda = \omega/2\Omega < 1$, where ω is the wave angular frequency and Ω is the Earth's angular speed For solar semidiurnal tides $\lambda = 0\ 9973$ Rotational modes with $\lambda \simeq 1$ are trapped very close to the pole[10] The main difficulty with invoking rotational modes as the source of the observed temperature variation is that these modes are evanescent and have very short vertical scales ($\lesssim$300 m), they would therefore require very strong local forcing, which does not exist at mesopause altitudes during polar night These modes might be viable if strong mean wind effects altered the effective rotation rate and if the OH airglow emissions were coming from altitudes much higher than now believed Also significant in the data of Fig 1 is the lack of any substantial power at the frequency of the diurnal tide If the semidiurnal tide were responding to high-latitude forcing then the diurnal tide ought to be even more prominent because certain diurnal modes respond more efficiently to high-latitude sources than do the semidiurnal modes

It is possible that the semidiurnal variation reflects near-inertial oscillations, because the inertial period at Spitsbergen is nearly semidiurnal (12 3 h) However, it seems unlikely that free inertial waves would show the phase coherence seen in Fig 1 over two complete cycles Moreover, inertial motions are mainly horizontal and are associated with small temperature fluctuations Also, near-inertial waves have very short vertical wavelengths, but the time series for emission intensity for two different OH bands ((8,3) and (6,2)) show semidiurnal variations that are essentially in phase, although the emission heights for the two bands are separated by a few kilometres

We propose that the observed semidiurnal temperature oscillation is a pseudotide driven by gravity-wave-mean-flow interactions modulated by the solar-driven tide The pseudotide is generated as follows the rate at which gravity waves force the mean flow increases as $|\bar{u}-c|$ decreases, where $\bar{u}$ is the component of the large-scale flow in the direction of wave propagation, and c is the phase velocity of the wave, both quantities are positive eastward For convenience, consider zonally propagating two-dimensional waves with $\bar{u}$ the zonal component of the semidiurnal tide Waves with $c > 0$ ($c < 0$) impart an eastward (westward) acceleration to $\bar{u}$ During the eastward (westward) phase of the semidiurnal oscillation eastward (westward) propagating waves are preferentially absorbed The net effect is to induce a semidiurnal contribution to $\bar{u}$ which is non-tidal This mechanism is discussed in more detail in ref 3

In the simple case of zonally propagating two-dimensional gravity waves the forcing of the mean flow can be expressed as $\partial^2\bar{u}/\partial t^2 + f^2\bar{u} = (\partial/\partial t)\bar{G}$, where $\bar{G} = -(1/\rho_0)(\partial/\partial z)\rho_0\overline{u'w'}$, $f = 2\Omega \sin\phi$ is the Coriolis parameter (ϕ is latitude), ρ_0 is a reference density profile, z is height, and u' and w' are respectively the zonal and vertical gravity-wave velocities The quantity $\bar{G}$ is the forcing of $\bar{u}$ due to the wave-momentum flux convergence An overbar refers to a spatial average taken over a distance equal to the wavelength of the longest gravity waves making significant contributions to the momentum flux When $\bar{G}$ is periodic with semidiurnal frequency $\omega \simeq 2\Omega$, $\hat{u} = -[i\omega/(\omega^2 - f^2)]\hat{G} \simeq -(1/\cos^2\phi)(1/\omega)\hat{G}$, where $\hat{G}$, $\hat{u}$ are the Fourier transforms of $\bar{G}$, $\bar{u}$ At the latitude of Spitsbergen the amplification factor $\alpha = |\omega^2/(f^2 - \omega^2)|$ ($= 1/\cos^2\phi$, for $\omega = 2\Omega$) is 23 for the semidiurnal frequency By contrast, $\alpha = 0\ 35$ for the diurnal frequency At 60° N, $\alpha = 4$ for the semidiurnal frequency Thus strong amplification in polar regions is limited to the semidiurnal frequency, and to very high latitude A semidiurnal oscillation with an amplitude of $\sim$10 m s^{-1} could be induced near mesopause heights for conservative gravity-wave amplitudes[3] and $\alpha \sim 2$

Thus it seems possible for a gravity-wave semidiurnal tide interaction at very high latitudes to force a large-amplitude pseudotide The plausibility of the interaction is enhanced by the relatively large semidiurnal tidal-wind speeds Semidiurnal tidal-wind velocities are not proportionately as small as temperature oscillations at high latitudes because the latitudinal structure functions for the wind components decay toward the poles much more slowly than do the temperature functions (that is, Hough functions) Our tidal model predicts semidiurnal tidal velocities of $\sim$20 m s^{-1} near 90 km at 75° N during the winter This estimate, together with the results presented in ref 3 for a gravity-wave phase speed of $\sim$20 m s^{-1}, suggest pseudotide amplitudes of $\sim$50 m s^{-1} at Spitsbergen, provided that momentum fluxes are comparable In the calculations gravity-wave amplitudes were 10 m s^{-1} at 80 km, compared with observed r m s amplitudes of $\sim$20–40 m s^{-1} (refs 11, 12) Amplitudes at very high latitudes have not been measured, but the latitude dependence is apparently not strong[11-14] Wintertime observations at Heiss Island (80 4° N) show semidiurnal wind amplitudes of $\sim$10 m s^{-1} (ref 15) These values are averages over the meteor region ($\sim$80–100 km) and are monthly averages based on three winters Because the dominant tidal modes at high latitude are apt to have short vertical wavelengths ($\sim$20 km) and because the induced tide is apt to be rather variable in time (reflecting variable gravity-wave fluxes), predictions of large semidiurnal velocities are consistent with the observations

To estimate the induced oscillation of temperature we must take into account divergent motions that result when mean quantities vary in latitude The temperature change, $\bar{T}$, resulting from adiabatic heating and cooling can be estimated as follows From the continuity equation $\bar{w} \sim (M/L)\bar{u}$, where L is the meridional length scale and M is the vertical length scale In obtaining this equation we have used $\bar{u} \sim \bar{v}$, where $\bar{v}$ is the meridional wind component From the first law of thermodynamics $\bar{T} \sim (1/\omega)\Gamma_a[(M/L)\bar{u}]$, where the quantity in square brackets is $\bar{w}$ and where Γ_a is the adiabatic lapse rate ($= g/c_p$, where g is the acceleration of gravity and c_p is the specific heat of air at constant pressure) With $\Gamma_a = 10^{-2}$ K m^{-1}, $M \sim 20 \times 10^3$ m$/2\pi \sim 3 \times 10^3$ m, $L \sim 10^6$ m (L is the half width of the region over which α is large and the driving tide is sensible, the tidal amplitudes vanish at the pole) and $\bar{u} \sim 50$ m s^{-1}, we obtain $\bar{T} \sim 10$ K This estimate agrees well with the observed amplitude of 13 K It is also consistent with the results of Myrabø[8] and VDSR mentioned above These results were based on averages over a number of days because the day-to-day variability of the semidiurnal variation in temperature can be quite large This large temperature variability perhaps reflects the unsteadiness of the gravity wave fluxes[3]

We note finally that some authors have observed a connection between stratospheric warmings and changes in the amplitude of the semidiurnal tide (ref 16 and VDSR) The observations presented here were made one day before the onset of a sudden warming was observed in stratospheric data[17] and several days before the characteristic mesopause cooling was observed in airglow data (VDSR) Thus there is no obvious connection between the large-amplitude semidiurnal variation in the data we have presented and the sudden warming However, VDSR observed an enhancement in semidiurnal amplitudes after the mesospheric cooling Processes associated with sudden warmings can affect tides by redistributing ozone and modifying the thermal drive, or by changing the background wind system and modifying mode coupling[18,19] or the transmission of vertically propagating gravity waves

Neither thermal driving nor mode coupling seems viable because neither mechanism seems able to explain the amplification of the very-high-order modes required to explain large-amplitude tides at very high latitudes The required amplification of these modes cannot be due to ozone redistribution at polar latitudes because of the absence of sunlight, or to mode coupling because this process is ineffective in generating very-high-order modes from the lower-order energy-containing ones[19] Moreover, there is no reason to believe that mode coupling is significantly stronger in the pre-warming atmosphere than in the post-warming one In addition, it is very unlikely that changes in the thermal drive and mode coupling would act to amplify the semidiurnal tide and not the diurnal one No such amplification of the diurnal oscillation is observed at Spitsbergen (VDSR)

The observed enhancement of the semidiurnal oscillation might be due to an enhanced flux of gravity waves associated with the breakdown of the polar vortex An enhanced prevalence of large-amplitude waves has been observed (C R Philbrick, personal communication) and the semidiurnal pseudotide forced by this mechanism would be favoured over a one

Perturbation of the background radiation by a moving gravitational lens

L. I. Gurvits & I. G. Mitrofanov

Space Research Institute, Academy of Sciences USSR,
Profsojusnaja 84/32, 117810 Moscow, USSR

Birkinshaw and Gull[1] considered the perturbation of the cosmic background radiation by a moving gravitational lens (GL). An estimate of the maximum amplitude makes it seem possible that this effect may soon be observed, leading to the measurement of non-Hubble velocities of cosmological objects. Such measurements may become a significant test for cosmological models. We present here the general formula for this effect, which differs essentially from that in ref. 1.

Brightness $B(\nu, \mathbf{n})$ is transformed from a reference frame (A) to another (C), moving with velocity $\mathbf{V}_{AC}$ as follows [2]

$$B_C(\nu, \mathbf{n}_C) = (1-\Delta_{AC})^3 B_A[\nu/(1-\Delta_{AC}), \mathbf{n}_A] \qquad (1)$$

where

$$\Delta_{AC} = 1 - \frac{(1-V_{AC}^2/c^2)^{1/2}}{1-\mathbf{V}_{AC} \cdot \mathbf{n}_C/c} \simeq -\frac{\mathbf{V}_{AC} \cdot \mathbf{n}_C}{c}$$

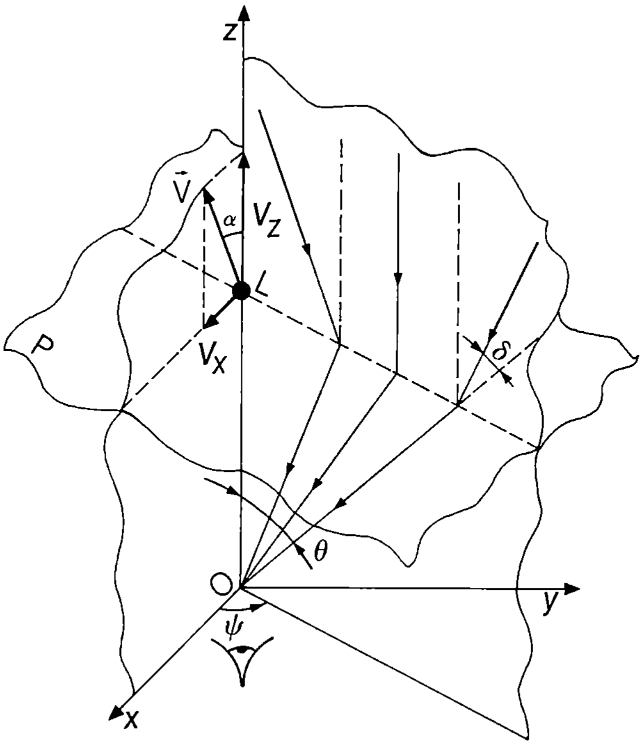

Fig 1 The geometry of the problem O is the observer, L is the position of the gravitational lens moving with velocity **V** in the X-Z plane, P is the picture plane, α is the angle between **V** and the Z axis, δ is the deflection angle, ψ is the position angle, and θ is the angle between the Z axis and the line of sight

ν is the radiation frequency in frame C, and $\mathbf{n}_A$ and $\mathbf{n}_C$ are the directions of propagation of the radiation at A and C, respectively To find the background brightness after lensing by a moving mass one uses transformation (1) twice the first time to transform from the background co-moving frame to the frame of a moving GL, and the second time to return from the moving GL frame to the background frame The deflection of geodetic lines in the GL frame is a cause of the perturbation in background brightness

Using this procedure one obtains for $\beta = V/c \ll 1$ the brightness perturbations

$$\frac{\Delta B(\nu, \mathbf{n})}{B_0(\nu)} = 2\beta[\cos\alpha \sin(\theta - \tfrac{1}{2}\delta)\sin\tfrac{1}{2}\delta - \sin\alpha\cos\psi\cos(\theta-\tfrac{1}{2}\delta)\sin\tfrac{1}{2}\delta] \times \frac{(h\nu/kT)\exp(h\nu/kT)}{\exp(h\nu/kT)-1} \qquad (2)$$

where B_0 and T are the initial background brightness, temperature and angles α, δ, ψ and θ are defined in Fig 1

In the Rayleigh-Jeans (RJ) part of a black-body spectrum the last factor of (2) is about 1 However, for the Wien part it is proportional to the frequency, but the brightness is exponentially small In the square brackets the first item corresponds to the longitudinal motion of GL It agrees with the previous result[3] in the RJ spectral region On the other hand, in ref 3 the 'transverse' part of the effect, corresponding to the second item of (2), was ignored For $\delta \ll \theta \ll 1$ the 'transverse' effect dominates the 'longitudinal' one It should be noted that transverse and longitudinal effects form different patterns in the picture plane The former does not depend on ψ, and thus the corresponding perturbation looks like a spot with circular symmetry, the latter includes the dipole term $\cos\psi$ and the corresponding perturbation has a central dipole asymmetry

Comparing (2) with equation (12) in ref. 1 one may conclude that the latter takes into account only the transverse effect. What is more, there is a discrepancy by a factor of -2 between amplitudes of the effect for the RJ spectral region. It seems that equation (12) in ref. 1 was obtained by excluding the factor $(1-\Delta_{AC})^3$ from the formula of brightness transformation such as (1).

An order of effect for the RJ spectrum may be estimated by a simple expression, which follows from (2),

$$\Delta B/B \sim \Delta T/T \sim \beta\delta \qquad (3)$$

Recently Collins *et al*[4] found indications of non-Hubble velocities of galaxies of the order of 1,000 km s^{-1}, i.e. $\beta \simeq 3\times10^{-3}$. One may use the angle between two lensed images to estimate the deflecting angle. There are some proposals (refs 5 and 6) that the two quasars 1146+111 B and C, separated by 157″, are in fact two lensed images. This value corresponds to $\delta \simeq 0.7\times10^{-3}$. Using these optimistic values we obtain $\Delta T/T \sim 2\times10^{-6}$. This is not far from today's sensitivity level, so the effect must be taken into account in future experiments.

We shall present elsewhere a general analysis of the complete effect based on this formula, both for $\delta < \theta$ and for $\delta \gg \theta$, and also for all β, not just for $\beta \ll 1$.

The near-parabolic flux and the origin of short-period comets

M. E. Bailey

Department of Astronomy, The University,
Manchester M13 9PL, UK

The origin of short-period comets, usually believed to arise by planetary perturbations acting on nearly parabolic orbits, has been unclear for many years[1]. Given the observed near-parabolic flux, the predicted number of such comets is too small by a factor of ~100 (refs 2–15). It has been suggested, therefore, that the adopted near-parabolic flux is in error[16], that a physical effect such as fragmentation[3,17,18] could operate, or that short-period comets do not come from the outer Oort cloud at all[9,10,13,19]. It has been proposed[13–15,20,21] that the problem could be resolved by postulating a comet belt or massive inner core to the Oort Cloud. Here I recalculate the flux of nearly parabolic orbits from the Oort Cloud, including the recently discovered dominant injection of comets by the galactic tide[22–25]. The observed number of short-period comets is consistent with the Oort Cloud having a massive inner core[26].

Consider a spherically symmetrical comet cloud characterized by an energy distribution $N(E)$ defined[26] so that the number of comets with energy per unit mass E in the range $(E, E+\mathrm{d}E)$ is

$$N(E)\,\mathrm{d}E = K(E/\hat{E})^{-\gamma}\,\mathrm{d}E \qquad (1)$$

where γ is the index of the energy spectrum ($\gamma = 5/2$ for Oort's standard model[27]), $E = -GM_\odot/2a$ is the specific energy of an orbit with semi-major axis a, $\hat{E} = -GM_\odot/2R_0$, $R_0 \simeq 2\times10^5$ AU is the outer radius of the cloud and K is a constant defined[26] in terms of the observed near-parabolic flux and other parameters of the model. One can assume that comets with perihelion distances $q < q_{\mathrm{lc}}$ are removed from the Oort Cloud by planetary perturbations, and adopt[28] $q_{\mathrm{lc}} \simeq 15$ AU. This defines a loss cylinder in velocity space, containing nearly parabolic comets with specific angular momenta $J < J_{\mathrm{lc}} = (2GM_\odot q_{\mathrm{lc}})^{1/2}$.

It is now possible to calculate the rate of injection of comets into the loss cylinder by stars and the galactic tide. The stellar injection rate per unit semi-major axis is[24,26]

$$F_{\mathrm{lc},*}(a) = 4\pi^2 f(a) J_{\mathrm{lc}}^2 \frac{GM_\odot}{2a^2}\begin{cases}\dfrac{\sigma_J^2(a)}{k^2(a)J_{\mathrm{lc}}^2} & a < a_* \\ 1 & a > a_*\end{cases} \qquad (2)$$

where a_* (see below) is the critical semi-major axis above which stellar perturbations alone are able to fill the loss cylinder, $f(a)$ is the phase-space distribution function defined in terms of equation (1) by[26]

$$f(a) = \frac{K}{8\pi^3} R_0^{-\gamma}(GM_\odot)^{-1/2} a^{\gamma-5/2} \qquad (3)$$

and $\sigma_J(a)$ is the r.m.s. change in specific angular momentum per revolution due to stellar perturbations. $k(a)$ is a slowly varying logarithmic function on the order of 2, which can be taken[24] to be

$$k^2(a) = \tfrac{1}{2}[\ln(a/2q_{\mathrm{lc}}) - 1] \qquad (4)$$

and[28]

$$\sigma_J^2(a) \simeq \tfrac{4}{3} P(a)\langle r^2 \varepsilon_*(r)\rangle \qquad (5)$$

where $P(a) = 2\pi(GM_\odot)^{-1/2}a^{3/2}$ is the orbital period and $\varepsilon_*(r)$ is the mean stellar energy transfer rate to comets at r with semi-major axes a (Heisler and Tremaine's expression[24] is not used because, as they remark, their result is invalid for $a \leqslant 4\times10^4$ AU.) The mean stellar energy transfer rate is given approximately by[29]

$$\varepsilon_*(a) \simeq \frac{4\pi G^2 M_*^2 n_*}{V_*}\begin{cases}(a/a_{\mathrm{c}})^2 & a < a_{\mathrm{c}} \\ 2\ln(a/a_{\mathrm{c}}) + 1 & a > a_{\mathrm{c}}\end{cases} \qquad (6)$$

where $a_{\mathrm{c}} \equiv \sqrt{\tfrac{12}{7}}\, b_{\min}$ and $b_{\min} = (2\pi n_* V_* T)^{-1/2}$ is the smallest impact parameter expected during the time T over which $\varepsilon_*(a)$ is averaged. Thus,

$$\frac{\sigma_J^2(a)}{k^2(a)J_{\mathrm{lc}}^2} = \frac{80\pi^2}{3}\,\frac{(GM_\odot)^{1/2}}{q_{\mathrm{lc}}}\,\frac{n_* M_*^2}{V_* M_\odot^2}\, a^{7/2} g(a) \qquad (7)$$

where

$$g(a) = \frac{1}{[\ln(a/2q_{\mathrm{lc}}) - 1]}\begin{cases}(a/a_{\mathrm{c}})^2 & a < a_{\mathrm{c}} \\ 2\ln(a/a_{\mathrm{c}}) + 1 & a > a_{\mathrm{c}}\end{cases} \qquad (8)$$

This allows the stellar-induced flux into the loss cylinder and a_* to be evaluated. Being concerned with filling the loss cylinder during one revolution, it is necessary to set $T = P(a)$, and adopt $n_* = 0.1$ pc^{-3}, $V_* = 30$ km s^{-1} and $\langle n_* M_*^2\rangle = \tfrac{4}{3}\times 0.03 M_\odot^2$ pc^{-3}, where the factor $\tfrac{4}{3}$ is to include the effects of close binaries[30]. This leads to $a_* \simeq 5.0\times10^4(q_{\mathrm{lc}}/15\ \mathrm{AU})^{2/7}$ AU, significantly larger than the value previously obtained[24]. This strengthens the conclusion[23,24] that stellar perturbations are relatively ineffective at filling the loss cylinder. (The results are different because with $T = P(a)$, $b_{\min}$ is typically in the range 1–2 × 10^4 AU and $g(a) \leqslant 1/2$. For comparison, if one sets $T = T_{\mathrm{SS}} = 4.5\times10^9$ yr, then $b_{\min} \simeq 700$ pc $\ll a$ and $g(a) \geqslant 1$. a_* is then $3.6\times10^4(q_{\mathrm{lc}}/15\ \mathrm{AU})^{2/7}$ AU, in agreement with the earlier value[24].) A similar result for a_* has been independently obtained by Fernández and Ip[31].

Next, consider the injection rate of comets by the galactic tide. This reduces[24] to

$$F_{\mathrm{lc,t}}(a) = 4\pi^2 f(a) J_{\mathrm{lc}}^2 \frac{GM_\odot}{2a^2}\begin{cases}\dfrac{10}{3\sqrt{2}}\,\dfrac{C_{\mathrm{gal}}}{GM_\odot q_{\mathrm{lc}}^{1/2}}\, a^{7/2} & a < a_{\mathrm{t}} \\ 1 & a > a_{\mathrm{t}}\end{cases} \qquad (9)$$

where a_t, the critical semi-major axis above which the tide just fills the loss cylinder, is given by

$$a_t = \left[\frac{3\sqrt{2}}{10} GM_\odot q_{lc}^{1/2} C_{gal}^{-1}\right]^{2/7} \simeq 3.3\times 10^4 \left(\frac{q_{lc}}{15\ \mathrm{AU}}\right)^{1/7}\ \mathrm{AU} \quad (10)$$

Here a galactic force law perpendicular to the galactic plane of the form $g_z = -C_{gal}z$, with $C_{gal} \simeq 10^{-29}\ \mathrm{s}^{-2}$ has been assumed[32]. This corresponds to a mid-plane density (see refs 24, 33) $\rho_0 = C_{gal}/4\pi G = 0.176 M_\odot \mathrm{pc}^{-3}$. For $a < a_t$ the ratio of the tidal to stellar injection rates is therefore

$$R_{t/*} = \frac{\sqrt{2}}{16\pi^2} \frac{q_{lc}^{1/2} V_*}{(GM_\odot)^{3/2}} \frac{C_{gal}}{\frac{1}{M_\odot^2}\langle n_* M_*^2\rangle} \frac{1}{g(a)} \quad (11)$$

which, with the adopted values of the parameters, reduces to $R_{t/*} = 1.933/g(a)$. Because $g(a) \simeq 1/5$ for $a = a_c \simeq 2\times 10^4$ AU one can conclude that the galactic tide dominates the stellar injection rate by about an order of magnitude at this value of a. For smaller a values, the tidal dominance of the injection rate increases.

This result (and that for a_* above) relies on equation (2), which in turn depends on a diffusion approximation to describe the quasi-steady distribution of comets near the loss cylinder. For $a \leq 2\times 10^4$ AU this assumption begins to break down because b_{min} becomes greater than a. Thus, although this approach should correctly give the general trend, the results are not expected to be precise. A recent Monte Carlo simulation by Heisler *et al*[34] indicates that the galactic tide dominates the stellar injection rate by a factor of ~4 at $a = 2\times 10^4$ AU.

An approximate total injection rate may thus be obtained by considering only the galactic tide. If a_0 is the semi-major axis corresponding to the inner edge of the Oort cloud, then

$$N_{tot} \simeq N_{tot,t} = \int_{a_0}^{R_0/2} F_{lc,t}(a)\, da \quad (12)$$

Substituting for f from (3) and introducing $x = a/a_t$, $\alpha_R = R_0/2a_t \gg 1$ and $\alpha_0 = a_0/a_t \ll 1$, this reduces to

$$N_{tot} = \frac{KR_0^{-\gamma}}{2\pi}(GM_\odot)^{3/2} q_{lc} a_t^{\gamma-7/2}\left\{\int_1^{\alpha_R} x^{\gamma-9/2}\, dx + \int_{\alpha_0}^1 x^{\gamma-1}\, dx\right\} \quad (13)$$

In this expression, the first term corresponds to comets with almost parabolic orbits and a nearly uniform distribution of perihelion distances, whereas the second corresponds to comets with rather shorter periods and perihelia close to q_{lc} (for example ref 28). The comets in this second group cannot be directly observed (as $q_{lc} \simeq 15$ AU), but those in the first group can be detected up to distances of the order of 5 AU. This allows the leading term of (13) to be re-written in terms of the observed nearly parabolic flux F_{obs}, defined here as the number of comets passing perihelion per unit time with perihelia less than some value D_{obs}. The ratio F_{obs}/D_{obs} is then nearly constant. Thus, from (13),

$$F_{obs} = \frac{KR_0^{-\gamma}}{2\pi}(GM_\odot)^{3/2} q_{lc} a_t^{\gamma-7/2} \int_1^{\alpha_R} x^{\gamma-9/2}\, dx \frac{D_{obs}}{q_{lc}} \quad (14)$$

so

$$N_{tot} = \frac{F_{obs}}{D_{obs}} q_{lc}\left\{1 + \frac{\int_{\alpha_0}^1 x^{\gamma-1}\, dx}{\int_1^{\alpha_R} x^{\gamma-9/2}\, dx}\right\} \quad (15)$$

The total number of short-period comets may now be obtained[13-15] by multiplying N_{tot} by three factors: the fraction f_{ι_0} of comets in the loss cylinder with small enough inclinations ($0 \leq \iota \leq \iota_0$) to be significantly affected by planetary perturbations, the mean planetary capture probability for each group of incoming comets including the effects of all the planets, and the average lifetime T_{SP} of observable short-period comets. The first factor may be approximately estimated by assuming that the incoming comets have random inclinations. In this case, although the assumption is not strictly accurate when the galactic tide drives the influx, $f_{\iota_0} = \frac{1}{2}(1 - \cos \iota_0)$. The second factor may be written as an integral over perihelion distance of the mean planetary capture probability $p(q)$, weighted according to the perihelion distribution of each group of comets. For the first group (distributed uniformly with q) this becomes

$$\bar{p} = \frac{1}{q_{lc}} \int_0^{q_{lc}} p(q)\, dq \quad (16)$$

whereas for the second group (concentrated close to $q = q_{lc}$) it is simply $\bar{p} = p(q_{lc})$. Following Fernández[13] in assuming that the mean planetary capture probability $p(q)$ has the step-wise form

$$p(q) = \begin{cases} 1/128 & 0.0 < q \leq 5.8\ \mathrm{AU} \\ 1/700 & 5.8 < q \leq 10.7\ \mathrm{AU} \\ 1/3{,}200 & 10.7 < q \leq 22\ \mathrm{AU} \\ 1/6{,}000 & 22 < q \leq 34\ \mathrm{AU} \end{cases} \quad (17)$$

gives $\bar{p} \simeq 0.054\ \mathrm{AU}/q_{lc}$ for the first group, and $\bar{p} = 1/3{,}200$ or $1/700$ for the second group, depending respectively on whether the planetary captures are dominated by Uranus ($q_{lc} = 15$ AU) or Saturn ($q_{lc} = 10$ AU). Adopting the values for Uranus, and setting[14,15] $\iota_0 = 30°$, $T_{SP} = 3{,}000$ yr, and $F_{obs} = 0.7\ \mathrm{yr}^{-1}$, corresponding to $D_{obs} = 2.5$ AU, then

$$N_{SP} \simeq \frac{F_{obs}}{D_{obs}} f_{\iota_0} T_{SP}\left\{\int_0^{q_{lc}} p(q)\, dq + p(q_{lc}) q_{lc} \frac{\int_{\alpha_0}^1 x^{\gamma-1}\, dx}{\int_1^{\alpha_R} x^{\gamma-9/2}\, dx}\right\} \quad (18)$$

or

$$N_{SP} \simeq 56.3\left\{0.054 + \frac{15}{3200}F(\gamma)\right\} \quad (19)$$

where $F(\gamma)$ is the ratio of the integrals appearing in the second term of (18). The observed number of short-period comets (~10^2) can thus be understood if $F(\gamma) \simeq 200$. This is clearly not possible in Oort's standard model with $\gamma = 5/2$, but for arguably more plausible models[26,30,35] with $\gamma < 0$ it is certainly possible. For example, adopting $R_0 = 2\times 10^5$ AU, $a_t = 3\times 10^4$ AU, $a_0 = 4\times 10^3$ AU and $\gamma = -2$, then we find $F(\gamma) \simeq 152$ and $N_{SP} \simeq 43$. On this model the flux of long-period comets through the Uranus capture zone is more than two orders of magnitude greater than expected from a simple linear extrapolation of the observed local flux.

A check on the model is provided by the total number of comets. This is readily calculated[26] as

$$N_0 = KR_0^{-\gamma}\frac{GM_\odot}{2}\int_{a_0}^{R_0/2} a^{\gamma-2}\, da$$

that is,

$$N_0 = \frac{F_{obs}}{D_{obs}}\pi(GM_\odot)^{-1/2} a_t^{5/2} \frac{\int_{\alpha_0}^{\alpha_R} x^{\gamma-2}\, dx}{\int_1^{\alpha_R} x^{\gamma-9/2}\, dx} \quad (20)$$

For the above parameters this gives $N_0 = 1.7\times 10^{13}$. With a mean mass per comet[36] ~2.6×10^{14} kg, the total mass of the cloud becomes $\simeq 700 M_\oplus$, a large but not unreasonable amount[37]. It is possible that such a mass of comets might already have been detected by the Infra-Red Astronomy Satellite[38-40].

Thus I have shown that the observed number of short-period comets may be understood in terms of the capture of Oort Cloud comets by planetary perturbations, provided that the cloud has a massive inner core and that the injection of new comets is dominated by the galactic tide. This is because the ratio of the tidal injection rate to that of the stars increases sharply ($\propto a^2$) for semimajor axes $\lesssim 3\times 10^4$ AU, and although injection by the galactic tide is less effective at smaller semi-major axes (equation (9)), the relative decline may be more than off-set if there is a sufficiently large number of comets in the inner core. As with some previous suggestions for overcoming the short-period comet problem[9,10,14,19], this analysis predicts that most short-period comets are initially captured by Uranus (or possibly Saturn), rather than Jupiter In particular, the present theory predicts that most short-period comet progenitors are injected by the galactic tide with relatively small semi-major axes close to a_0 ($\simeq$5,000 AU) In this case the short-period comet population would bear little or no relation to the observed near-parabolic flux, and the usual links between these comets and the more numerous observed long-period group are brought into question These results indicate the importance of detailed Monte Carlo simulations[41] aimed at discovering whether such original orbits evolve into observable short-period comets

I thank S V M Clube and W M Napier for comments on the manuscript and S D Tremaine for helpful suggestions and a preprint[34] This work was supported by the SERC

Inferences on the evidence for radioactive ^{53}Mn in the early Solar System

Typhoon Lee

Institute of Earth Sciences, Academia Sinica, PO Box 23-59,
Taipei, Taiwan (R O C) 10769

Several now-extinct radionuclides are believed to have been present in the early Solar System[1] and have been used to infer the time-scales for various processes during its formation. However, the precise interpretation of the chronometric significance of an extinct nuclide depends on whether isotopic heterogeneities exist in that nuclide and/or in its daughter product. This is probable because such heterogeneities have already been found in many elements. Birck and Allègre[2] have recently reported data suggesting the presence of a new extinct nuclide, ^{53}Mn (mean life $\tau = 5$ Myr). In this letter I show that their data are inconsistent with the prediction of a single-stage model in which both Mn and its daughter element Cr were isotopically homogeneous. I also explore the virtues and consequences of the three alternative interpretations of the inconsistency: (1) the host material has experienced multiple-stage evolution, (2) ^{53}Mn was heterogeneously distributed, or (3) ^{53}Cr has intrinsic anomalies.

The discovery of ^{26}Al, whose mean life is shorter than that of ^{53}Mn, in the early Solar System suggests the possibility that ^{53}Mn may have also existed[3] Recent searches for ^{53}Mn began with that of Nitoh *et al*[4] Lee and Tera[5 6] placed more stringent upper limits on its abundance However, positive results were not obtained until Birck and Allègre[2] developed superior analytical techniques enabling high-precision isotopic measurement of Cr (ref 7) They also discovered isotopic anomalies in ^{54}Cr in ordinary Allende inclusions, which were confirmed by Papanastassiou *et al*[8] Papanastassiou[9] further discovered much larger ^{54}Cr and ^{53}Cr anomalies in FUN (fractionation and unknown nuclear) inclusions The discovery of anomalies intrinsic to the Cr isotopes accentuates the importance of considering the effects of Mn and Cr isotopic heterogeneities in the discussion of the reported evidence for the presence of ^{53}Mn

Figure 1*a* shows the systematics of ^{53}Mn–^{53}Cr evolution in a diagram of ^{53}Cr/^{52}Cr against ^{55}Mn/^{52}Cr The time (before present) evolution of ^{53}Cr/^{52}Cr due to ^{53}Mn decay for object P formed at t_1 from source S can be described by

$$({}^{53}\mathrm{Cr}/{}^{52}\mathrm{Cr})_P(t) = I_1 + ({}^{53}\mathrm{Mn}/{}^{55}\mathrm{Mn})\,(t_1)\,(1 - \exp(t - t_1)/\tau) \times ({}^{55}\mathrm{Mn}/{}^{52}\mathrm{Cr})_P \qquad (1)$$

provided that this object and its source share the same initial ^{53}Cr/^{52}Cr(t_1) ($\equiv I_1$) and ^{53}Mn/^{55}Mn(t_1) and that the object is a closed system against Mn and Cr transport Notice that equation (1) represents a straight line in Fig 1*a* connecting the object, the source and the initial, whose slope increases with time up to the initial Mn ratio, whereas its intercept remains fixed at the initial Cr ratio However, at any time, the line always passes through the source composition for that time (heavy lines in Fig 1*a*) A group of such objects formed simultaneously at t_1 with initially homogeneous Mn and Cr ratios will thus form a linear array This is the well-known isochron for an extinct nuclide If such a group, after forming from the source, has remained closed until now (that is, experienced only single-stage evolution) then an isochron would be observed today and taken as evidence for the presence of ^{53}Mn at the formation time of the group I have thus shown that, in a single stage evolution model with initial isotopic homogeneities, the isochron always passes through the source point Applying this to the Allende meteorite and considering either different inclusions or different minerals in a single inclusion as a group formed directly from the solar nebula, we would thus expect that all such isochrons should pass through the normal Solar System point

Birck and Allègre[2] reported two 'isochrons', one of which consists of whole-rock data for the Allende inclusion with a slope corresponding to an initial ^{53}Mn/^{55}Mn ratio of $6\ 7 \times 10^{-5}$ The other consists of whole rock data for Allende inclusions with a slope corresponding to an initial ^{53}Mn/^{55}Mn ratio of $3\ 7 \times 10^{-5}$ Figure 1b shows these isochrons and also some key data points The whole inclusion isochron hinges on the data for G6 as noted in ref 2, also, it does not pass through SB The mineral isochron data span a relatively narrow range in Mn/Cr, giving a difference in ^{53}Cr/^{52}Cr only six times the standard error Further Cr isotopic studies, especially on primitive high-Mn/Cr samples, appear necessary to substantiate these ^{53}Mn isochrons

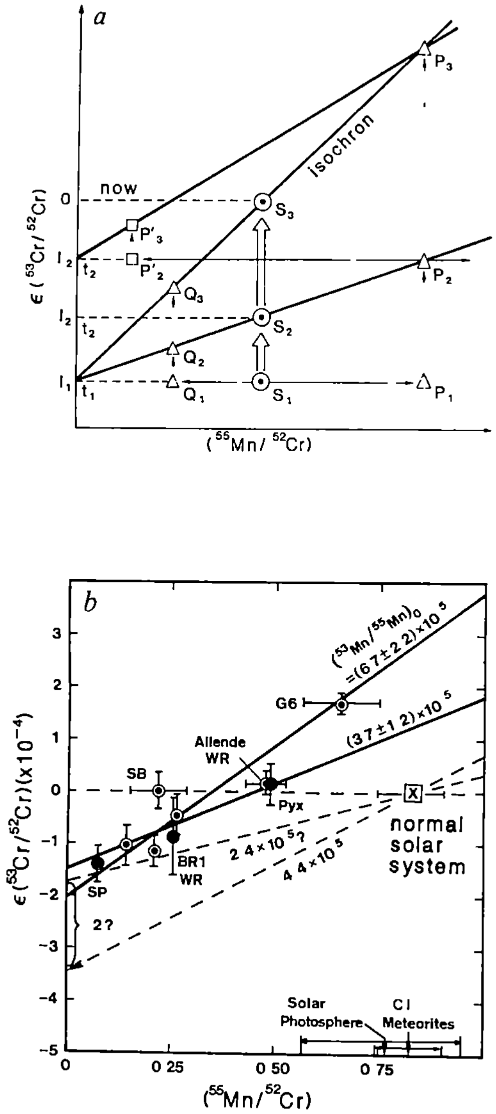

Fig 1 Mn-Cr isochron diagram $\varepsilon(^{53}Cr/^{52}Cr)$ is the fractional deviation of $^{53}Cr/^{52}Cr$ from the normal in unit of 0 01% *a*, Schematics The evolution of the Cr ratios by ^{53}Mn decay for a group of objects (*P*, *Q*, etc) formed from source *S* at time t_1 is described by equation (1) if they share the same initial Cr and Mn isotopic ratios as the source at t_1 and if they remain a close system They plot as a linear array ('isochron') whose intercept is fixed at the initial Cr ratios I_1 and whose slope gradually steepens, eventually reaching the initial $^{53}Mn/^{55}Mn$ ratio At any time the isochron for a group directly formed from the source (single-stage evolution) always passes through the source composition at that time, so the tie lines I_iS_i always coincide with isochrons P_iQ_i for $i = 1, 2, 3$ at time t_1, t_2 and 'now' Therefore, in this single-stage homogeneous model, the isochrons for Allende inclusions are expected to pass through the putative source composition, that of the Solar System (⊙) In contrast, the Solar-System point may show an offset from the isochrons in a multiple-stage model For example, the isochron for a group of objects like *P'*, which formed from an intermediate source reservoir P_2 at time t_2 that ultimately formed from *S* at an earlier time, does not pass through *S* The direction of the offset depends on whether the Mn/Cr for *P* is higher or lower than that of *S* *b*, Observed isochrons[2] and interpretations The observed isochrons do not pass through the Solar-System point and the uncertainty in the Solar-System Mn/Cr estimates based on either meteoritic or photospheric observations does not seem to be large enough to eliminate the offset If a two-stage evolution model for the Allende samples is invoked as the explanation, then the intermediate source reservoir must have a Mn/Cr higher than the solar value because of the direction of the offset Alternatively, Mn isotopic heterogeneity can explain the offset if the solar reservoir has a $^{53}Mn/^{55}Mn = 2\ 4 \times 10^{-5}$ assuming that it and the samples started with the same initial $^{53}Cr/^{52}Cr$ The offset can also be explained if the initial $^{53}Cr/^{52}Cr$ for the Allende inclusions is higher than that of the normal solar reservoir by about 0 02% The ratio of the inferred intrinsic ^{53}Cr excess to the observed ^{54}Cr excess (~0 3) for these ordinary inclusions is identical to that measured in the unusual FUN inclusion EK1-4-1 (ref 9) and thus may have come from a single anomalous component of Cr

In Fig 1*b* I have also plotted the normal Solar System point at $\varepsilon(^{53}Cr/^{52}Cr) = 0$ and $(^{55}Mn/^{52}Cr) = 0\ 85$ (ref 10) The 'isochrons' do not pass through the Solar System points, which contrasts with the prediction of the above model

We must first consider the possibility that the currently accepted Mn/Cr ratio for the Solar System is in error The spectroscopically determined solar photospheric value is 0 60 (corresponding to a $^{55}Mn/^{52}Cr$ ratio of 0 76) with an uncertainty of ~25% (ref 11) This estimate is consistent with the 'cosmic' value of 0 71, based on type CI meteorites, which has a nominal uncertainty of ~13% (see ref 10 and references therein) However, this is based almost exclusively on the data of Orgueil, whereas some of the limited data on Alais are discrepant An Mn/Cr of 0 3 is required to shift the Solar System point to the isochron If this is the correct interpretation, our present estimate for the Solar System Mn/Cr has to be too high by about a factor of two This seems unlikely in view of the consistency between the two estimates using different methods and their associated errors

If the isotopic measurements and the estimated solar Mn/Cr value are correct then one or more of the three alternatives mentioned earlier must explain the offset of the Solar System point Although the combination of more than one cause is possible it would be too intractable to allow a useful discussion, so I shall exclude the simple model's assumptions only one at a time The first alternative, multiple-stage evolution of the host material, is difficult to quantify This is because of the lack of constraints on the evolution during intermediate stages There are many combinations of the duration and the Mn/Cr ratio for the intermediate stage that can explain the reported offset Figure 1*a* shows a relatively simple two-stage evolution model that can be used to explain the offset and its direction Object P_1 formed at t_1 from S_1 would reach point P_2 at t_2, hence a sample formed from P_2, acting now as the intermediate source reservoir, would have the initial ratio I'_2, much higher than I_2, which is the initial for an object formed directly from S_2 Connecting the initial with the intermediate source, line $I'_2\ P_3$ is the isochron observed today for the samples that experienced the two-stage evolution It passes through P'_3 but not through S_3, thus producing an offset from the Solar System point We note that the direction of the offset depends on whether the intermediate-stage reservoir has a Mn/Cr ratio higher or lower than the solar value Since the reported isochrons are to the left of the Solar System point, the intermediate-stage reservoir must have a Mn/Cr ratio higher than the solar value This is somewhat surprising because in refractory samples such as Allende inclusions this ratio is lower than the solar value The required high-Mn/Cr intermediate source reservoir from which the inclusions formed must be less refractory than the inclusions

The remaining two alternatives have to do with isotopic heterogeneities rather than chemical fractionation The offset of the normal Solar System point from the isochrons can be understood if Allende inclusions have a higher $^{53}Mn/^{55}Mn$ than the Solar System However, because the initial $^{53}Cr/^{52}Cr$ of the inclusions is lower than normal and we assume that the initial Cr ratios of the inclusions were the same as the source (that is the solar) reservoir, the ^{53}Mn abundance in the normal Solar System material must be non-zero so that its decay can eventually increase the $^{53}Cr/^{52}Cr$ to the present value The required $^{53}Mn/^{55}Mn$ ratio can be obtained by connecting the Solar System point to the initial Cr ratio of the observed isochrons The slope of this line corresponds to a $^{53}Mn/^{55}Mn$ of about $2\ 4 \times 10^{-5}$ (see Fig 1*b*) We note that inclusion SB has a normal $^{53}Cr/^{52}Cr$ today If it also started from the same initial Cr ratio as other inclusions then it coincidentally started from the right amount of ^{53}Mn, higher than that for other inclusions, to give a normal $^{53}Cr/^{52}Cr$ today Or, more likely, it equilibrated later with the Solar System reservoir after all the ^{53}Mn had decayed away This situation is reminiscent of the case of ^{26}Al where heterogeneities were also suspected[1]

Table 1 Estimated composition of the anomalous component

Nuclide	Observed abundance*	e − process abundance† $\eta = 0\ 0710$	$\eta = 0\ 0837$	Normal

* For assumptions see text
† Ref 12, all ^{54}Mn are assumed to have decayed into ^{54}Cr

The last alternative is that the Allende samples began with a ^{53}Cr/^{52}Cr higher than that for the normal solar system material The required amount can be found from Fig 1*b* If we draw an isochron through the Solar System point with a slope equal to the average of the published isochrons, this line would intercept the vertical axis at ~0 02% below the initial for the Allende samples Thus the offset can be explained if the inclusions started with an initial intrinsic ^{53}Cr excess of 0 02% relative to the Solar System ratio at the time of formation of the inclusions Because these samples already have excesses in ^{54}Cr of about 0 06%[7,8], it seems plausible that the neighbouring neutron-rich Cr isotope also has some accompanying excesses The possibility that part of ^{53}Cr effects in ordinary inclusions is intrinsic to this nuclide is enhanced by the recent discovery of a large ^{53}Cr excess in FUN inclusion EK1-4-1 by Papanastassiou[9], who concluded that it is more reasonble to interpret the large effect as the result of intrinsic variations in ^{53}Cr than by invoking the *in situ* decay of ^{53}Mn If so, and if both of the observed ^{53}Cr and ^{54}Cr effects in EK1-4-1 are caused by mixing an anomalous component with the normal, then the ratio of ^{53}Cr to ^{54}Cr in that component would be 0 16%/0 48% = 0 3 times the normal ratio After allowance is made for the contribution of ^{53}Mn effects, the ratio of the inferred intrinsic ^{53}Cr excess to the observed ^{54}Cr excess in ordinary inclusions is also (0 02%/0 06%) = 0 3 Therefore, if the intrinsic Cr anomalies inferred for the ordinary inclusions are also to be explained by the admixing of an anomalous component with the normal Solar System matter then a single component would be sufficient for both EK1-4-1 and ordinary inclusions

It is important to consider whether the ^{53}Mn, ^{54}Cr and the inferred ^{53}Cr were co-produced and represent a single 'anomalous' component We can estimate the composition of this component by assuming that it lacks ^{50}Cr and ^{52}Cr (ref 2) Using the data on inclusion BR1 (^{54}Cr excess = 0 048% (ref 2), ^{53}Mn/^{55}Mn = 37 p p m (ref 2) Mn/Cr = 0 21 (ref 2), and ^{53}Cr excess = 0 016%, inferred above) we arrive at the composition relative to ^{54}Cr given in the first column in Table 1 The desired composition seems to consist of comparable numbers of ^{54}Cr, ^{53}Cr and ^{53}Mn atoms but no ^{50}Cr and ^{52}Cr It would be interesting to explore if such a pattern can be produced in a single nucleosynthetic source As a first step, Table 1 shows a comparison of this composition with the production patterns given by Hainebach *et al*[12] as well as the normal It may indeed be possible to produce the desired composition in a single e-process zone characterized by η, the neutron excess parameter, somewhere between 0 071 and 0 0837, however, overproduction of ^{52}Cr could be a problem The production pattern is too sensitive to η to allow a meaningful interpolation between the two η values where the nucleosynthetic calculations were performed Because ^{53}Mn is neutron-poor and ^{53}Cr and ^{54}Cr are neutron-rich, one might attempt to assign these three nuclides to at least two different zones However, the observed ^{53}Mn abundance is small, so a single-zone model remains a possibility This particular e-process model is shown here merely to illustrate the usefulness of such an estimated composition and the possibility of producing it in a single zone Such a zone would produce Ti highly enriched in ^{50}Ti but more ^{46}Ca than ^{48}Ca Thus it cannot fully account for the rough qualitative correlation observed in Allende inclusions between ^{54}Cr, ^{50}Ti and ^{48}Ca Also, stellar nucleosynthesis considerations suggest that e-process products ejected from a massive star are expected to be a mixture of materials from zones covering a broad spectrum of η[13]

We have demonstrated that the offset of the Solar System point from the ^{53}Mn isochron reported in ref 2 disagrees with the prediction of a model in which Allende inclusions formed directly from the solar nebular with homogeneous initial ^{53}Mn/^{55}Mn and ^{53}Cr/^{52}Cr ratios This disagreement could mean that the inclusions have a more complicated history If they have formed from an intermediate source reservoir which in turn formed from the solar reservoir, then this intermediate source must have a higher Mn/Cr than the solar ratio Alternatively, the offset could be explained by heterogeneities in the distribution of ^{53}Mn and the inclusions had an initial ^{53}Mn twice the average Solar System value The third possibility is that when they were formed the inclusions had an intrinsic ^{53}Cr excess of 0 02% relative to normal Solar System matter A single component of anomalous Cr with a ^{54}Cr/^{53}Cr three times the normal ratio can explain not only this inferred ^{53}Cr excess and observed ^{54}Cr effects in ordinary inclusions but also the much larger Cr anomalies found in the unusual FUN inclusion EK1-4-1 If ^{53}Mn is also co-produced with this component then the nucleosynthesis of these iron-group nuclides would be much better constrained, and a single e-process zone would be a possible source

I thank Drs D A Papanastassiou (Caltech) and J L Birck (UCSD and Univ Paris) for comments that enabled me to improve the paper, Dr K K Liu of the Academia Sinica for useful discussions, and the National Science Council (Taiwan, R O C) for travel grants to meetings where the ideas in this paper were first formed

EISCAT observations of the E-region semidiurnal tide

T. S. Virdi, G. O. L. Jones & P. J. S. Williams

University College of Wales, Department of Physics, Penglais,
Aberystwyth SY23 3BZ, UK

Many observers have reported a semidiurnal tide in the E-region of the ionosphere[1,7] Theory demonstrates the possibility of several tidal modes with the relative strength of each mode depending on the efficiency of generation in the stratosphere, the attenuation suffered in propagating through the mesosphere and mode-coupling in regions of nonlinearity. To determine which modes actually occur it is important to observe the tide at all heights in the E-region and at a range of latitudes. EISCAT, the European incoherent scatter radar[2,3], is an ideal facility to make such observations at 69.5° N At this latitude, measurements are usually

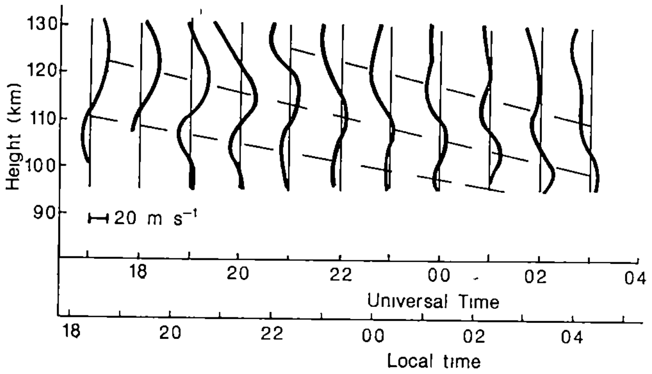

Fig. 1 Height profiles of ion velocity parallel to the magnetic field line, 14-15 February 1985

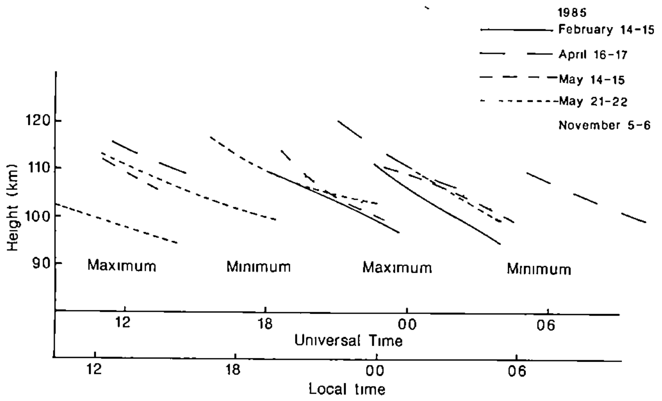

Fig 2 The descending phase-fronts of the semidiurnal tide as demonstrated by the maxima (upward) and minima (downward) of ion velocity parallel to the magnetic field above Tromsø on five days during 1985

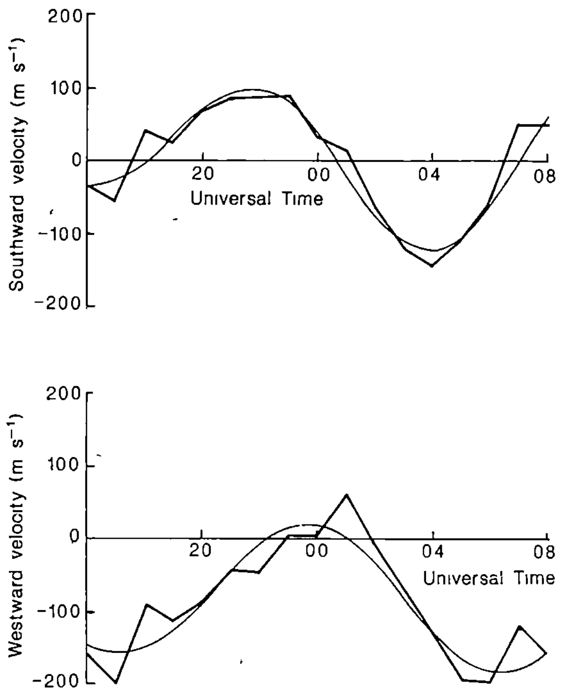

Fig 3 Horizontal velocity in the southward and westward direction at a height of 101 km, 5-6 November 1984 Heavy line, observed velocity, tight line, best-fitting diurnal and semidiurnal tide

perturbed by strong auroral heating, but near sunspot minimum auroral disturbances are sometimes very small and the underlying pattern of the semidiurnal tides can be observed. Such conditions occurred in 1985 and here we report observations on five different days that illustrated the dominance of the (2,4) mode at high latitudes.

At altitudes below 120 km in the ionosphere, the ion-neutral collision frequency is much greater than the ion-gyro frequency so that movement of the ion population is mainly controlled by the neutral atmosphere Measurements of ion velocity can therefore monitor neutral winds

The data presented here were taken while EISCAT was performing the Common Programme CP1 The antenna at Tromsø transmitted along the magnetic field line and observed the whole E-region with a height resolution of 3 km Remote antennas at Kiruna and Sodankyla observed the signals scattered from heights of 101, 110, 119, 131 and 312 km The data were analysed to provide height profiles of electron density, electron and ion temperature and plasma velocity

Figure 1 shows hourly averages of plasma velocity along the field line, $v_{\|}$, as a function of height during 14-15 Feburary A sinusoidal variation with height is observed, and this pattern descends steadily at a rate of 2-3 km h^{-1}

In Fig 2 the heights of the maxima and minima in $v_{\|}$ are plotted against time for each of the five days The pattern is consistent, and small differences from day to day can be accounted for by seasonal changes in the neutral atmosphere, day-to-day variations in the relative strength of the different diurnal and semidiurnal modes, the effects of auroral electric fields, especially above 120 km, and random errors in the measurements themselves

To determine the actual wind velocity associated with the tidal modes we calculated the full vector of plasma velocity, $\mathbf{v}_p$, by combining the separate components of velocity measured at the three EISCAT stations and applying a small correction for the electric field, derived from measurements at 312 km Figure 3 shows typical results the horizontal north-south and east-west velocities on 5-6 November are plotted against time for a height of 101 km, showing the semidiurnal tide

Theory[4,5] predicts that the tidal mode (m,n) shows a downward phase propagation with a vertical wavelength given by

$$\lambda_{z,mn} = 2\pi H / \sqrt{\frac{H}{h_{mn}}\left(\frac{\gamma-1}{\gamma}+\frac{\mathrm{d}H}{\mathrm{d}z}\right)-\frac{1}{4}}$$

where H is the scale height of the atmosphere at height z, γ is the ratio of specific heats at constant pressure and constant volume, and h_{mn} is the equivalent depth of the tidal mode In Table 1 average values of h_{mn} and $\lambda_{z,mn}$ are quoted for various semidiurnal modes at a height of 110 km, corresponding to the MSIS83 model of the atmosphere[6] for the five days

In Fig 4 the value of λ_z is used to predict the rate of descent of the phase front for each mode The average rate of descent of the phase front actually observed for $v_{\|}$ is also plotted

The pattern descends from 120 to 100 km at an average rate of 2 5 km h^{-1} suggesting a vertical wavelength of about 30 km. We can therefore eliminate the (2,2) and (2,3) modes, but allowing for uncertainties in the atmospheric model, especially

Table 1 Predicted vertical wavelength

Mode (m,n)	h_{mn} (km)	$\langle\lambda_{z,mn}\rangle$(km)
(2, 2)	7 85	96
(2, 3)	3 67	53
(2, 4)	2 11	38
(2, 5)	1 37	30
(2, 6)	0 96	25

Table 2 Observed vertical wavelength

Date	North-south 101 km	North-south 110 km	North-south 119 km	East-west 101 km	East-west 110 km	East-west 119 km
16 April	—	6.7	—	—	9.0	6.5
14 May	—	6.4	4.7	10.9	8.8	4.6
21 May	8.5	6.3	—	11.8	8.8	6.2
5 November	10.2	6.8	—	11.9	9.6	—
Average	9.4	6.6	4.7	11.5	9.0	5.8
Wavelength (km)		44.6			37.5	

Time of maximum (UT)

in the estimate of dH/dz, and for the perturbing effects of electric fields the observations are compatible with (2,4), (2,5) or (2,6).

More precise evidence involves measurements of the full vector of ion velocity whenever tristatic data are available. In the E-region v_p is largely determined by (1) the semidiurnal tide in the neutral atmosphere, (2) the diurnal tide, and (3) the effect of ionospheric electric fields. At 101 km the effects of the electric field are very small and the amplitude and phase of the semidiurnal and diurnal modes can be determined by a least-squares fit. At greater heights, as the ion-neutral collision frequency decreases, the ion velocity is increasingly affected by the electric field. At 110 and 119 km, however, it is possible to make an accurate correction for this and the phase of the semidiurnal tide can be determined. Table 2 summarizes results for all days with adequate data, and Fig. 4 shows the average time of minimum southward component at each height.

The variation of phase with height corresponds to a vertical wavelength of 41 ± 2 km, which strongly suggests the dominance of the (2,4) mode at high latitudes.

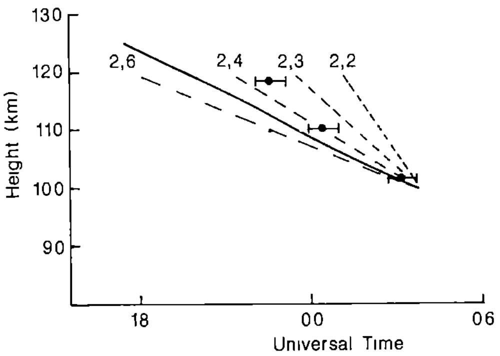

Fig. 4 The predicted rate of descent of several semidiurnal modes (broken lines) and the observed rate-of-descent of the minima of the ion velocity parallel to the magnetic field line (continuous line) and the time of minimum southward horizontal velocity at 101, 110 and 119 km (points with error bars).

We thank the Director and staff of EISCAT for making the observations and analysing the data. EISCAT is supported by the research councils of France, Finland, Germany, Norway, Sweden and the UK.

Long-range transport and deposition of acidic nitrogen species in north-west Europe

Richard G. Derwent* & Katrin Nodop†

* Modelling and Assessments Group, Environmental and Medical Sciences Division, Harwell Laboratory, Oxfordshire OX11 0RA, UK
† EMEP Chemical Coordinating Centre, Norwegian Institute for Air Research, Lillestrøm, Norway

The mechanisms of the long-range transport and deposition of acidic nitrogen compounds over north-west Europe are not yet well understood. Aerosol nitrate concentrations have been steadily rising in southern England[1] over the past three decades, as have the nitrate concentrations in precipitation at almost all sites in north-west Europe, including the most remote[2,3]. The life cycle of acidic nitrogen compounds potentially involves a wide range of trace constituents including nitric oxide (NO), nitrogen dioxide (NO_2), gaseous nitric acid (HNO_3), higher nitrogen oxides (such as N_2O_5), nitrate aerosol and nitrate in precipitation. Here we show that a simple model, incorporating an assumed life cycle of nitrogen-containing trace gases and the known NO sources, can account for much of the nitrate in rain observed over north-west Europe.

The spacial distributions of dry and wet deposition of acidic nitrogen compounds were calculated using a simple trajectory model, the details of which are described elsewhere[4]. The formulation of the model is based on the EMEP (European Monitoring and Evaluation Programme) long-range sulphur transport model[5], although we have made some major simplifications. These have involved the assumption of straight line trajectories, mixing heights held constant at 1,000 m, windspeeds at 8 m s^{-1}, and statistically averaged precipitation-removal rates constant throughout Europe. Figure 1 shows the life cycle of the acidic oxidized nitrogen compounds that has been used and the rate coefficients used to link each of the modelled species. The model consists of a set of coupled differential equations, one for each species including ozone (O_3), representing mass conservation and was solved using FACSIMILE, a variable-order Gear's method program[6] on an IBM PC XT microcomputer.

The major source of acidic nitrogen compounds in north-west Europe is the emission of NO from motor vehicles and stationary combustion. The calculations described here used the NO emissions[7] on the 150 km × 150 km EMEP grid for 1978 from

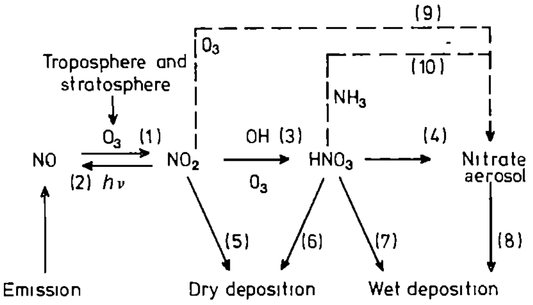

Fig. 1 The life cycle of the nitrogen-containing trace gases and the rate coefficients for the interconversion processes between them (1) 3.8×10^{-4} p.p.b.$^{-1}$ s^{-1}, (2) 2.1×10^{-3} s^{-1}, (3) 3.4×10^{-5} s^{-1}, (4) 3.0×10^{-5} s^{-1}, (5) 4.0×10^{-6} s^{-1}, (6) 2.0×10^{-5} s^{-1}, (7) 9.0×10^{-6} s^{-1}, (8) 1.3×10^{-5} s^{-1}, (9) 1.0×10^{-6} p.p.b.$^{-1}$ s^{-1}, (10) 2.4×10^{-4} p.p.b.$^{-1}$ s^{-1}. The solid lines refer to processes in the base model and the dotted lines to those in the base model + NH_3 + night-time chemistry.

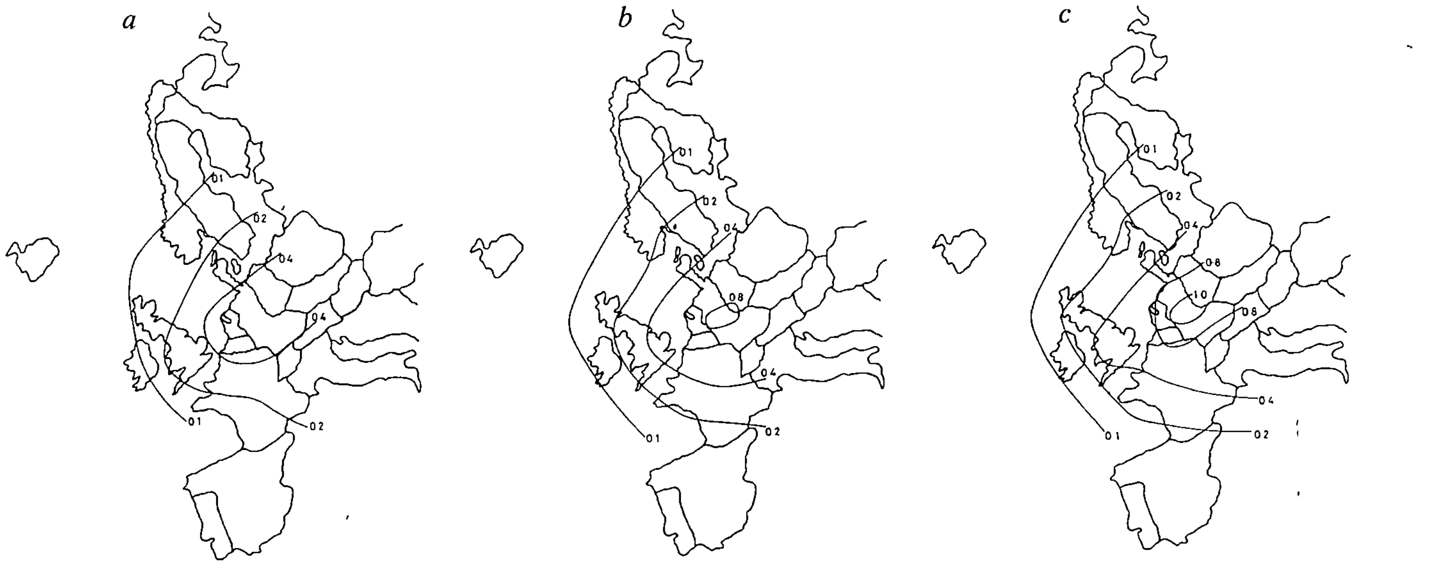

Fig 2 The calculated nitrate concentration in rain over north-west Europe in mg N l^{-1} NO_3 in *a*, the base model, *b*, the base model + NH_3 chemistry, *c*, the base model + NH_3 + night-time chemistry

stationary combustion alone The contribution from motor vehicles to total NO emissions has yet to be specifically treated on the EMEP grid but it is known to be significant overall and could therefore influence both the magnitude and spatial distribution of the emissions The model allows for the oxidation of NO to NO_2 by the well known ozone reaction and then to gaseous nitric acid by reaction with OH radicals A tropospheric background ozone concentration of 30 p p b (30 parts per 10^9, 60 $\mu g\ m^{-3}$) has been employed at the start of each trajectory and is replenished by vertical exchange along the trajectory The OH radical concentration was taken to be that same concentration (2×10^6 molecule cm^{-3}) which would account for the SO_2 oxidation in the EMEP sulphur transport model[5] In the assumed life cycle, HNO_3 is subsequently scavenged by alkaline soil particles of the coarse atmospheric aerosol and by sea-salt aerosol to form nitrate aerosol Dry deposition arises through removal of NO_2 and HNO_3 at the Earth's surface and wet deposition through wash-out of HNO_3 and rain-out of nitrate aerosol Wet deposition was estimated using a constant scavenging coefficient[4] (Fig 1) and an annual rainfall of 1,000 mm None of the processes in Fig 1 is yet adequately defined on a European scale, including the emissions, for oxidized nitrogen species

The concentrations of NO, NO_2, HNO_3 and nitrate aerosol together with the dry and wet deposition rates of the oxidized nitrogen compounds at a given location were obtained by solving the differential equations describing their production and loss for 24 separate 96-h trajectories through to that location, three trajectories within each of eight wind direction sectors 45° wide The long-term mean behaviour at this location was obtained by weighting the results for each trajectory by the frequency of the 96-h back trajectories assigned to each 45° sector in the daily analysis completed by the Meteorological Synthesizing Centre-W for the 636-day period from 1 February 1981 to 29 October 1982 (ref 8) This process was repeated for each of the 64 UN ECE EMEP receptor sites located within the study region for which the above daily sector analysis was available

The calculated concentrations of nitrate in precipitation at each of the 64 receptor sites were plotted out and contours were drawn, joining places of identical rainfall composition (see Fig 2*a*) Most of north-west Europe lay within the 0 1 mg N l^{-1} NO_3 contour under the base model assumptions The total area integrated dry and wet deposition of oxidized nitrogen compounds to the 2×10^6 km^2 land area of Belgium, Denmark, France, FRG, Ireland, Netherlands, Norway, Sweden and the UK amounted to 420 and 450×10^9 g N yr^{-1} The mean residence time for oxidized nitrogen in this base model was found to be 1 2 days, corresponding to a mean transport distance of 800 km The calculated nitrate concentrations in precipitation in Fig 2*a* showed a systematic underestimation of the observed[9] concentration data in Fig 3

In formulating the base model, two additional processes have been specifically omitted (1) scavenging of gaseous nitric acid by ammonia and its subsequent condensation to form ammonium nitrate aerosol, (2) reaction of NO_2 with ozone at night-time to form N_2O_5 and its subsequent reaction with water droplets to form nitrate aerosol We now illustrate the potential importance of these two processes on the spatial distribution of wet nitrate deposition

The formation of ammonium nitrate aerosol was treated by including an additional differential equation for ammonia, representing its emission from animal and industrial sources on the same 150×150 km grid[10], its dry deposition and reaction with HNO_3 to form ammonium nitrate aerosol and its subsequent wet deposition The modelling problem was simplified by assuming no volatilization and redissociation of ammonium nitrate aerosol and by neglecting any competitive scavenging of NH_3 by sulphuric or hydrochloric acid gases These assumptions should exaggerate the importance of ammonium nitrate aerosol formation on the nitrogen life cycle The rate coefficients for the various processes were estimated as few of the relevant processes have yet been studied in any detail except for the thermodynamics of ammonium nitrate formation[11]

The formation of N_2O_5 at night-time was determined using the known rate coefficient of the NO_2+O_3 reaction[12] The NO_3 produced was assumed to be scavenged to form N_2O_5 which, in turn, reacted heterogeneously with water droplets to form nitrate aerosol Constant night-time conditions were taken so that our assumptions should exaggerate the importance of this route in parallel with the optimistic assumptions also made for the ammonium nitrate aerosol formation route The assumptions made for the two additional routes, distinguished from the base model in Fig 1, should therefore be seen to be optimistic but not unreasonably so

Figure 2*b*,*c* shows the nitrate concentrations in rain calculated for the base model + NH_3 and the base model + NH_3 + night-time chemistry A slight widening of the area covered by the 0 1 mg N l^{-1} NO_3 contour is apparent compared with the base model

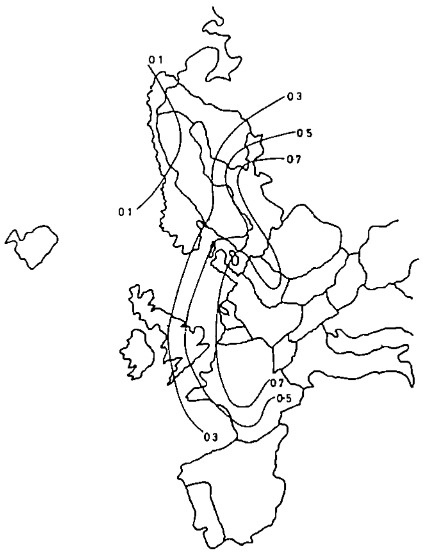

Fig 3 The observed[8] nitrate concentration in rain over north-west Europe in mg N l^{-1} NO_3

results in Fig 2*a*. However, the main change is the marked increase in the magnitude of the peak nitrate concentration in precipitation from 0.64 to 0.82 and 1.08 mg N l^{-1} NO_3. The location of the peak nitrate concentration with precipitation remains in the centre of the FRG with a band of high concentration extending towards the UK through the low countries. A marked increase in the calculated nitrate content of precipitation is noted throughout all the region studied, completely removing the previously noted systematic underestimation of the observations in Fig 3. All these remarks concern the wet deposition of oxidized nitrogen compounds and not the total wet nitrogen deposition which would include a further contribution specifically from the deposition of ammonia and its derivatives.

The effect of the ammonia and night-time chemistry has been to reduce the total area integrated dry deposition of oxidized nitrogen compounds to 140×10^9 g N yr^{-1} and increase their wet deposition to 710×10^9 g N yr^{-1}. The total wet and dry deposition has, however, remained unchanged and all that has been affected is a change in the deposition route from dry deposition to wet deposition. The average residence time of oxidized nitrogen has increased to 1.3 days. Total wet and dry deposition of oxidized nitrogen compounds is controlled by the NO emission strength which has been left unchanged, but the detailed chemistry controls the split between wet and dry deposition. This split is crucial because only wet deposition is directly measurable over north-west Europe. Furthermore, wet and dry deposition may have different ecological effects.

The model results were compared with measurements at 25 EMEP sites for which nitrate in precipitation data are available for either 1981 or 1982 or both. Table 1 shows how the model results correlate with the observations revealing a high degree of correlation ($R^2 \simeq 0.8$) between the model calculations and observations for the 25 sites. The slopes are significantly different between the various model experiments and approach unity only when the ammonia and night-time chemistry is introduced. In all cases, the intercepts are not statistically different from zero indicating the apparent absence of background contribution to nitrate in precipitation. This is an apparent contrast with the analogous situation for sulphate in precipitation[5].

Table 1 Comparison of the observed and model calculated values of nitrate in precipitation at 25 EMEP sites in north-west Europe

Correlations	Slope	Intercept (mg N l^{-1} as NO_3)	Correlation coefficient (R^2)
Base model on data	0.62±0.1	0.02±0.05	0.78
Base model + NH_3 on data	0.80±0.1	0.03±0.07	0.78
Base model + NH_3 + night-time chemistry on data	1.03±0.2	0.01±0.09	0.76

The simple model, with the assumed life cycle and the known NO sources over north-west Europe are therefore able to account for much of the nitrate in rain observed over north-west Europe. However, an adequate explanation requires a better meteorological description and a more detailed understanding of the atmospheric chemistry of NO_x, ammonia and ozone than has been used here and will require a much improved database for ammonia and ozone across north-west Europe in addition to that for NO, NO_2, HNO_3 and nitrate aerosol. Furthermore, as European NO emissions have almost certainly increased over the past 30 years then total wet and dry deposition will have risen proportionately. However, because of possible increased NH_3 emissions[13] and possible increased background ozone concentrations[14], this work demonstrates that the split between wet and dry deposition may also have changed markedly leading to a more dramatic increase in wet nitrate deposition compared with total deposition. Future trends in wet nitrate deposition may not necessarily be dictated solely by NO_x emissions and by the application of NO_x control technologies in vehicles and large combustion plant unless steps are taken to understand and control future NH_3 and ozone concentrations and their possible changes over north-west Europe.

This work was supported in the UK by the Department of Environment and at the Norwegian Institute for Air Research through the UN ECE EMEP Programme and through a contract from the Umweldbundesamt of the FRG. We acknowledge discussions with John Garland, Frank Leeuw, Oystein Hov and Anton Eliassen.

Baryonyx, a remarkable new theropod dinosaur

Alan J. Charig & Angela C. Milner

Department of Palaeontology, British Museum (Natural History), Cromwell Road, London SW7 5BD, UK

An extremely large claw bone, some 30 cm long, was found in Wealden (Lower Cretaceous) deposits in a Surrey claypit in January 1983. This led to the discovery the following month of the well-preserved skeleton of a new large theropod dinosaur. Only one other theropod specimen comprising more than a few bones had ever been found in Britain, and that discovery was more than a century ago. Indeed, no large theropod, reasonably complete, had previously been discovered in Lower Cretaceous rocks anywhere in the world. Our study so far suggests that the Surrey dinosaur was a typical large theropod in certain respects, resembling, for example *Allosaurus*[1]. In several other respects, however, it differs sufficiently from all known dinosaurs to merit designation as the representative of a new species, genus and family.

More than three years have elapsed since the skeleton was excavated by the British Museum (Natural History) in May–June 1983. We estimate that 70% of the bones collected have already been prepared from the encasing siltstone concretions, although many require further treatment. The immense amount of work involved suggests that it will be at least another four years before a full account of this important creature can be published; we have therefore decided to publish a preliminary account immediately, bestowing a name on the animal.

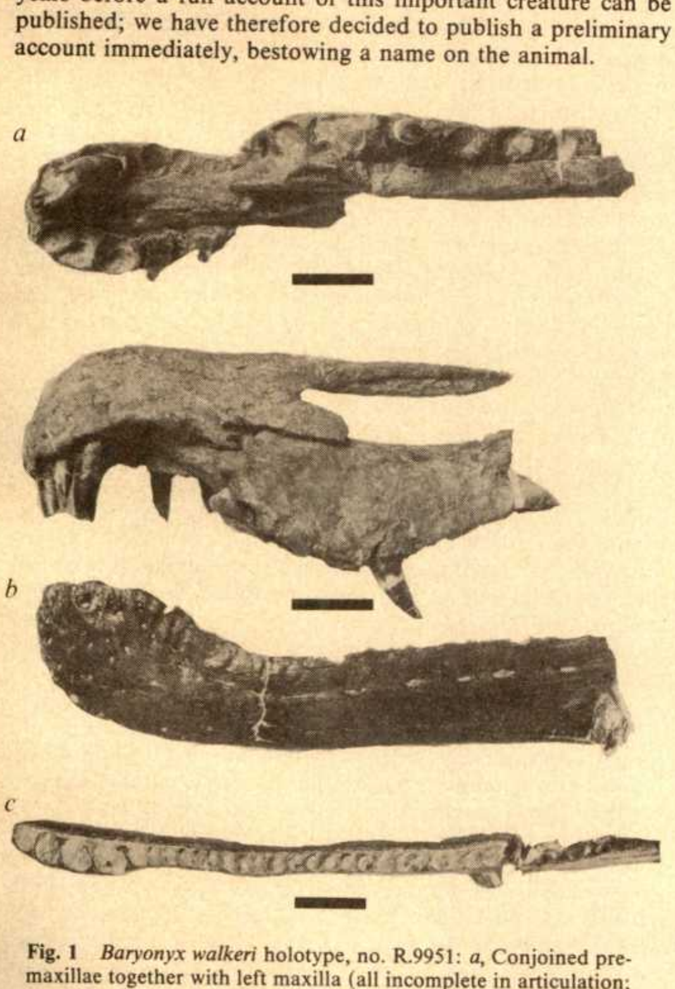

Fig. 1 *Baryonyx walkeri* holotype, no. R.9951: *a*, Conjoined premaxillae together with left maxilla (all incomplete in articulation; in occlusal (ventral) view. *b*, Premaxillae and left maxilla as above, also with incomplete left dentary in approximately correct relative orientation; from the left side. *c*, Left dentary; in occlusal (dorsal) view, to show the full complement of tooth sockets. Scale bars, 5 cm.

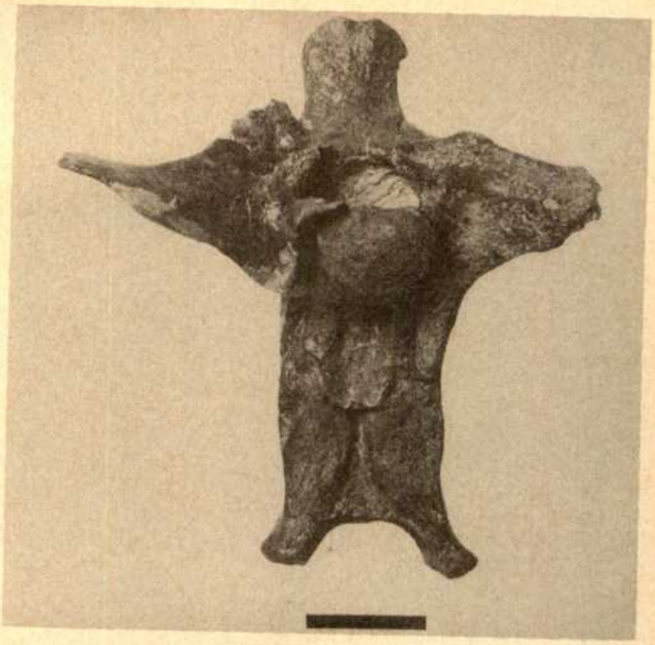

Fig. 2 *Baryonyx walkeri* holotype, no. R. 9951: Occiput, from behind. Scale bar, 5 cm.

Family **Baryonychidae** nov.

Diagnosis. As for genus *Baryonyx*, below.

Genus *Baryonyx* nov.

Derivation of name. Gk, *βᾰρύ*, heavy, strong; *''ονυξ*, talon, claw.

Type-species. *B. walkeri* nov.

Diagnosis. As for species *B. walkeri*, below.

Species *Baryonyx walkeri* nov.

Derivation of name. For Mr William J. Walker, who found the first indication of the skeleton, namely the large claw bone (ungual phalanx).

Holotype. B.M.(N.H.) Palaeo. Dept. R. 9951.

Material. Conjoined premaxillae, front of left maxilla, conjoined nasals, lacrimal and parts of adjacent bones, frontals, anterior end of braincase, occiput, left dentary, some post-dentary bones of lower jaw; teeth in both jaws and in isolation; axis, most of the other cervical vertebrae, some dorsal vertebrae, one caudal vertebra; cervical rib, dorsal ribs, gastralia, chevrons; both scapulae, both coracoids, possible clavicle; both humeri, phalanges of manus including unguals (one of them, not certainly from manus, extremely large); pieces of ilia and pubes, ischium; proximal end of left femur and distal end of right, left fibula lacking distal end; right calcaneum; distal ends of metatarsals, phalanges of pes including unguals; various unidentified pieces; suspected gastroliths.

Locality. Claypit at Smokejacks Brickworks (Ockley Brick Company Limited), Wallis Wood, Ockley, near Dorking, Surrey, England. Map reference TQ13: 113 373.

Horizon. Weald Clay, near the base of the Barremian, Wealden (Lower Cretaceous); approximate age 124 million years.

The bones, though largely disarticulated and scattered, were all found within an area 5 m × 2 m; except where previously disturbed by the bulldozer, they were generally not far from their natural positions, that is most of the pieces of the skull, pectoral girdle and fore-limbs were at one end and most of the pelvic girdle and hind-limbs at the other. They were not crushed or distorted to any significant degree. Many had been broken cleanly before fossilization; most had become encased in sideritic siltstone nodules before the broken ends had weathered or eroded, but a few lay unprotected in clay. So far we have recognized few other vertebrate remains mixed with those of this one individual of *Baryonyx*; these include fish teeth and scales, the humerus of a small *Iguanodon* and a small phalanx. The hardness of the siltstone concretions necessitated the com-

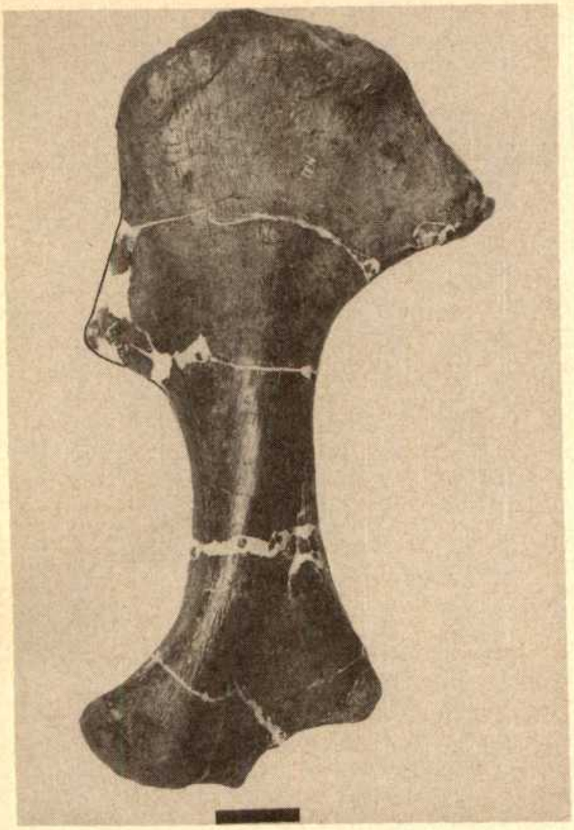

Fig. 3 *Baryonyx walkeri* holotype, no. R.9951: Left humerus, in anterolateral view. Scale bar, 5 cm.

bined use of mechanical (Vacublast, air-abrasive, diamond saws and dental mallets) with chemical (thioglycollic acid[2]) methods of preparation.

Diagnosis. The new theropod is distinguished by a unique combination of characters. These include: the prenarial extension of the snout into an extremely narrow rostrum with a spatulate, horizontal expansion at its end, slightly downturned in lateral view (Fig. 1); the long, low external naris, a flat triangle with its apex directed forwards, situated far back from the front of the snout and ascending gently towards the rear; the seemingly mobile articulation of the premaxilla and maxilla above a subrostral notch (Fig. 1); the small median knob at the posterior end of the conjoined nasals, cruciform in dorsal view, with the anterior limb of the cross drawn forwards into a low thin median crest; the deep occiput (Fig. 2) with paroccipital processes directed horizontally outwards and with basipterygoid processes descending far below the basioccipital and diverging laterally only slightly; the unusually high number of teeth

$$\frac{\mathrm{pm}\ 7+\mathrm{m}?}{\mathrm{d}\ 32}$$

contrast with the usual theropod count of

$$\frac{\mathrm{pm}\ 5+\mathrm{m}\ 16}{\mathrm{d}\ 16}$$

the largest being the third in the premaxilla and the third and fourth in the dentary, the crowns lightly fluted on the lingual side, with very fine serrations (about 7 per millimetre) on the anterior and posterior keels, the roots long and slender; no obvious interdental plates (unlike *Megalosaurus*, where they are very conspicuous, high and separate from each other); the long, strongly opisthocoelous cervical vertebrae with short neural spines, with well developed epipophyses, and with ends of the centra not 'offset' so that when they are correctly apposed the neck does not show the typical theropod upward curve; the relatively well-developed humerus (Fig. 3), with both ends broadly expanded but extremely flattened, offset 35° against each other, shaft massive and almost straight; the ilium with a long, straight posterior process; and at least one pair of huge talons (probably on the hands, Fig. 4). There are other distinguishing characters of a more esoteric nature.

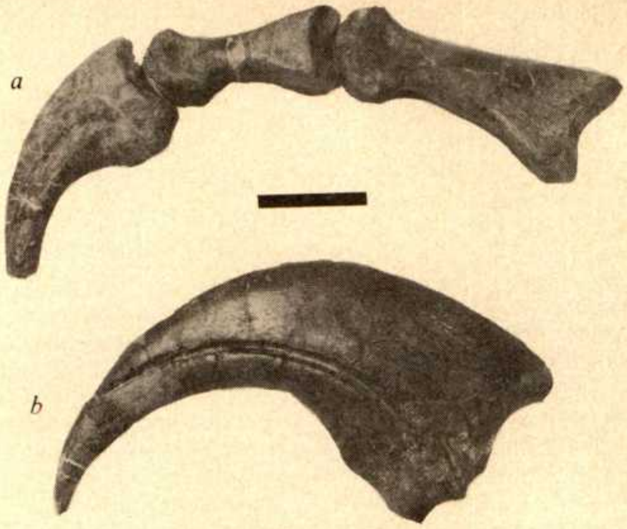

Fig. 4 *Baryonyx walkeri* holotype, no. R.9951: *a*, 'Normal' digit, presumably of hand. *b*, Especially large ungual phalanx. Length of scale bar 5 cm.

Baryonyx shows a strange mixture of primitive and specialized characters. The downturned tip to the snout, the apparent mobility between premaxilla and maxilla and the subrostral notch, the elongation of the cervical vertebrae and the form of the posterior process to the ilium are typical of many thecodontians; the humerus is also primitive in some respects. It is remarkable that so many characters frequently found in Triassic archosaurs should still be present in those from the Early Cretaceous. In contrast, the opisthocoely of the cervical vertebrae and their epipophyses, the lack of a supinator process and ectepicondylar groove to the humerus, the inturned head to the femur and the apparent absence of dermal armour clearly demonstrate that *Baryonyx* is a theropod (as currently defined) with the 'fully improved' stance and gait that distinguish dinosaurs from their thecodontian ancestors. It is not a crocodilian, for neither the skull, the cervical centra, the pelvis nor the ankle shows any of the appropriate specializations. Even so, if the animal is to be considered a theropod, it possesses unique specializations of its own: the terminal 'rosette' to the upper jaw, the extreme narrowness of the skull just behind it, the median knob and crest on the nasals, the large number of teeth (double that of a typical theropod), the lack of an upward curvature to the neck, and the huge offensive/defensive talon. It might also have been quadrupedal to some extent (see below), in which case such stance and gait—whether primitive or secondarily derived—would certainly be unique among theropods.

Therefore we propose that the most proper systematic position for *Baryonyx*, on the evidence presently available, is in a new family (Baryonychidae) of the Theropoda; the information currently available does not indicate a particular relationship to any other group of theropods. (The nature of the articulation between premaxilla and maxilla is somewhat reminiscent of *Dilophosaurus*[3,4] from the Lower Jurassic Kayenta Formation of Arizona, placed by Welles[4] in the Halticosauridae, but *Dilophosaurus* has paired crests on top of its head, whereas *Baryonyx* appears to have only one.)

The only other material that may be assigned to the same family are two fragmentary snouts from the Aptian of Niger, described[5] as the mandibular symphyses of a spinosaurid. They are, however, almost identical to the conjoined premaxillae of

Baryonyx, and comparison with *Spinosaurus*[6] does not suggest spinosaurid affinities.

The possible life habits of *Baryonyx* are unclear. The elongated skull, the long neck and the form and strong development of the humerus might all suggest quadrupedality, facultative at least, even though the flattened slender ends of the humerus makes it unlikely that the stance and gait were predominantly quadrupedal. The lateral position of the external nares, far back from the tip of the snout, seems to preclude an aquatic or amphibious existence, and the form of the postcranial skeleton is wholly suggestive of life on land. Nevertheless the elongated snout with its terminal expansion and the large number of finely serrated teeth may well be indicative of ichthyophagy. Taquet's article[6] on the Niger theropod made the same suggestion, comparing the elongated snouts with those of the Recent *Gavialis gangeticus* and commenting that "*il est tentant d'imaginer des Dinosaures Spinosauridés pêchant le long des fleuves ou au bord des lacs à la manière des Hérons ou des Cigognes.*" We independently conceived a similar idea for *Baryonyx*, though as a quadrupedal predator crouching on the bank rather than as a biped stalking through the shallows. A scavenging habit has also been suggested for the new dinosaur, but the evidence for either mode of life is inconclusive. The associated fossil fauna is dominated by the remains of the herbivorous ornithopod dinosaur *Iguanodon* and of many insects[7], the latter under continuing study by Jarzembowski.

Whether the huge talon was one of an only pair remains unknown; likewise whether it was borne by the fore-limb or by the hind. The ungual is exactly like those of *Allosaurus*, only much bigger. Clearly it was a weapon of offence and/or defence; but it seems likely that the great size of *Baryonyx* (it may have weighed a couple of tons or more) would have precluded any possibility of emulating its contemporary *Deinonychus* from the Cloverly Formation of Montana[8], a biped of much smaller dimensions which bore a large, laterally-compressed, sickle-like claw on the second digit of the pes and which balanced on the other hind-leg while slashing at its victim. If, however, the great talon of *Baryonyx* was on the manus, it could be connected with the powerful development of the humerus. All this must have some bearing on facultative quadrupedality (the claw would have had to be held clear of the ground while the animal was walking) and on ichthyophagy; could *Baryonyx* have used the claw, like a grizzly bear, for 'gaffing' fish out of the water? *Baryonyx* is the dinosaur that in 1983 received world-wide publicity, and became nicknamed 'Claws'. We are expecting its remains to provide a great deal more information over the next few years.

Our thanks are due to the many people who helped in different ways, too numerous to specify. They include Mr William Walker, the Directors and staff of the Ockley Brick Company Limited, the collecting teams (Museum staff and others), the Museum photographers, Mr Philip Palmer, and Mr Ronald Croucher and his colleagues in the Museum's Palaeontological Laboratory.

Functional architecture of cortex revealed by optical imaging of intrinsic signals

Optical imaging of cortical activity offers several advantages over conventional electrophysiological and anatomical techniques. One can map a relatively large region, obtain successive maps to different stimuli in the same cortical area and follow variations in response over time. In the intact mammalian brain this imaging has been accomplished with the aid of voltage sensitive dyes[1-5]. However, it has been known for many years that some intrinsic changes in the optical properties of the tissue are dependent on electrical or metabolic activity[6-13]. Here we show that these changes can be used to study the functional architecture of cortex. Optical maps of whisker barrels in the rat and the orientation columns in the cat visual cortex, obtained by reflection measurements of the intrinsic signal, were confirmed with voltage sensitive dyes or by electrophysiological recordings. In addition, we describe an intrinsic signal originating from small arteries which can be used to investigate the communication between local neuronal activity and the microvasculature. One advantage of the method is that it is non-invasive and does not require dyes, a clear benefit for clinical applications.

The imaging of changes in membrane potential in central nervous system (CNS) preparations with voltage sensitive dyes, which are usually associated with fast signals, is often distorted by much slower intrinsic signals[6,11]. The observation of only slow signals from the surface of monkey striate cortex stained with a voltage sensitive dye[14] prompted us to test whether slow reflectance signals could be observed without using any dye, and to compare the relative merits of intrinsic and dye-related imaging. For optical recording from the rat somatosensory cortex, the exposed cortex was viewed with a compound microscope equipped with fluorescence epi-illumination through a glass-coverslip sealed chamber. The rat somatosensory cortex includes a region that is subdivided into smaller areas, known as barrels, each of which responds to stimulation of a single mystacial whisker[15]. Using the photodetector array[16] to monitor changes in reflected light from an active barrel field, we observed a decrease in reflectance in response to whisker stimulation. In dye stained preparations, this intrinsic signal was distinguished from the dye signal by measurement at a wavelength range outside the absorption band of the dye[6]. This made it possible to compare directly maps obtained by the reflected light and voltage sensitive dye signals in response to stimulation of one whisker. Both showed signals in a well-localized cortical region and the centres of the active areas overlapped very closely (Fig. 1*a*, *b*). Although the reflected light signal was much slower than the dye signal (Fig. 2*a*), representing different processes, it was still as useful for visualizing the active cortical region.

To determine the optimal conditions for the measurement and to characterize the signal source, we examined the time course and wavelength dependence of the signal. The reflected light signal in the rat somatosensory and in the cat and monkey visual cortex had a slower rise time (>1 s) than the dye related signals (Fig. 2*a*, *b*). This time course is clearly very different from neuronal electrical activity. By comparing the optical signals in response to long and short stimuli we found that the rise time and time to peak were nearly independent of stimulus duration (Fig. 2*d*). Examination of the relaxation time course of the signal was important for choosing the appropriate inter-stimulus interval. Short duration stimuli (0.5-2 seconds) pro-

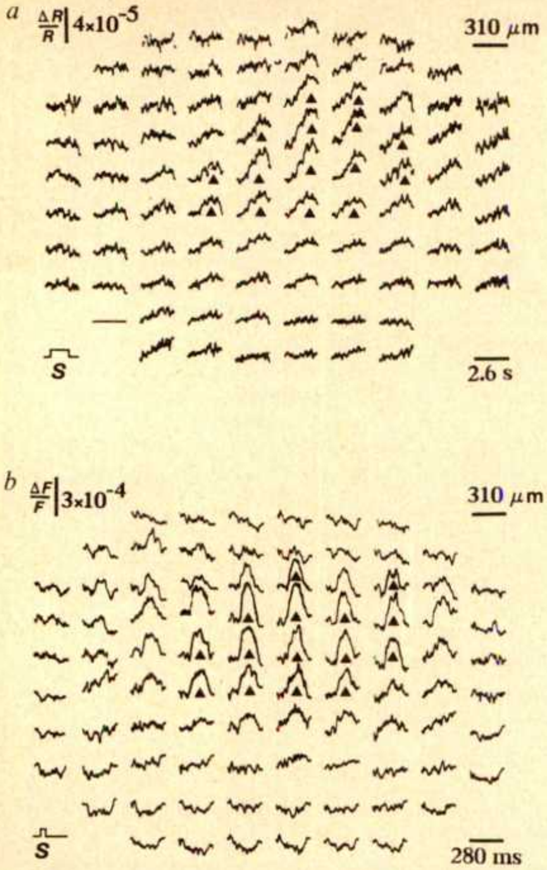

Fig. 1 Mapping of a single barrel in rat cortex with the intrinsic signal and its confirmation with a voltage-sensitive dye. *a*, The spatial distribution of the reflected light signals in response to a mechanical stimulation of a single whisker. Simultaneous intensity changes in reflected light were measured with 96 photodetectors, averaged over 200 trials. Signals marked by triangles are the largest 15 signals selected by computer integration. A wavelength of 665 to 750 nm was used. A semi-silvered mirror was used as a reflector. *b*, As *a* but using fluorescence mapping, averaged over 80 trials. Again, the largest 15 signals were marked by triangles. The centres of the two maps of the barrel are superimposed. Note that in this experiment the area of activation with the intrinsic signal is smaller than that seen with the dye signal. (We do not know if the difference is significant because the two measurements were not simultaneous and the fluorescence measurement was done first.) The cortex was stained with 0.1 mg ml^{-1} RH-795 for 90 min. We used an excitation filter at 530 nm (bandwidth 70 nm), an FT-580 dichroic mirror and an RG610 barrier filter. Common mode noise due to the heartbeat artefact and respiratory movements was removed by subtracting a signal-free trace from the rest of the traces. The duration of the stimulus (*S*), the size of cortical area viewed by each detector, the time scale, and the fractional change in light intensity ($\Delta R/R$ or $\Delta F/F$) reaching the detectors, are marked at the corners of the map. Note the difference in time scale of *a* and *b*. For a discussion of the area of an optically detected barrel relative to its anatomically determined size see the discussion in ref. 5. In similar mapping experiments, using the intrinsic signal, two individual barrels could be resolved if two whiskers were stimulated.

Methods. The optical monitor is described elsewhere[3,6,16]. The detector amplifiers have a sample-and-hold option that facilitated the high gain d.c. recordings. To minimize the large noise associated with heartbeat, the stimulus and data collection were triggered by the heartbeat, and each stimulus associated trace was subtracted from a trace obtained without stimulus[5,17]. We used 22 rats, 21 cats and one monkey. Rats were anaesthetized with an intraperitoneal injection of urethane. Cats and monkeys were anaesthetized with continuous infusion of sodium pentothal, paralysed with succinylcholine or curare/gallamine, and artificially respirated. The visual stimulus was a square-wave grating, 0.3–1 cycles per degree, drifting at a rate of 2–3 cycles per s. The surface of the cortex was positioned perpendicular to the axis of the microscope objective by a modified stereotaxic apparatus. Most of the light reaching the photodetectors was stray light (80–90%) reflected from the epi-illuminator attachment, the objective lenses, and the coverglass of the chamber attached to the skull. Note that the real fractional change of reflected light from cortex is therefore 5–10-fold larger than that shown on the vertical calibration scales. No attempt was made to minimize the stray reflections because they did not contribute to the noise originating from movements of the cortical surface.

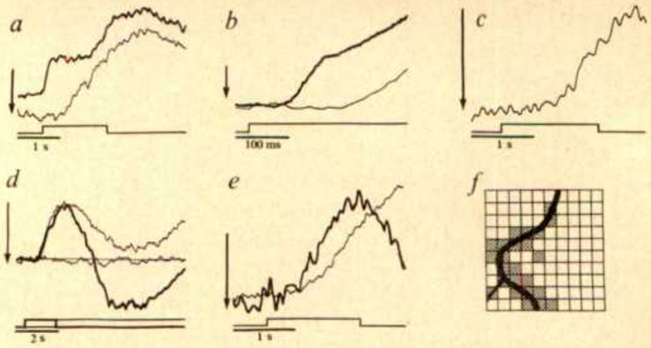

Fig. 2 Characterization of the reflected-light signal in rat, cat and monkey cortex. *a*, Comparison between reflected light signal (fine trace) and the fluorescence signal (bold trace) in the rat somatosensory cortex. Cortical activity was evoked by a 15° deflection of 6 whiskers. The two signals were normalized to the peak. *b*, Comparison between reflected light signal (thin trace) and signal from voltage-sensitive dyes (bold trace), measured from the same cortical area of the cat visual cortex (note the expanded time scale). The amplitudes were normalized so that the late component of the fluorescence would have a similar slope to the light reflection signal. Note the two components of the fluorescence signal in *a* and *b*. (The late component of the fluorescence signal is produced by the intrinsic signal, and not by a change in membrane potential. Cortex stained with non-voltage-sensitive fluorescent dyes, such as fluorescein, gave signals with a time course identical to the intrinsic signal.) *c*, The reflected light signal from the monkey visual cortex shown on a slow time scale. *d*, The relaxation time course of the signal. The shape of the intrinsic signal depended on the duration of the stimulus, having an undershoot to a short (1.5 s) stimulus, but not to a longer (8 s) stimulus. The flat trace was obtained without a stimulus to show the noise associated with the measurements. *e*, Comparison of the time course of the reflected light signal from the barrel (bold line) in the rat cortex and the arterial signal outside the barrel field (fine line). The arterial signals were seen along the full course of an artery (3 mm) which traversed the stimulated barrel. *a–e*, Vertical arrows, size and direction of fractional change in reflected light, $\Delta R/R$ (fine traces; scale in *a–c*, 10^{-4}; *e*, 2×10^{-4} bold trace: scale in *e*, 10^{-4}; scale in both traces *d*, 5×10^{-4}) or of fractional change in fluorescence, $\Delta F/F$ (bold traces; scale in *a*, 10^{-3}; scale in *b*, 2×10^{-4}). *f*, The spatial distribution of the largest reflected light signals monitored at a wavelength of 850 nm (bandwidth of 40 nm), in cat cortex. Detectors that had a signal larger than 50% of the maximal signal are shaded in grey. Their distribution co-localized with an artery (150 μm in diameter) in the field of view even at this wavelength.

duced a large and slow (10 s) undershoot following the peak of the signal. Because of the slow recovery time of the undershoot, to avoid distortion of the signals it is necessary to use interstimulus intervals of at least 10 s for visual stimuli lasting 1–2 s.

The cerebral vasculature is the source of one component of the intrinsic signal. In the rat experiment the largest signals were observed along arteries, but not veins, and only when the arteries passed through an activated barrel. The signal associated with arteries was delayed relative to the signals from the active barrel (Fig. 2*e*). The arterial signal was seen at wavelengths ranging from 400 to 1,100 nm (for example, 850 nm, Fig. 2*f*). The other signal components that were useful for functional mapping showed the optimum signal-to-noise ratio at a wavelength range of 610–750 nm. We observed that when using another dye (RH414, ref. 17) the arteries constricted, and only the artery-associated signal disappeared, suggesting that the signal represented changes in blood flow in response to local neuronal activity[18,19]. This arterial signal could undoubtedly be a useful tool in studying the relationship between neuronal activity and microcirculation but when making functional maps it can introduce distortions. The distortions can be eliminated from the maps with the appropriate analysis, as shown below.

Having optimized the stimulus and recording conditions we obtained optical maps for different stimulus orientations in the

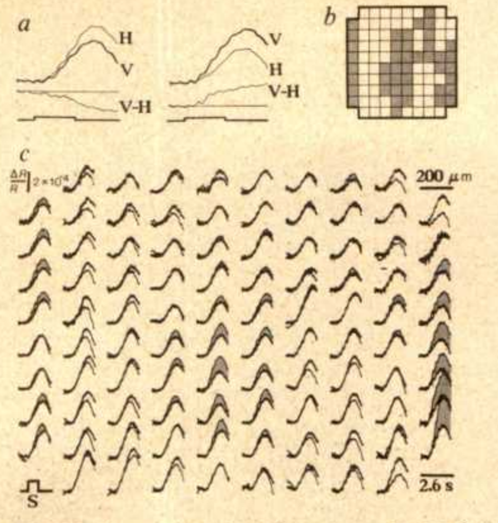

Fig. 3 Visualization of the orientation columns in cat visual cortex. *a*, Demonstration of the signal sensitivity to the orientation of the stimulus. Right traces: the response to vertical drifting gratings (V) and to horizontal drifting gratings (H). The difference between these two traces is shown in the third trace ($V-H$). An electrode penetration at this site recorded from cells which responded only to vertical gratings. Left traces: as for right, but the optical signals are from detectors that monitored cortical area in which units responded only to horizontal stimuli. *b*, A two-state map of the orientation columns. For each pixel, we integrated the signals for the vertical and horizontal stimuli. Shaded detectors, those giving a larger response to horizontal than to vertical stimuli. *c*, The raw data. Two superimposed patterns of reflected light signals in response to horizontal (fine lines) and vertical (bold lines) drifting gratings. These experiments were interlaced. Positions where the response to horizontal stimuli was larger than the response to vertical stimuli are shaded in grey. The pattern of optical signals may seem puzzling as optical signals are seen everywhere, also in areas where single unit responses were not recorded for a given stimulus orientation[20]. We attribute this to a component of the signal that is independent of stimulus orientation and lateral spread of activity along dendritic and axonal processes. The signals were averaged over 100 trials. The signal to noise ratio varied from animal to animal and also depended on the physiological state of the animal. In some experiments the pattern became apparent after averaging 10 trials. In other experiments 200 trials were required. Objective criteria such as excessive noise or unusually slow signals could be used to predict whether an optical map is accurate.

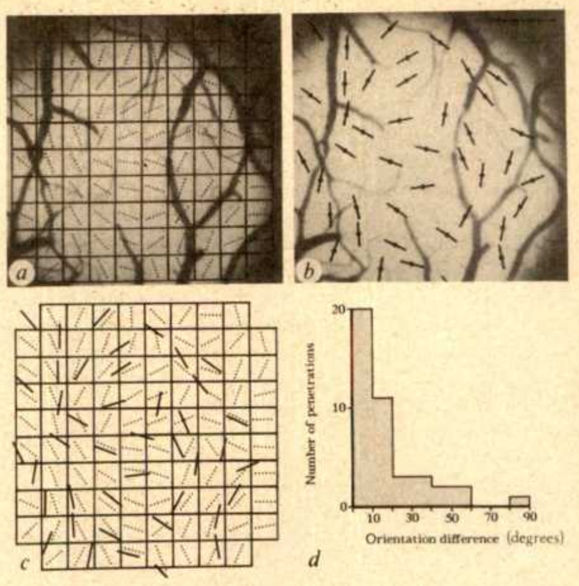

Fig. 4 Electrophysiological confirmation of the optical map of orientation columns. *a*, Optical map of the optimal stimulus orientation, for each cortical site. Since the size of the signal at any given site depends on the inhomogeneous distribution of signal sources as well as the orientation of the stimulus, we took the ratio (rather than the difference) of the integrals of the optical responses to the orthogonal stimulus for each pixel. The ratio approach minimized map distortions produced by inhomogeneous distribution of signal sources (for example, arteries or capillaries). From this ratio we calculated a vector for each pixel. The angle of the optimal stimulus orientation (dotted line) was calculated by vectorial addition of two sets of experiments (see text). The position of the photodiode array (grid) is shown relative to the cortical surface. This map was highly reproducible. A second set of experiments done several hours apart provided an identical orientation map, such that in 95% of the detectors the average difference in the optimal orientation angle determined by the two independent experiments was less than 5°. *b*, The results of the electrophysiological mapping with 42 perpendicular penetrations with tungsten electrodes. The preferred angles of orientation for the single units were determined with a hand-held projector. The location of each penetration was marked on a photograph of the cortical surface. Scale marker, 500 μm. *c*, Superimposed optical (dotted lines) and electrophysiological maps (bold lines). Although there were discrepancies at a few sites, a pixel adjacent to the site of electrode penetration often had an orientation very close to that determined electrophysiologically. Note that large deviations were not associated with the vascular pattern. *d*, Evaluation of the correspondence between the orientations determined electrophysiologically and optically. The histogram shows the deviations between the optimal angle determined by single unit recordings and the optically determined angle at that site or within 100 μm away. Several sources of error are associated with this comparison including the error in the precise marking the sites of the electrode penetrations and the fact that each pixel sums the activity over an area of 200 × 200 μm. Note that 74% of the points fell within 20°, the estimated accuracy of the single unit recordings.

cat visual cortex. These maps were compared to maps generated by multiple electrode penetrations. Although signals to both vertical and horizontal stimulus presentations were seen everywhere, in restricted regions of cortex, the optical signals showed a larger response to a horizontal drifting grating (Fig. 3*a*, left, thin trace) than to a vertical grating (thick trace). Other regions showed the opposite behaviour, giving a larger optical signal to the vertical grating (Fig. 3*a*, right). In other cortical sites the optical signals were nearly identical and in those sites single units did not respond to the pair of stimulus orientations used. The difference between the signals to orthogonal stimuli (vertical (V) − horizontal (H)) showed the signal component that was sensitive to orientation. The spatial distribution of the regions preferring the horizontal stimulus is shown as a two-state coded map in Fig. 3*b*. The raw data are shown in Fig. 3*c*.

We combined the results from vertical and horizontal stimulus presentations (Fig. 3*c*) with results from presentations at orientations of 45° and 135° to obtain a more precise map of the orientation columns. We determined the optimal orientations of each pixel by vector addition (Fig. 4*a*). To confirm the optical map the same area of cortex was mapped, using a double-blind procedure, by making a series of 42 electrode penetrations (Fig. 4*b*). The two maps showed a good correspondence (Fig. 4*c*, *d*). From similar experiments in three different cats we conclude that the intrinsic signals can be used to map the orientation columns.

Our findings from the intrinsic and dye signals leads to several conclusions concerning their relative merits. The principle advantage of optical mapping using voltage-sensitive dyes is that the time resolution is <1 millisecond, while that of the reflected light signals is in the order of seconds. The better time resolution of the dyes is essential for analysing the cortical circuitry and for understanding the sequential flow of information and its processing at different cortical sites. However, at present the dyes have several shortcomings; some of them may induce pharmacological side effects and cause photodynamic damage upon prolonged or intense illumination, they bleach and the depth of penetration into the cortex is limited[1-5]. Often, the dye signals are distorted by the intrinsic signals[6,11].

A voltage-sensitive dye, NK2367, was used by Blasdel and Salama to study the functional architecture of the monkey striate cortex[14]. There are several discrepancies between their work and ours. The first issue is whether their signal came from the dye, as they claim, or from an intrinsic source. The slow time course of the signals seen in both studies suggests that their signal did not come from the dye, as in all other preparations using NK2367 the signal included a fast component[21-24] even if a slow glial signal was also present[25]. Furthermore, the standard evidence to attribute a signal to a dye is the observation of different signals at different wavelengths, and this evidence was not provided. Another issue is the usefulness of the intrinsic signal for mapping. Although Blasdel and Salama observed an intrinsic signal, they did not find it useful for functional mapping. Finally, there is the question of distortion of maps by the cortical vasculature. As we show, the blood vessel signals only appear when the cortex is active (that is, in the presence of a stimulus). The fact that no pattern is seen in the control experiment, in the absence of a visual stimulus leads Blasdel and Salama to conclude that the vascular pattern does not contribute to the maps. In their work, however, the vascular pattern is visible in the functional maps. Although we see arterial signals in our raw data, there is no arterial contribution to the functional maps (for example, Fig. 4), possibly because of the method of analysis and data acquisition, the low spatial resolution of the recording system or a lower noise level.

The exact origin of the multiple components of the reflected light signal will determine the ultimate spatial resolution and remains to be investigated. In addition to the arterial component, which probably reflects changes in blood volume or flow, a second component probably originated from local activity light scattering signals as described in previous reports[6-11,26]. The third component may originate from local changes in the absorption associated with the conversion of oxyhaemoglobin to haemoglobin[27-29] in the capillaries, in response to metabolic demands. In fact we have recently found that this component is a significant constituent of the intrinsic signal.

We thank Drs L. Katz and E. Kaplan for their useful comments. Supported by NIH grants NS14716 and EY05253, NSF grants BNS9318794 and 8351738 and grant AFOSR-85-0301 from the US Air Force and by IBM.

Control of malarial invasion by phosphorylation of the host cell membrane cytoskeleton

K. Rangachari, A. Dluzewski, R. J. M. Wilson* & W. B. Gratzer

It has been shown that the entry of the malaria parasite into the red blood cell requires the presence of ATP in the host cell cytoplasm[1,2]. In red blood cell ghosts that contain no ATP the receptor on the extracellular surface remains in place and parasites will bind to the membrane, but will not enter[3]. ATP is thus necessary for one of the steps[4] in the invasion sequence that follows recognition and attachment. The process of entry appears to involve the active participation of the host cell membrane cytoskeleton[5]. We have suggested[2] that the function of the intracellular ATP may be to regulate phosphorylation of the cytoskeleton. We now present evidence that the activity of the membrane-associated cyclic AMP-independent kinase of the red blood cell is inseparable from invasion; the active substrate may be spectrin.

Kinases are found in both the membrane and cytoplasm of the human red cell, and there is extensive turnover of phosphoryl groups on cytoskeletal proteins. Spectrin is phosphorylated in the cell by a cAMP-independent (casein) kinase at four sites, clustered at one end of the smaller (β) subunit[6]. Early evidence that phosphorylation at these sites was linked to metabolic shape control[7] did not survive closer scrutiny[8,9] and there is no known function for the phosphorylation. However, it does appear that the phosphorylation state of spectrin can be perturbed by external stimuli[10,11] and migration of intramembrane particles may also be linked to spectrin phosphorylation[10,12]. Rearrangement of intramembrane particles appears to occur during entry of the malarial parasite. A bare area of membrane develops in the region of contact[13] and a dense zone, consisting almost certainly of clustered intramembrane particles, can be discerned in the electron microscope at the parasite-host cell junction when the merozoite begins to move into the cell[4]. To establish whether invasion depends on phosphorylation of spectrin (or of other membrane proteins) we used our earlier observation that malaria parasites can, under defined conditions, be made to enter resealed red blood cell ghosts[14] and the discovery that the cAMP-independent kinase can be extracted from the membrane by a medium of high ionic strength[9].

We found that fresh ghosts hypotonically lysed in the presence of ATP could be subjected to one buffer wash before resealing in the presence of the original haemolysate and 1 mM ATP, without loss of susceptibility to invasion. Freshly lysed ghosts were exposed to a buffer containing 0.65 M potassium chloride to extract the kinase[9], then recovered by centrifugation and resealed with haemolysate and ATP. Inoculation of these ghosts with purified schizonts of *Plasmodium falciparum* revealed drastically reduced susceptibility to invasion (Table 1).

A crude preparation of the cAMP-independent kinase can be made from a high-salt extract of membranes[15]. When this was added (~100 μg per ml final protein) to the haemolysate, invasion of salt-extracted ghosts was substantially restored. This enzyme preparation contains a wide range of membrane proteins, of which the kinase makes up a very small part. It is thus open to question whether it was kinase, rather than some other

Table 1 Effect of cAMP-independent kinase on invasion of red cells by *P. falciparum*

Sample	Invasion ratio* 1	2	3	4	5	6	7	8	Average
Untreated	1.3	3.0	1.5	2.0	2.7	0.9	0.7	—	1.73±0.36
Kinase extracted	0.6	0.4	0.3	0.9	0.8	0.1	0	0.2	0.41±0.12
Kinase replaced	1.9	1.2	1.0	1.8	2.0	0.9	0.8	1.0	1.33±0.19

* Ratio of fraction of parasitized cells after one generation (~24 h) to that in the culture after addition of inoculum. Numbers 1–8 are separate experiments with different cultures: the kinase in experiments 1–5 was the purified enzyme, and in 6–8 was the crude preparation. Averages and standard mean errors are given.

Ghosts were prepared by hypotonic lysis of washed human red cells in 5 mM phosphate, 2 mM magnesium chloride, 2 mM ATP, *p*H 7.4. The membranes were collected by centrifugation and extracted with four volumes of 0.65 M potassium chloride, 0.1 mM EDTA, 0.25 mM dithiothreitol, *p*H 7.4, on ice for 15 min to remove kinase[9]. The pellet was washed once with 0.14 M potassium chloride, 2 mM ATP. Extracted and untreated ghosts were resealed by incubation at 37 °C with a diluted haemolysate (usually 1:8 with isotonic saline, containing 2 mM magnesium chloride, 2 mM ATP) and a kinase preparation as required. The total added protein, estimated colorimetrically[19], was ~100 and $<0.4\ \mu g\ ml^{-1}$, in the case of the crude and purified kinase, respectively. The resealed ghosts were twice washed with culture medium (RPMI 1640 + 10% human serum) and suspended at 50% haematocrit. Schizonts of *P. falciparum* were purified from *in vitro* cultures[17,18] and were added to the ghosts. The extent of parasite invasion was determined after ~24 h by counting the number of new parasites in 1,000 cells in thin smears, stained with Giemsa's solution. A crude kinase preparation was obtained by extraction of cytoskeleton-depleted red cell membranes with a medium containing 0.5 M NaCl as described[15]. The extract was fractionated, after precipitation with ammonium sulphate, by two successive elutions from Sephadex G-100, the first in 0.1 M, the second in 0.5 M NaCl. Two zones of activity eluted from the second column, the first with spectrin in the void volume, the second (free kinase) later. Activity was assayed with [γ-^{32}P]ATP and casein[15]. The peak active fractions were concentrated by vacuum dialysis.

membrane constituent, that was responsible for restoration of capacity for invasion. A further fractionation of the kinase preparation was therefore undertaken using the chromatographic procedure described in ref. 16. The activity elutes at high ionic strength from Sephadex G-100, in two regions, one of high relative molecular mass (M_r), which also contains extracted spectrin, the other of M_r ~34,000. The latter is free kinase, and contains little contaminating protein. The total protein added back in this form to the ghosts before resealing had a concentration of $<0.4\ \mu g\ ml^{-1}$. Phosphorylation of membrane proteins was measured by autoradiography of electrophoretic gels of the total solubilized membrane protein after incubation of hypotonic ghosts with ^{32}P-labelled ATP. The single high-salt extraction (Table 2) removed about half of the endogenous cAMP-independent kinase activity. A second extraction led to extensive vesiculation and misshapen residual ghosts, and was therefore not used. Nevertheless, ghosts in which spectrin phosphorylation was reduced by up to 50% showed consistent reduction of invasion by *P. falciparum* (60–80%; Table 1). Addition of the kinase restored invasion to essentially the original level. Kinase which did not cause phosphorylation (inactived by some days' storage) also did not restore invasion. The requirement for ATP is absolute; non-hydrolysable analogues are ineffective[2].

Table 2 Effect of salt-extraction and replacement of kinase on phosphorylation of spectrin in ghosts

Sample	Relative areas under zone profiles Protein stain	Autoradiograph	Relative ^{32}P incorporation
Untreated	1.00	1.00	1.00
Salt-extracted	1.15	0.60	0.52
Kinase replaced	1.03	1.27	1.23

Unsealed ghosts were incubated with 1 mM [γ-^{32}P]ATP (20–40 c.p.m. $pmole^{-1}$) in hypotonic buffer (as in Table 1) on ice for 20 min. The ghosts were made isotonic and resealed at 37 °C, washed twice in isotonic saline and lysed in the hypotonic buffer. Membranes were collected by centrifugation, dissolved in 1% SDS in boiling water and subjected to gel electrophoresis and autoradiography[2]. The autoradiograph and Coomassie blue-stained gel were both evaluated by densitometry. The relative degree of phosphorylation of spectrin is expressed as the ratio of the areas under the zone profiles, taking that for unextracted membranes to be unity. Some 80–90% of the label was found in the spectrin.

The presence of cAMP in resealed ghosts had no influence on invasion efficiency, which is therefore not related to cAMP-dependent kinase(s). We conclude that a substrate for the cAMP-independent membrane kinase must be phosphorylated if malarial invasion is to occur. This is presumably the basis of the requirement for intracellular ATP[1,2].

Spectrin is by far the most abundantly labelled protein under the conditions of these experiments. On addition of kinase to the extracted cells the enhanced incorporation of label is about 80–90% in spectrin. Given the earlier evidence for direct involvement of the host cell spectrin in the invasion process[1,14], it is a reasonable conjecture (although it cannot be regarded as proven) that spectrin is the invasion-linked substrate for the cAMP-independent kinase.

This investigation received financial support from the UNDP/World Bank/WHO Special Programme for Research and Training in Tropical Diseases. We thank Dr J. C. Pinder for discussion and advice on kinase preparation.

Plant chitinases are potent inhibitors of fungal growth

Angela Schlumbaum, Felix Mauch,
Urs Vögeli & Thomas Boller

Abteilung Pflanzenphysiologie, Botanisches Institut,
Universität Basel, Hebelstrasse 1, CH-4056 Basel, Switzerland

The antimicrobial arsenal of plants is thought to consist mainly of secondary metabolites, among which the phytoalexins are the best-studied[1–3]. But plants may also possess antimicrobial proteins[4,5]: it has been reported that wheat-germ agglutinin, a chitin-binding lectin from wheat embryos, inhibits growth of the fungus *Trichoderma viride*[4]. This has led to the notion that plant lectins, with their intriguing biochemical similarity to animal antibodies, have an antibody-like antimicrobial function[4,6,7]. We report here that the main proteinaceous inhibitor of fungal growth in bean leaves is chitinase, an enzyme that can be induced by the plant hormone ethylene, or by pathogen attack. Among commercial preparations of purified chitin-binding lectins (from wheat germ, tomato, potato, pokeweed and gorse), only those containing contaminating chitinase activity inhibit fungal growth. Our data indicate that plant chitinases, but not chitin-binding lectins, are important antifungal proteins in plants.

The resistance of plants to potentially pathogenic microorganisms is based on multiple biochemical factors[1]. Particularly important are the phytoalexins, antimicrobial micromolecules that are not present in healthy plants but accumulate in response

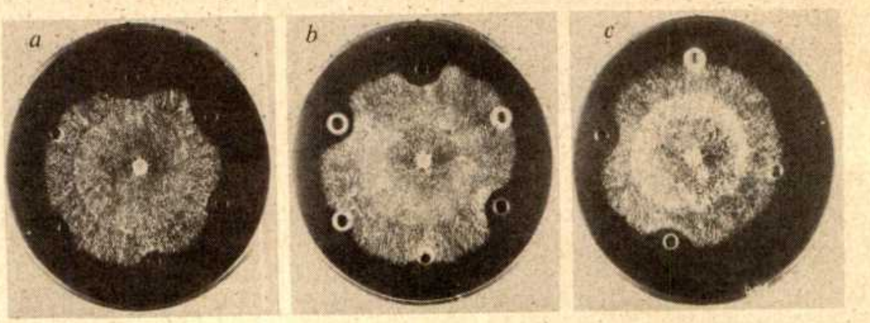

Fig. 1 Growth inhibition of *T. viride* in response to various protein preparations. *a*, Purified bean chitinase[13]. Wells contain 20 μl of the following solutions in μg ml^{-1} (from top, in clockwise direction): 600; 150; 37; 9; 2; 0.6. *b*, Purified chitinase and crude protein extracts from primary bean leaves. Wells contain 20 μl of the following solutions in μg ml^{-1} (from top, in clockwise direction): Purified bean chitinase (130); purified bean chitinase (130) in the presence of antiserum against chitinase; crude protein (12 mg ml^{-1}) from leaves treated with 10 nl ml^{-1} ethylene for 48 h; crude protein (12 mg ml^{-1}) from control leaves; crude protein (12 mg ml^{-1}) from ethylene-treated leaves in the presence of antiserum against chitinase; and crude protein (12 mg ml^{-1}) from ethylene-treated leaves in the presence of preimmune serum. The chitinase activities, determined after the addition of the sera, corresponded to the following concentrations of bean chitinase in μg ml^{-1} (from top, in clockwise direction): 130; 0.1; 130; 1.4; 1.3; 130. *c*, Purified bean chitinase and wheat germ agglutinin (WGA). Wells contain 20 μl of the following solutions (from top, in clockwise direction): commercial wheat germ agglutinin (25 mg ml^{-1}); commercial wheat germ agglutinin (5 mg ml^{-1}); wheat germ agglutinin purified by affinity chromatography on regenerated chitin, 3.5 mg ml^{-1} (with a chitinase activity corresponding to 115 μg ml^{-1} bean chitinase); and bean chitinase, 100 μg ml^{-1}.

Methods. *T. viride* (a gift of Dr Dahmen) was grown on Petri dishes containing 2% malt extract agar at the bottom and 1.5% malt extract agar at the top. One day after inoculation, when the colony diameter was 3-4 cm, wells punched into the 1.5% agar layer 1 cm from the growing front were filled with 20 μl of the various preparations. The plates were photographed 8-12 h later. The crude protein extracts were prepared using 0.1 M potassium phosphate buffer, *p*H 7.0 (4 ml per g fresh weight). After centrifugation (10 min at 10,000 *g*), the supernatant was precipitated overnight with ammonium sulphate at 97% saturation, taken up in half the extraction volume and dialysed twice against 0.01 M potassium phosphate buffer, *p*H 7.0. The extracts were filtered through a 0.22 μm membrane filter (Sartorius, type SM 16534), lyophilized, and taken up in water. Chitinase and protein were measured as previously described[13].

to microbial infection[1-3]. Many of these phytoalexins inhibit growth of fungi at concentrations of 10-50 μg ml^{-1}. In addition, plants may possess proteins with antibiotic activity[4,5]. This was first demonstrated when Mirelman *et al.*[4] found that wheat-germ agglutinin (WGA), a chitin-binding lectin, inhibited growth of the fungus *T. viride* at concentrations of $\geq$600-1200 μg ml^{-1}. Several lectins have since been reported to inhibit fungal growth under similar conditions[8,9]. Plant lectins that bind to fungal cell walls are therefore thought to have an antifungal role[5,6-9].

Another group of plant proteins with potential antifungal functions are the hydrolases that can attack the main components of fungal cell walls, chitin and β-1,3-glucan[1,10]. We have studied chitinase, an enzyme with no known endogenous substrate in higher plants[10,13], which has been purified from various plant tissues, including wheat germ[11], tomato leaves[12] and bean leaves[13]. This enzyme is strongly induced in response to the plant hormone, ethylene[13], and in response to infection by pathogens[12,14,15]. Purified plant chitinase readily liberates chitin oligomers from purified fungal cell walls[12,13] and acts as a lysozyme against bacterial cell walls[10,13]. This is indirect evidence for antimicrobial activity of the enzyme.

To examine antifungal activity directly, we tested the effect of purified bean chitinase on growth of *T. viride*, using the method of Mirelman *et al.*[4]. We observed a marked concentration-dependent inhibition of fungal growth around the wells containing chitinase (Fig. 1*a*). The smallest concentration of chitinase that resulted in a distinct inhibition zone was 2 μg ml^{-1}. This means that chitinase is 300 times as potent as the WGA preparation of Mirelman *et al.*[4].

Boiled chitinase had no effect on fungal growth. Most plant chitinases are basic proteins[10], but another basic protein, cytochrome *c*, did not inhibit fungal growth in the bioassay at concentrations up to 10 mg ml^{-1} (data not shown). When antibodies were raised against purified bean chitinase in a rabbit, the antiserum was found to block chitinase activity. It also blocked the inhibitory effect of chitinase on fungal growth (Fig. 1*b*) whereas preimmune serum of the same rabbit had no such effect.

We tested crude protein extracts from bean leaves in the fungal growth assay, using a protein concentration (12 mg ml^{-1}) equivalent to that in leaves (Fig. 1*b*). Protein extracts from ethylene-treated leaves produced much larger inhibition zones than extracts from control leaves. This correlates well with strong induction of chitinase by ethylene[13]. The crude extracts from ethylene-treated leaves had a chitinase activity equivalent to 130 μg ml^{-1} pure chitinase. The same amount of pure chitinase produced an inhibition zone of a similar size. The inhibitory effect of the crude extract was almost completely overcome by the addition of antiserum against chitinase, whereas preimmune serum did not affect it (Fig. 1*b*). These data indicate that chitinase is the main inhibitor of fungal growth in crude protein preparations from bean leaves.

We have also examined bean leaves from plants infected with bean rust, *Uromyces phaseoli*, using the bean cultivar Warox, which is hypersensitively resistant to the pathogen used. We found that chitinase was about tenfold induced in response to infection. Crude extracts from infected leaves produced larger inhibition zones than did extracts from uninfected control leaves; again, adding the antiserum against bean chitinase prevented the formation of an inhibition zone (Table 1).

Table 1 Inhibtition of fungal growth by crude extracts from rust-infected and uninfected bean leaves

Test Preparation	Protein mg ml^{-1}	Chitinase μg ml^{-1}	Inhibition of Fungal Growth
Extract from	7.0	3.3	+
uninfected leaves	3.5	1.6	−
Extract from	6.6	30	+++
infected leaves	3.3	15	+++
	1.7	7.5	++
Extract from infected leaves and antiserum	6.6	<0.05	−

Bean seedlings (c. Warox, supplied by van Waveren Pflanzenzucht, Rosdorf, FRG) were sprayed 10-14 days after germination with 1% Tween-80 (controls) or with 1% Tween-80 containing 6×10^4 spores of bean rust per ml (*U. phaseoli*, supplied by Dr U. Gisi). The plants were kept for 48 h at 100% humidity and further incubated in a greenhouse for 12 days. Protein extracts from primary leaves were prepared as described in the legend to Fig. 1. Chitinase activity[13] is expressed in equivalents of pure bean chitinase[15]. The effect on growth of *T. viride* (tested with 20 μl of each preparation as in Fig. 1) is expressed in qualitative terms: +++ stands for strong inhibition, + for just detectable inhibition.

Table 2 Effect of chitin-binding plant lectins on fungal growth

Lectin preparation	Protein mg ml^{-1}	Titre μg ml^{-1}	Chitinase μg ml^{-1}	Inhibition of fungal growth
Tomato lectin*	2	<0.5	13	+++
Potato lectin*	2	0.9	1.7	+
Pokeweed lectin†	5	30	0.7	++
Pokeweed lectin*	3	0.2	<0.05	–
Gorse lectin UEA II*	2	60	0.06	–

The titre for the agglutination of trypsinized red blood cells and the chitinase activity[13], expressed in equivalents of pure bean chitinase[15], were determined for each lectin preparation. The effect on growth of *T. viride* (tested with 20 μl of each preparation as in Fig. 1) is expressed in qualitative terms as in Table 1.

* Obtained from Sigma.

† Obtained from Serva.

To reexamine the antifungal effect of WGA[4], we verified that purified WGA (Serva) agglutinated trypsinized red blood cells (titre: 2.4 μg ml^{-1}) and found that it contained no measurable chitinase activity. This WGA preparation did not inhibit growth of *T. viride* even at concentrations of 25 mg ml^{-1} (Fig. 1*c*). Preparations of WGA from Sigma, Calbiochem and Pharmacia were similarly free of contaminating chitinase and did not inhibit fungal growth.

Mirelman *et al.*[4] purified WGA by affinity chromatography on sepharose-2-acetamido-N-(5-aminocaproyl)-2-deoxy-β-D-glucopyranosylamine. However, affinity chromatography of WGA may result in copurification of WGA and chitinase[11]. WGA prepared by affinity chromatography on regenerated chitin[11,16] (a readily available affinity matrix) agglutinated trypsinized red blood cells with a titre of 3.3 μg ml^{-1} and contained contaminating chitinase activity equivalent to ~40 μg bean chitinase per mg protein. (Wheat-germ chitinase had previously been purified from a similar affinity-purified WGA preparation[11].) This chitinase-contaminated WGA preparation strongly inhibited growth of *T. viride* at a concentration of 3.5 mg ml^{-1} (Fig. 1*c*). The antiserum against bean chitinase did not inhibit the chitinase activity in WGA and did not reduce the size of the inhibition zone caused by the contaminated WGA. When pure bean chitinase was added to chitinase-free commercial WGA, the combination inhibited fungal growth in the same way as affinity-purified WGA (data not shown). Thus, the inhibitory effect of WGA observed by Mirelman *et al.*[4] may have been caused by contamination with chitinase.

We have also tested the effect of several other commerical lectins with a specificity for N,N'-diacetylchitobiose or N,N',N''-triacetylchitotriose (Table 2). The tomato and the potato lectin preparations contained contaminating chitinase activity. Both inhibited fungal growth. The chitinases present in these preparations were found to be serologically related to bean chitinase as the antiserum against bean chitinase totally inhibited the chitinase activity of both. The antiserum also suppressed the growth-inhibiting activity of the lectin preparations completely (data not shown). We obtained two different preparations of pokeweed (*Phytolacca americana*) lectin. One preparation (Serva), had lower lectin activity than the other. It was contaminated with chitinase and inhibited fungal growth (Table 2). The other preparation (Sigma), although more active as a lectin, did not contain chitinase and did not inhibit fungal growth. A gorse agglutinin, UEA II, contained almost no chitinase activity and did not inhibit fungal growth. Collectively, these data show that preprations of chitin-binding lectins inhibit growth of *T. viride* only when they are contaminated by chitinase. Of further commercial lectin preparations with other specificities examined (concanavalin A, bean phytohemagglutinin A, peanut agglutinin, osage orange lectin), none was contaminated by chitinase, and none inhibited fungal growth.

We have demonstrated directly that plant chitinases are highly potent growth inhibitors of *T. viride*. It is likely that the effect is attributable to enzymatic attack on newly formed chitin in the growing hyphal tips[11] disturbing the balance between synthesis and hydrolysis required for tip growth[17]. It is intriguing that chitinase and β-1, 3-glucanase are coordinately induced by ethylene or by pathogen attack in plants[10,14]. Chitinase alone, at concentrations of 2 μg ml^{-1}, is sufficient to stop growth of *Trichoderma viride*, a non-pathogenic test fungus. Inhibition of several other fungi, however, requires the presence of a combination of chitinase and β-1, 3-glucanase at similar concentrations (F.M., B. Mauch and T.B., in preparation). On a concentration basis, antimicrobial plant hydrolases, either alone or in combination, are inhibitors of fungal growth at least as potent as the phytoalexins. They may be similarly important in the defences of plants against pathogens.

Sulphonolipids are molecular determinants of gliding motility

Darren R. Abbanat, Edward R. Leadbetter, Walter Godchaux III & Alan Escher

Department of Molecular and Cell Biology, U-131,
University of Connecticut, Storrs, Connecticut 06268, USA

A variety of bacteria[1] that possess no obvious locomotor organelles are, nonetheless, able to translocate on solid surfaces (but not through liquids). In no case has the mechanism of this 'gliding' motility been elucidated[2]. Our recent discovery that unusual sulphonolipids[3,4] (Fig. 1) are major cell-envelope components peculiar to the *Cytophaga-Flexibacter* group of gliding bacteria[5] led us to examine whether these lipids are important in this motility. Mutants deficient in both gliding and sulphonolipid synthesis were isolated from mutagenized cultures of *Cytophaga johnsonae* (our laboratory strain, originally ATCC 17061). In some of these mutants, restoration of sulphonolipid content through provision of a specific biosynthetic precursor resulted in recovery of the ability to glide. The sulphonolipids are the first molecules shown to be specifically required for gliding motility (surface translocation).

Cultures ($A_{650} = 0.8$) mutagenized with *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (0.3 mg ml^{-1}) for 60 min were diluted and plated on LTY agar (Fig. 2 legend); 48 spreading-deficient clones were selected on the basis of colony morphology. The colonies formed by gliding cells expand rapidly, are thin and have finger-like projections at their edges, whereas those of nonmotile cells are compact, rounded and have sharply-demarcated edges (Fig. 2). In minimal liquid medium (fructose plus inorganic salts, with sulphate as the sole sulphur source), all the mutant strains considered below grew with the same doubling time (±5%) as

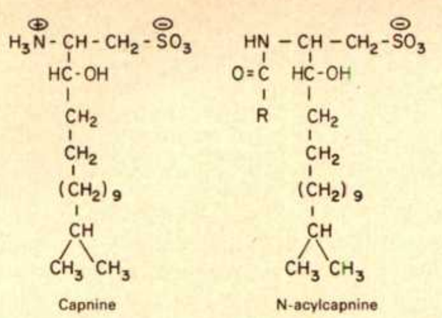

Fig. 1 Structures of the sulphonolipids. R–CO– represents one of a variety of long-chain fatty acids[4]. *N*-acylcapnine is the predominant species found in the parent strain of *C. johnsonae*; capnine is apparently a precursor of the acylated form.

the parent strain, so their abnormal colony morphology was not the result of growth defects. These spreading-deficient strains were examined for sulphonolipid content. Cells were grown in minimal medium containing $Na_2^{35}SO_4$ and lipid radioactivity was measured after separation by thin-layer chromatography (methodological details are given in ref. 5). Four strains were found to be deficient in some aspect of their sulphonolipid content.

Mutant 21A2I contained less than 2% of the amount of sulphonolipid found in the parent strain (Table 1) and was a virtual nonglider, as judged not only by the failure of its colonies to spread (Fig. 2, top row) but also by direct observation using the phase-contrast microscope. Gliding cells form 'rafts'—groups of cells gliding together—that can be observed when they detach from the colony edge. In the parent strain these rafts moved at an average rate of about 25 μm min^{-1} (Table 1). In contrast, the edges of colonies of mutant 21A2I were smooth and no gliding movement of cells could be observed.

We have shown[6] that L-cysteate is the immediate precursor of carbons 1 and 2, the sulphonate group and (probably) the amino group of capnine (Fig. 1). Cysteate is thought to condense with an activated fatty acid to form, ultimately, capnine[6], in a manner analogous to the biosynthesis of sphingosine from serine and a fatty acyl coenzyme A[7]; capnine is then *N*-acylated. Provision of L-cysteate in the growth medium restored the sulphonolipid content of mutant 21A2I to normal (Table 1); as is the case in the parent strain[5], virtually all the sulphonolipid thus formed was in the form of *N*-acylcapnine. Provision of L-cysteate also restored gliding motility; colony spreading became normal (Fig. 2, bottom row) and rafts were formed and moved at about the same speed as those of the parent strain (Table 1). Evidently mutant 21A2I is unable to form cysteate, an obligatory precursor of capnine, from the standard sulphur sources provided in these experiments but when given cysteate it can synthesize sulphonolipid and therefore can glide. A second mutant, number 42, is apparently a 'leaky' version of 21A2I. It contains detectable sulphonolipid but only 13% of normal levels; its colony-spreading and raft-movement rates are also low (70 and 30% of the parent-strain rates, respectively) and L-cysteate restores gliding ability to normal.

The effects of cysteate are stereospecific; D-cysteate, which does not compete with L-cysteate for incorporation into capnine (unpublished observations), did not restore gliding motility (Fig. 2, middle row). Hence, the effect of L-cysteate on gliding must be a biological one and not some gross physical effect of a sulphonate in the medium. A number of other compounds tested, including L-homocysteate, taurine, L- and D-cystine, L-cysteine sulphinic acid, L-methionine, L-djenkolate and 2-mercaptoethanesulphonic acid (coenzyme M), proved equally ineffective in restoring gliding. We also note that *C. johnsonae* cannot use cysteate as the sole sulphur source (unpublished observation) and that sulphur and carbon from exogenous L-cysteate are incorporated into sulphonolipids but not into protein[6]; indeed, the compound appears not to be metabolized except by incorporation into capnine. Thus it is not likely that cysteate restores gliding via some metabolic transformation other than conversion to sulphonolipid. These observations support the conclusion that sulphonolipids are necessary for gliding and militate strongly against other interpretations, as for example that 21A2I is a double mutant, or that it is deficient in some cellular product that is independently necessary both for sulphonolipid synthesis and for gliding. Such interpretations require two distinct roles for cysteate in restoring both sulphonolipid content and gliding motility.

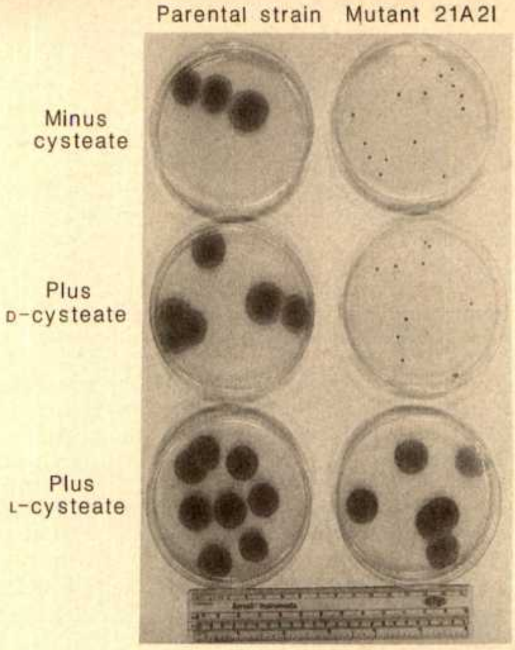

Fig. 2 Colony spreading in *C. johnsonae*. Cells of the parent strain or mutant 21A2I (as indicated) were cloned on LTY medium (0.05% yeast extract, 0.05% Tryptone, solidified with 1.8% agar) containing (where indicated) D- or L-cysteate (25 μM). After growing for 84 h at 30 °C, the colonies were stained with tetrazolium blue to enhance contrast for photography. A six-inch ruler is shown for scale.

Two additional gliding-deficient, sulphonolipid-deficient mutants were studied. Number 36 is phenotypically identical to 21A2I in mutant colony spreading and raft movement. It has normal total lipid sulphur content, over 99% of this in the form of free (non-acylated) capnine and there is no detectable *N*-acylcapnine (whereas in the parent strain, the converse is true). As expected, provision of L-cysteate does not restore gliding.

Table 1 Properties of mutant 21A2I

Strain	Addition to growth medium	Raft movement (μm min^{-1})	Sulphonolipid content (μmol per g cells, wet wt)
Parent	None	25±6	6.2±1.2
Parent	L-cysteate	24±8	10.0±2.6
21A2I	None	None	<0.1
21A2I	L-cysteate	35±8	9.4±2.6

Where indicated, L-cysteate was present at 25 μM. Raft movement was measured directly, on colonies grown as described in Fig. 2 legend, using a phase-contrast microscope fitted with a television monitor. Values are the mean (±standard deviation) of at least 12 independent determinations; 21A2I showed no raft formation or gliding movement in unsupplemented medium. When cysteate was absent, sulphonolipid content was measured, as described in the text, using $Na_2^{35}SO_4$ as the sole sulphur source. Cysteate, when added, was labelled with ^{35}S. Values are the mean (±s.d.) of at least six independent determinations.

Evidently, mutant 36 can synthesize cysteate and capnine but is defective in the *N*-acylation of capnine. This suggests that ability to form the *N*-acylated lipid is the specific requirement for gliding, but this conclusion must be regarded as tentative in the absence of supporting evidence. Another mutant, number 15, glides slowly (raft-movement and colony-spreading rates are 28 and 40% of the parent-strain values, respectively). Its lipid sulphur content is 40% of that found in the parent strain; it has traces of both capnine and *N*-acylcapnine, but most of the sulphur is found in abnormal sulphonolipids that do not co-chromatograph with either. Their nature is under investigation.

As has been reported[8] for many other non-gliding, non-spreading mutants of this bacterium, cells of the four mutants reported here display several behaviours characteristic of wild-type cells when examined microscopically in wet mounts of suspensions on glass slides. These include cell movements described[9] as spinning and pivoting, latex microsphere (260 nm diameter) movement over cell surfaces, and brief translocational movements of the cells (which, in the case of our mutants and parent strain, rarely exceed a single cell length on glass surfaces). We therefore conclude that sulphonolipids, although required for gliding motility and colony spreading on agar, are not required for the movements of *C. johnsonae* seen in wet mounts.

It seems reasonable to suppose that the cell and cell-surface movements observed in the wet mounts are caused by some subset of the machinery responsible for biologically significant gliding motility (cell translocation over long distances on solid surfaces). At present, however, the evidence[8-11] for this is indirect and the machinery remains undescribed. Our demonstration of the importance of the novel sulphonolipids in gliding motility provides new opportunities for examining the molecular basis of that process in these bacteria and for clarifying the relationship between cell movements in wet mounts and the mass translocation of cells over solid surfaces.

This research was supported by NSF grant PCM8214050.

Ion channels in human neutrophils activated by a rise in free cytosolic calcium concentration

V. von Tscharner, B. Prod'hom*, M. Baggiolini & H. Reuter*†

Theodor Kocher Institute and * Department of Pharmacology,
University of Berne, 3010 Berne, Switzerland

A rapid, transient rise in the free cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) is one of the earliest events in neutrophil activation and is assumed to be involved in many of the subsequent cellular reactions[1-3]. Both Ca^{2+} release from intracellular stores and Ca^{2+} influx from the extracellular space contribute to the rise in $[Ca^{2+}]_i$[4]. In an attempt to assess the relative importance of these pools and the sequences leading to the rise in $[Ca^{2+}]_i$, we have studied the time course of changes in $[Ca^{2+}]_i$ after stimulation with *N*-formyl-methionyl-leucyl-phenylalanine (fMLP) or platelet-activating factor (PAF) using the Ca^{2+} indicators quin-2 and fura-2. We observed a time lag of 1–3 s between stimulation and rise in $[Ca^{2+}]_i$. This lag depends on the agonist concentration but is independent of extracellular Ca^{2+}. Thus Ca^{2+} release from intracellular stores is rate limiting for the rise in $[Ca^{2+}]_i$. After this, cation channels in the plasma membrane (measured with the patch clamp method[5]) are opened. These non-selective channels, which also pass Ca^{2+}, are activated by the initial rise in $[Ca^{2+}]_i$, but by neither fMLP nor inositol 1,4,5-trisphosphate (IP_3) directly.

The time courses of change in $[Ca^{2+}]_i$ were measured in purified human neutrophils loaded with the indicators quin-2 (ref. 6) or fura-2 (ref. 7). Shortly before stimulation the cells were suspended in an isotonic saline solution containing either 1 mM $CaCl_2$ or 1 mM EGTA with no $CaCl_2$. Figure 1 shows the increase in $[Ca^{2+}]_i$ measured with quin-2 after stimulation of the neutrophils with the calcium ionophore ionomycin or the chemotactic peptide fMLP. A rise in $[Ca^{2+}]_i$ was observed in both cases in the presence and absence of extracellular Ca^{2+}. The time courses, however, were different: the fluorescence changes induced by ionomycin started in less than 0.2 s, whereas those induced by fMLP were delayed up to 3 s ($\sim$1 s with fMLP 10^{-7} M; Fig. 1). The rate of fluorescence increase following either stimulus was about twice as fast when extracellular Ca^{2+} was present, because Ca^{2+} influx from the extracellular space is added to Ca^{2+} release from intracellular stores[8-10]. The experiments with ionomycin show that: (1) $[Ca^{2+}]_i$ changes mediated by the ionophore occur without a measurable time lag and (2) the time resolution of our testing system (depending on mixing, Ca^{2+} buffering by the indicator and the response time of the apparatus) was well above the range of the lag periods after stimulation with fMLP. Thus the delay in the response to fMLP reflects the time required for stimulus transduction.

We performed further experiments using fura-2 as the indicator and either fMLP or PAF as stimuli. Fura-2 can be used at lower concentrations than quin-2, resulting in less buffering of $[Ca^{2+}]_i$ because of its higher fluorescence quantum yield[7]. The fura-2 fluorescence changes were comparable to those seen with quin-2. A lag period of similar duration was observed between stimulation with either fMLP or PAF and the increase in $[Ca^{2+}]_i$. The lag time shortens and the rate of fluorescence change increases markedly with increasing concentrations of fMLP (Fig. 2). Similar families of curves were recorded upon stimulation with PAF (not shown). With either stimulus the duration of the lag was virtually identical with or without extracellular Ca^{2+} (6 experiments).

Thus the rise in $[Ca^{2+}]_i$ is initiated by a rate-limiting process that does not depend on extracellular Ca^{2+}. But it is clear that Ca^{2+} influx does occur in fMLP- or PAF-stimulated cells (Fig. 1)[8-10]. What controls the Ca^{2+} permeability of the plasma membrane? We have performed patch clamp experiments[5] and have measured ion channel activity in the neutrophil plasma membrane directly. Channels with similar properties were recorded in both cell-attached and isolated, inside-out membrane patches. In resting cells the occurrence of channel openings was extremely rare and the opening probability was not increased in the presence of fMLP (10^{-8} to 10^{-6} M) in the pipette solution. This strongly suggests that the channels are not directly coupled to the agonist receptor. If fMLP was added to the bathing medium with Ca^{2+} concentrations of 1-2 mM, about half (13/24) of the cells responded with increased channel openings. If cells were loaded with fura-2 in the absence of external Ca^{2+} (ref. 11) $[Ca^{2+}]_i$ was reduced to about 10^{-9} M and fMLP did not induce channel openings. Extensive single channel activity was observed in inside-out membrane patches, provided the Ca^{2+} concentration in the bathing solution (which is in contact with

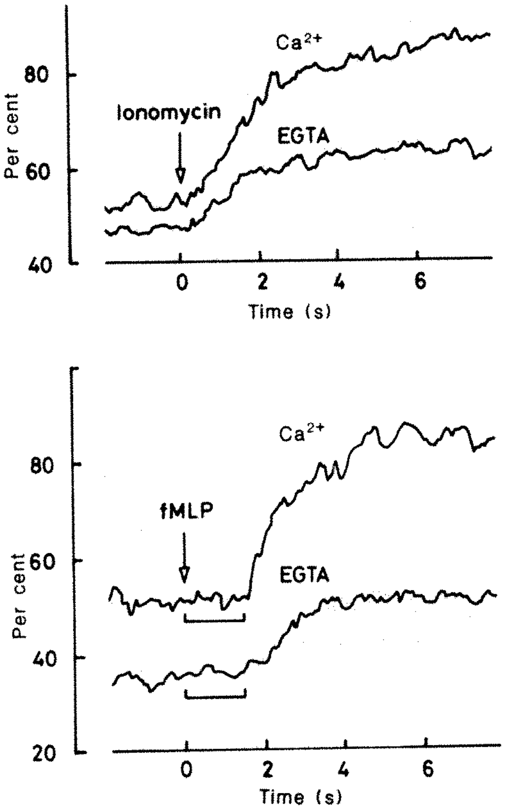

Fig. 1 Quin-2 fluorescence curves in human neutrophils following addition (arrow) of ionomycin (2×10^{-6} M) or fMLP (10^{-7} M). The upper traces (Ca^{2+}) were obtained in the presence of 1 mM $CaCl_2$ in the medium, and the lower traces (EGTA) in a calcium-free medium with 1 mM EGTA added 5 min before stimulation. The lag times between fMLP addition and onset of quin-2 fluorescence increase are indicated by the bars underneath the tracings. **Methods.** Neutrophils were obtained from buffy coats of donor blood stored for up to 24 h at 4–10 °C (Swiss Red Cross Laboratory, Berne, Switzerland) and purified by centrifugation through a discontinuous Lympho-paque gradient[21]. The cells collected at the boundary between the two density layers (95–98% neutrophils) were washed three times by centrifugation (160*g* for 5 min at room temperature) in a saline medium containing 136 mM NaCl, 4.8 mM KCl, 1.2 mM KH_2PO_4, 5 mM glucose, buffered at *p*H 7.4 with 20 mM *N*-2-hydroxyethylpiperazine-*N*-2-ethanesulphonate (HEPES/NaOH). The final suspension was adjusted to 4×10^6 cells per ml and kept at room temperature until use. Loading with the fluorescent indicator: Neutrophils (4×10^6 cells per ml) were incubated for 30 min at 37 °C in the presence of quin-2 acetoxymethyl ester (0.4 nmol per 10^6 cells) dispensed from a 2 mM stock solution in dimethyl sulphoxide. The process was followed fluorimetrically and was considered to be complete when a maximum was observed in the 510/465 (nm/nm) fluorescence intensity ratio (510 nm is just above the fluorescence peak; 465 nm is an arbitrary reference point that changes very little as loading proceeds). A filter fluorimeter was specially constructed for high time resolution measurements. The excitation wavelength was selected from a 500 W Osram Hg-lamp with a band filter of 334 ± 10 nm. A 470 nm cut-off filter was inserted on the emission side allowing the measurement of the whole emission band with a photomultiplier (EMI 9798QB) connected to an amplifier with a response time of 30 ms. Broad band emission measurement and the indicated amplifier's response time resulted in a reasonably high signal-to-noise ratio. Loaded neutrophils were stimulated at 37 °C in disposable polystyrol cuvettes (8 mm inner diameter) under magnetic stirring. The agonist was injected through a light-tight opening in the lid of the cuvette holder with a Hamilton syringe. Injection was timed by a triggering signal to the recorder. Intracellular calibration of the quin-2 signal was used to determine the quin-2 saturation fraction *q*. Ionomycin (2×10^{-6} M) was added to the cells in the presence of 1 mM extracellular Ca^{2+} to bring about complete saturation of intracellular quin-2 and the fluorescence was taken as F_{max}. All quin-2 fluorescence was then quenched by addition of 10 mM $MnCl_2$ and the background fluorescence was taken as F_0. In agreement with earlier work[22] the fraction of total quin-2 present as calcium complex *q* is then calculated according to the relations:

$$q=\frac{(F-F_{min})}{(F_{max}-F_{min})}$$

where

$$F_{min}=F_{max}-\tfrac{5}{6}(F_{max}-F_0)$$

the inner surface of the patch) was higher than 10^{-7} M. We have also measured the activity of these channels in saponin treated cells. We exposed whole cells to low (0.005%) saponin concentrations for ~10 min after establishing a gigaohm seal between pipette tip and membrane[12]. Saponin makes membranes permeable to small molecules. If Ca^{2+} was present in the external medium (10^{-5}–10^{-3} M) we observed activation of ion channels identical to those seen in inside-out patches, but if the Ca^{2+} concentration was lowered to 10^{-8} M the activity disappeared. Two types of single channel currents could be identified (Fig. 3). Although we have no direct evidence that the two current levels in Fig. 3 result from openings of two distinct populations of ion channels, in experiments with excised inside-out patches the larger currents disappeared more rapidly (within a few minutes) than the smaller ones, transitions between current levels were not strictly coupled and in many patches only one type of current could be seen. Therefore, we suggest that the currents flow through two separate types of ion channels.

With identical solutions (130 mM KCl or K-aspartate) on both sides of an inside-out membrane patch the current-voltage relationships were roughly linear with slope conductances of 18–25 pS and 4–6 pS at about 24 °C, respectively. Both channels discriminate only poorly between Na^+, K^+ and Ca^{2+}. This was assessed by measuring the reversal potential of single channel currents with two different ion species on either side of excised inside-out patches of membrane (Fig. 4*a*,*b*). With 90 mM $CaCl_2$ solution in the pipette and 130 mM KCl or K-aspartate solution in the bath, the reversal for both channel currents was near 0 mV (Fig. 4*d*), indicating that both channels were permeable to Ca^{2+} and K^+. The same was true when a 130 mM NaCl solution replaced the K-aspartate solution in the bath or the $CaCl_2$ solution in the pipette. Outward currents through the channels at positive membrane potentials were usually larger than inward currents (Fig. 4*d*). Channel openings were seen more often at positive than at negative membrane potentials, implying some voltage dependence of channel gating. However, single channel currents could only be measured if the Ca^{2+} concentration in the bath was raised to above 10^{-7} M (Figs 3*c* and 4*c*). Therefore, a rise in $[Ca^{2+}]_i$ is an essential step in the gating of both channels. Open times ranged from a few milliseconds up to several seconds. The smaller conductance channel was more likely to stay open for many seconds. IP_3, which has been shown to release Ca^{2+} from interacellular stores in neutrophils[13], does not by itself induce ion channel activity when added to the internal surface of the membrane (Fig. 3*b*).

Our findings strongly suggest that in neutrophils the first step leading to a change in $[Ca^{2+}]_i$ is the release of Ca^{2+} from intracellular stores. This Ca^{2+} release seems to be induced by IP_3 (ref. 13) formed after agonist-receptor occupancy[14]. The increase in $[Ca^{2+}]_i$ due to Ca^{2+} release causes transient openings of Ca^{2+}-gated ion channels in the membrane through which more Ca^{2+} ions flow into the cytoplasm. Over a time period of 1-2 min the fluorescence signals decrease again (not shown) indicating a reduction in the free cytoplasmic Ca^{2+} concentra-

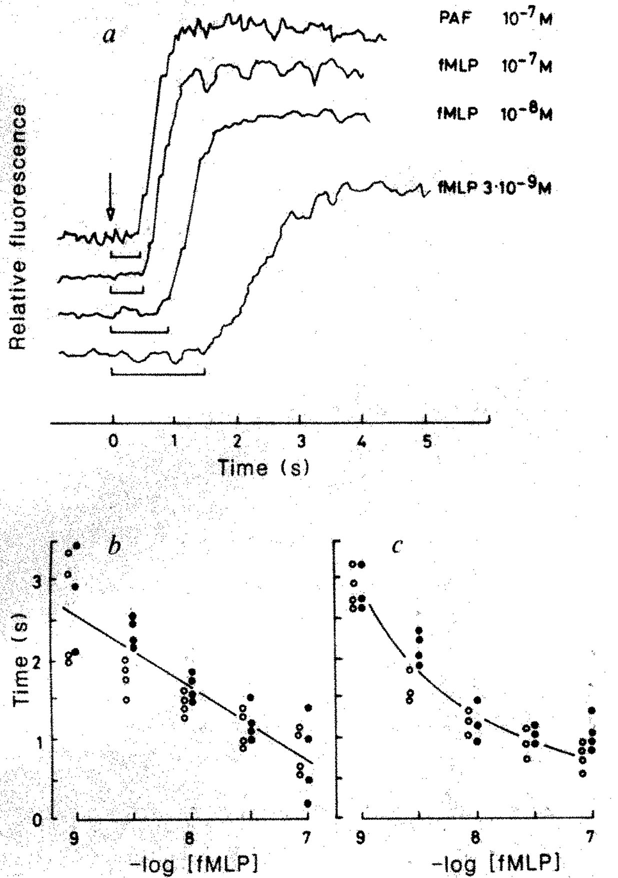

Fig. 2 *a*, Fura-2 fluorescence increase in human neutrophils stimulated with PAF or fMLP. The lag times between agonist addition (arrow) and the onset of fluorescence increase are indicated by the bars under the single tracings. Average $[Ca^{2+}]_i$ prior to stimulation with agonists was 1.3×10^{-7} M. *b*, Plot of the lag time between fMLP addition and onset of fluorescence increase against fMLP concentration. Single values obtained with the same cell preparation in the presence (●) and absence (○) of extracellular calcium are shown with the calculated regression line. No statistical difference was observed between the regression lines through the values obtained with or without extracellular calcium. *c*, Time for an increase in fluorescence to 90% of maximum against concentration of fMLP. Data from the same series of experiments as *b*.

Methods. The neutrophils were prepared as described (Fig. 1) and loaded with fura-2 (0.1 nmol per 10^6 cells) using the same protocol as for quin-2. Fluorescence measurements were made with the instrument described in Fig. 1 legend. Excitation was at 334 ± 10 nm and emission was recorded through a band-pass filter of 500 ± 10 nm. Since lag time measurements do not require it, absolute calibration of the fura-2 signal was omitted to allow frequent repeats of the assay with single batches of cells. A fluorescence decrease due to degranulation as seen in mast cells[23] was not observed.

tion. In intact cells we found spontaneous inactivation of the cation channels which may contribute to this fall in $[Ca^{2+}]_i$. Since the opening of the poorly selective cation channels is not rate limiting for the initial rise in $[Ca^{2+}]_i$, the observed lag period is independent of the external Ca^{2+} concentration. Influx of Na^+ in addition to Ca^{2+} ions through these channels accounts for the depolarization associated with neutrophil stimulation[15]. We found no evidence for voltage-dependent Ca^{2+} channels as in neoplastic B lymphocytes[16]. The channels described in this paper also differ from other Ca^{2+}-activated non-selective cation channels[17,18] in being highly permeable to Ca^{2+} ions. Although the exact role of Ca^{2+} in other neutrophil reactions (for example, superoxide anion production, degranulation, aggregation) is still

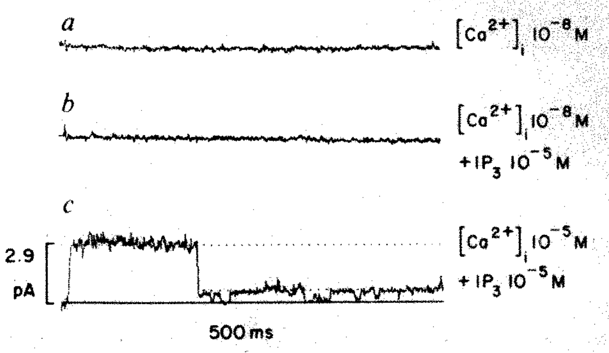

Fig. 3 Ion channel activation by $[Ca^{2+}]_i$ in an inside-out patch of neutrophil membrane. *a*, 10^{-8} M $[Ca^{2+}]_i$; *b*, 10^{-8} M $[Ca^{2+}]_i + 10^{-5}$ M IP_3; *c*, 10^{-5} M $[Ca^{2+}]_i + IP_3$. No channel openings were seen in *a* or *b*, but two outward current levels resulting from openings of ion channels can be seen in *c*. Presence of IP_3 was not required for activation of the channels. The membrane potential of the patch was held at −100 mV and currents were recorded during voltage steps of 500 ms duration to +100 mV.

Methods. Single channel currents were recorded in an excised, inside-out patch of membranes from human neutrophils using the patch clamp method[5]. The bath solution (23-25 °C) contained 130 mM K-aspartate, 20 mM HEPES buffer (*p*H 7.4) and 10^{-8} M $[Ca^{2+}]_i$ (0.32 mM $CaCl_2$ + 1 mM EGTA; apparent stability constant $10^{7.5}$ M^{-1}), or 10^{-5} M (unbuffered) free $[Ca^{2+}]_i$; the solution in the recording pipette contained 90 mM $CaCl_2$ and 10 mM HEPES buffer (*p*H 7.4). Digitized records (1 ms per point) were analysed by a computer (PDP 11/04). Capacity transients and leakage currents during voltage steps have been subtracted. Heavy lines in the records indicate the closed state of the channel while dotted lines show the average current levels when the channels are open.

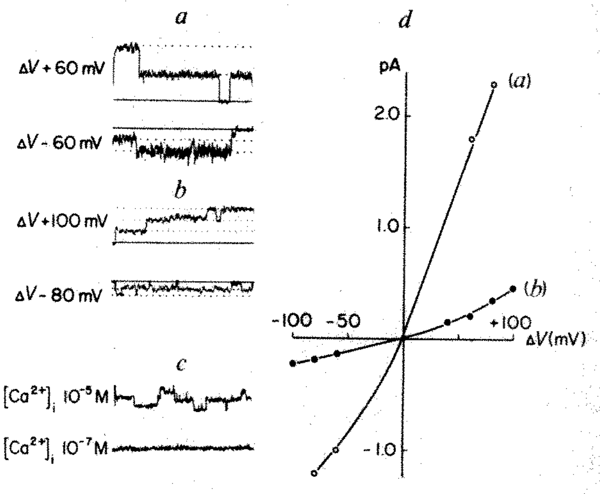

Fig. 4 Examples of current traces (*a*–*c*) and corresponding current–voltage relationships (*d*) of two types of ion channels in excised inside-out membrane patches from human neutrophils. Bath and pipette solutions were the same as in Fig. 3. Outward currents through open channels (upward deflections from heavy base line) were carried by K^+ ions, while inward currents (downward deflections) were carried by Ca^{2+} ions (*a*, *b*). Channel openings were observed only when the $[Ca^{2+}]$ at the inner surface of the membrane patch was raised above 10^{-7} M (*c*). Time scales are 0.5 s in *a* and *b* and 10 s in *c*. Current amplitudes during single channel openings at different membrane potentials have been plotted in *d*. ○, Current-voltage relationship from single-channel currents in *a*; ●, current-voltage relationship from single-channel currents in *b*. Note that outward currents at positive pulse potentials (Δ*V*) are larger than inward currents at negative potentials. The reversal potential is near 0 mV, indicating similar permeabilities for K^+ and Ca^{2+} through the channel.

unclear[19], the rise in $[Ca^{2+}]_i$ appears to be an important intermediary step in neutrophil activation[15,20].

We thank the Swiss National Science Foundation (grants 3.353-0.82 to M.B. and 3.059-0.84 to H.R.) for generous support and Markus Gerber for technical assistance.

A complementary DNA clone for a macrophage-lymphocyte Fc receptor

Victoria A. Lewis, Terry Koch, Helen Plutner & Ira Mellman*

Department of Cell Biology, Yale University School of Medicine,

Connecticut 06510, USA

Macrophages, granulocytes and many lymphocytes express or secrete receptors for the Fc domain of immunoglobulins (Ig)[1]. These Fc receptors (FcRs) are heterogeneous and can be distinguished on the basis of their cellular distribution and specificities for different immunoglobulin isotypes. Although their functions are not completely understood, FcRs are known to be involved in triggering various effector cell functions and in regulating differentiation and development of B-cells[1-4]. One of the best characterized is the mouse macrophage-lymphocyte receptor for IgG_1 and IgG_{2b} (ref. 5). On macrophages, this FcR mediates the endocytosis of antibody-antigen complexes via coated pits and coated vesicles[6,7], the phagocytosis of Ig-coated particles[8], and the release of various inflammatory and cytotoxic agents[1]. It is possible that the receptor possesses an intrinsic ligand-activated ion channel activity responsible for some of these functions[9,10]. The IgG_1/IgG_{2b} FcR has been isolated and shown to be a transmembrane glycoprotein of relative molecular mass (M_r) 47,000–60,000 (47–60 K) containing four *N*-linked oligosaccharide chains and a large (>10K) cytoplasmic domain[11]. It is also immunologically indistinguishable from the murine Ly-17 alloantigen which, in turn, is tightly linked to the *Mls* lymphocyte activation locus[12-14]. Here we describe the isolation and characterisation of a complementary DNA clone encoding the whole of the IgG_1/IgG_{2b} FcR expressed by the mouse macrophage-like cell line $P388D_1$. The receptor is a member of the immunoglobulin superfamily and, like Ly-17, maps to the distal portion of chromosome 1. cDNA probes detect one or two mRNA species in FcR^+ macrophage and B-cell lines, but not in FcR^- cells or a receptor-deficient variant derived from a FcR^+ B-cell line[15]. Finally, DNA hybridization analysis indicates the receptor gene is partially deleted or rearranged in the FcR^- variant.

FcR cDNAs were isolated from a $P388D_1$ λgt11 library (obtained from A. Ezekowitz, Harvard University) using both antibody and oligonucleotide probes. Antibody screening was performed[16] using a monospecific rabbit antiserum raised against sodium dodecyl sulphate (SDS)-denatured FcR purified from the J774 mouse macrophage cell line[11]. A single positive phage was plaque-purified and found to contain a 580 base pair (bp) insert (pFcRAb). For oligonucleotide screening, a double stranded 42 bp probe corresponding to residues 2-15 of the FcR's chemically determined N-terminal amino-acid sequence was made (Fig. 1*a*). Two plaques (pFcR11 and pFcR13) were purified, subcloned and found to contain 0.8 and 1.5 kilobase (kb) inserts respectively. The clone isolated by antibody screening cross-hybridized with those obtained by oligonucleotide screening (not shown). Their specificity for the FcR was confirmed by nucleotide sequence analysis of the 5′ ends of pFcR11 and pFcR13. Both contained sequences corresponding to the N-terminal amino acid-sequence (Fig. 1*b*).

Figure 1*c* shows the complete nucleotide sequence compiled from the three inserts, and the amino acid sequence of the FcR thereby deduced. The largest clone, pFcR13, includes the receptor's entire coding region as well as 3′ untranslated sequences containing a consensus $poly(A)^+$ addition sequence and a $poly(A)^+$ tract. pFcR11 corresponds to the 5′ half of the 1.5 kb pFcR13 clone, whereas pFcRAb corresponds to the 3′ half: they overlap with each other by only 27 nucleotides. From the deduced amino acid sequence, the FcR contains an N-terminal hydrophobic signal peptide. However, some ambiguity remains regarding the identity of the actual initiator AUG codon as the putative signal sequence contains three methionine residues (at positions −13, −29 and −39) any of which could begin a signal sequence. We believe that Met−13 is the best candidate because the putative signal it begins contains the hydrophobic and cleavage domains typical of shorter signal peptides[17]. Although Met−29 lies in a nucleotide sequence most closely (but not precisely) corresponding to a consensus start site for translation[18], it implies a signal peptide beginning with an atypically long stretch of polar residues (G. von Heijne, personal communication).

The amino acid sequence of the mature FcR starts with a Thr and contains four potential *N*-linked glycosylation sites (Asn-X-Ser/Thr, X ≠ Pro; at positions 36, 63, 137 and 144), a single hydrophobic membrane-spanning segment followed by a charged stop-transfer sequence, and a large hydrophilic cytoplasmic domain. These results agree well with the results of our previous biochemical investigations which used endoglycosidase digestion to identify four *N*-linked oligosaccharides and protease digestion of ^{35}S-methionine-labelled microsomes to locate a cytoplasmic segment possibly >10 kD in length[11]. While the length of the cytoplasmic domains predicted from the position of the first stop codon is only 47 residues (6.7 K), the size determined from SDS polyacrylamide gel electrophoresis data could easily be an overestimation, as found previously[19]. Nevertheless it is interesting that the first stop codon is followed by two long open reading frames of 32 and 65 amino acids prior to the occurrence of multiple stop sites. Although the digestion experiments also showed that ~15 K of the receptor was resistant to proteolysis from either side of the membrane, the nucleotide sequence reveals that this protection was not due to the presence of multiple membrane-spanning domains. As the FcR contains only a single hydrophobic domain it is probable that its putative ion channel activity[9,10] could occur only by receptor aggregation. However, the FcR's predicted membrane spanning segment of 29 amino acids is somewhat longer than those found in most membrane proteins.

Fig. 1 IgG_1/IgG_{2b} Fc receptor nucleotide sequence and predicted amino acid sequence. *a*, Nucleotide sequence of synthetic oligonucleotide probe based on N-terminal amino-acid sequence of the intact FcR protein isolated from J774 cells. Assignment of residue 1 (Thr) was ambiguous and therefore omitted, as was residue 16 (Ile). Overlapping 27- and 24-mers (underlined) corresponding to amino acids 2–15 from coding and non-coding strands were chemically synthesized. Five deoxyinosine residues were inserted at positions of highest ambiguity. Asterisks denote three positions of mismatch between the sequence of the synthetic probe and the isolated cDNA clone. *b*, Schematic representation of cDNA clones representing the complete FcR coding sequence. pFcRAb and pFcR11 correspond to the 3′ and 5′ halves of the coding sequence respectively and overlap by 27 nucleotides just 3′ to sequences coding for the putative transmembrane domain (overlined). pFcR13 completely contains both pFcRAb and pFcR11. Black boxes, sequences corresponding to the synthetic oligonucleotide probe. Open boxes, poly$(A)^+$ tracts. *c*, Nucleotide and predicted amino-acid sequence of pFcR13. Nucleotides are numbered in the 5′ to 3′ direction starting with the first nucleotide in the codon of the N-terminal residue in the mature protein. Nucleotides 5′ to base 1 have negative numbers and include residues encoding a putative signal peptide and a 5′ untranslated region. The four glycosylation sites are lightly overlined, cysteine residues involved in forming Ig-like domains are boxed, and the consensus polyadenylation signal is underlined. The single putative transmembrane domain is indicated by the heavy overline, and is followed by a hydrophilic stop-transfer sequence of three lysine residues. *d*, Amino-acid sequence alignment of FcR, N-CAM, and a mouse λ-light chain (MOPC 104E) Ig-like domains. Common residues are boxed, and gaps inserted by dashes to achieve maximum alignment. The amino-acid residue that begins each line is given in parentheses. FcR sequence corresponds to the first Ig domain; sequence of the MOPC 104E variable region is given. Similar alignments can be obtained using rabbit polymeric IgR, murine Thy-1, Ia antigen β-chain, or Lyt-2 sequences. We thank Alan F. Williams (MRC, Oxford) for assistance with this analysis.

Methods. *a*, FcR was purified to homogeneity by immunoaffinity chromatography using an anti-FcR monoclonal antibody, 5F2a[11], coupled to a 0.5 ml epoxy-activated, silcon-based HPLC matrix provided by Beckman Instruments (final concentration 30 mg IgG per ml resin). The detergent phase of a TX-114 lysate was prepared from 5 ml packed J774 cells (as previously described for immunoprecipitation[11]), filtered and passed once over the column at 0.2 ml min^{-1} at 4 °C. Following extensive washing with Tris-buffered saline, bound material was eluted with 0.5 M propionic acid containing 25 mM β-D-octylglucoside, immediately neutralized and dialysed exhaustively against glass-distilled water. Final yield was 39 μg of FcR per 2.5×10^9 cells. N-terminal sequence analysis was performed on a modified Beckman 890C spinning cup sequenator and allowed the unambiguous assignment of 20 contiguous amino acids with gaps at positions 1 and 16. *b*, A $P388D_1$ λgt-11 cDNA library was screened using a monospecific polyclonal anti-FcR antiserum followed by ^{125}I-labelled protein A essentially as described[16]. A single clone was isolated and designated pFcRAb. The library was then re-screened using a double-stranded, high-specific-activity oligonucleotide probe as described by Ullrich *et al.*[25]. All λgt-11 isolates were plaque-purified and subcloned into pUC9 or Bluescribe plasmid vectors. *c*, DNA sequencing was performed on both strands of all three cDNA clones by the method of Sanger *et al.*[26] after insertion into the M13 bacteriophage vector mp19. Sequential overlapping subclones were produced by the method of Dale *et al.*[27]. pFcRAb was also partially sequenced (on only one strand) by the method of Maxam and Gilbert[28].

The amino acid sequence of the IgG_1/IgG_{2b} FcR bears striking similarities to immunoglobulin and certain immunoglobulin-like molecules. The receptor's external domain contains four evenly spaced Cys residues (positions 28, 70, 109, 153) which define an internal repeat. These repeats have conserved amino-acid sequences surrounding each Cys which are typical of V-related immunoglobulin-like domains[20] suggesting the presence of interchain disulphide bonds forming two such domains. Particularly good matches exist between sequences adjacent to Cys 28, Cys 70 of FcR and rabbit polymetic immunoglobulin receptor[19] domain I (not shown), immunoglobulin V_L-domains such as MOPC 104E, and N-CAM[21] (Fig. 1*d*). Thus the patterns around the Cys residues seem closest to V and V-like domains but the length of sequence between the Cys residues is far too short to account for a V-like fold. If β-strands are assigned on the basis of sequence similarities then it seems possible that the FcR domains may be folded in the C-domain pattern (A. F. Williams, personal communication). Computer searches of nucleic acid and protein sequence databases (GenBank, Staden) indicated further similarities between the FcR and other immunoglobulin-like molecules including class II MHC antigen β-chain, Lyt-2 antigen and murine Thy-1 (which, like N-CAM,

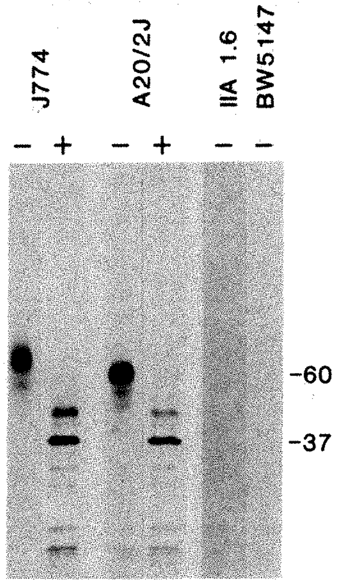

Fig. 2 Immunoprecipitation of ^{35}S-FcR from macrophage, B- and T-lymphoma cell lines. J774, A20/2J, IIA-1.6 and BW5147 cells were metabolically labelled with ^{35}S-methionine, lysed using Triton X-114 and immunoprecipitated with anti-FcR antiserum as described previously[11]. Radiolabelled bands corresponding to the mature receptor were detected in lysates of J774 cells (64K) and A20/2J cells (60K). Endoglycosidase F treatment (+ lanes) of immunoprecipitated ^{35}S-FcR gave identical 37K peptides (arrow), and several minor bands resulting from incomplete digestion or proteolytic degradation[11]. Both the T-lymphoma BW5147 and the selected variant of A20/2J, IIA-1.6, failed to synthesize immunoprecipitable FcR. Molecular weights in kilodaltons.

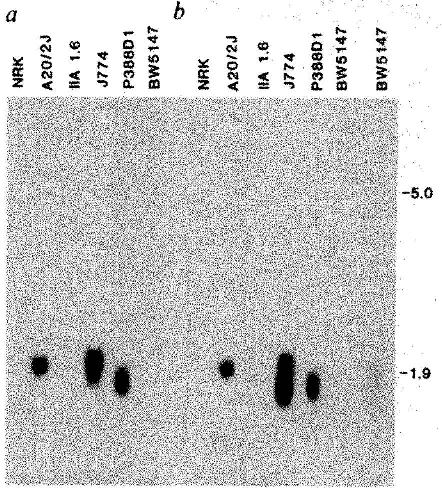

Fig. 3 Northern blot analysis of poly(A)$^+$ RNA isolated from FcR-positive and -negative cell lines. RNAs were prepared by guanidine-HCl lysis and phenol/chloroform extraction. Poly(A)$^+$RNA was selected by oligo-dT cellulose chromatography, resolved on 1.0% agarose-formaldehyde gels, and transferred to Zetabind nylon membranes. RNAs were hybridized with the 3′ encoding clone, pFcRAb, *a*, stripped at 95 °C with 0.1 × SSC/0.1% SDS, and re-hybridized using the 5′ encoding clone, pFcR11, *b*. Purified inserts were labelled by nick-translation to a specific activity of 0.5×10^9 c.p.m. per μg. Hybridization and washings (0.2 × SSC/0.1% SDS at 50 °C) were carried out essentially as described[29]. Cell lines used included rat fibroblasts (NRK, FcR$^-$), A20/2J B-cells (FcR$^+$), the FcR$^-$ A20 variant IIA-1.6, the macrophage-like cell lines J774 and P388D$_1$ (both FcR$^+$), and the T-cell lymphoma BW5147 (FcR$^-$). Autoradiographs represent 5 h exposures, except for BW5147 which was exposed for 5 h and 48 h (panel B). The 3′ probe pFcRAb hybridized with single bands only in FcR$^+$ cell lines (1.9 kb in A20/2J and J774, 1.7 kb in P388D$_1$) (panel A). The 5′ probe pFcR11 recognized an additional lower molecular weight band (1.6 kb) in J774 cells and in BW5147 cells after long exposures (using the 3′ probe, no hybridization was detected after similarly long exposures). Sizes of murine 28S (5.0 kb) and 18S (1.95 kb) ribosomal RNAs are indicated.

is expressed in neural tissues)[21].

As mentioned above, the IgG_1/IgG_{2b} FcR has been shown to be immunologically related to the Ly-17 alloantigen, a polymorphic locus which maps to mouse chromosome 1 (refs 12, 13). Thus, it was of interest to determine the chromosomal localization of the gene recognized by FcR cDNA. Using labelled pFcRAb, we probed DNA from a chromsome panel derived from CHO × mouse fibroblast somatic cell hybrids (provided by D. Pravtcheva and F. Ruddle)[22]. Conditions were chosen for an *Eco*RI digestion such that pFcRAb hybridized with a single murine band that was easily differentiated from is CHO homologue (Fig. 4). Analysis of DNA from 9 hybrid cell lines consistently assigned the FcR gene to mouse chromosome 1 (not shown). We also probed DNA from a second CHO × mouse panel (provided by C. Kozak) that included cell lines characterized by having undergone translocations involving only portions of mouse chromosomes (ref. 23). These results indicate that the FcR structural gene, and therefore the Ly-17 structural gene, is uniquely localized to the region of chromosome 1 distal to the *Pep*-3 locus[14].

To confirm that the cDNAs detected mRNA only in FcR$^+$ cells, and to investigate the relationship between receptor species expressed in different cell types, hybridization analysis was performed using poly(A)$^+$ RNA isolated from FcR$^+$ or FcR$^-$ cells. Because the presence or absence of FcR is usually determined only on the basis of surface expression[1], we first analysed cell lines by immunoprecipitation after labelling with ^{35}S-methionine. Using a rabbit anti-FcR antiserum, labelled receptor was precipitated from two macrophage cell lines (J774 and P388D$_1$, only the former is shown) and one B-cell line (A20/2J) (Fig. 2). Although the apparent relative molecular masses of the macrophage and B-cell products were different (64K against 60K), the difference was due to glycosylation heterogeneity, as Endo F treatment of the two immunoprecipitates yielded a 37K deglycosylated peptide. Two cell lines, T-cell line BW5147 and a variant of the A20/2J B-cell line, IIA-1.6 (obtained from B. Jones), selected *in vitro* for the loss of surface FcR[15] were shown not to synthesize immunoprecipitable FcR (Fig. 2). Expression of other surface antigens (such as surface immunoglobulin and Ia) in the IIA-1.6 variant, however, is the same as its normal parent A20/2J[15].

Northern blot analysis using pFcRAb as a probe only detected single transcripts in mRNA from the FcR$^+$ cell lines (Fig. 3*a*). The J774 macrophage and A20 B-cell lines contained mRNAs of similar sizes (1.9 kb) whereas the P388D$_1$ transcript appeared slightly smaller (1.7 kb). Somewhat different results were obtained using pFcR11 as a probe. Although pFcR11 hybridized with all the transcripts detected by pFcRAb, an additional band (1.6 kb) was detected in J774 mRNA (Fig. 3*b*). Because pFcR11 corresponds to the 5′ half of the FcR cDNA and pFcRAb corresponds to the 3′ half (Fig. 1*b*), these results suggest that some cell lines (for example, J774) may make two related FcR species which are more homologous at their N-terminal than at their C-terminal regions. We are now determining whether multiple FcR isoforms are indeed expressed.

Although the 5′ probe (pFcR11) detected small amounts of the 1.9 and 1.6 kb transcripts in BW5147 cells, neither the 3′ probe (pFcRAb) nor the 5′ probe hybridized with poly(A)$^+$ RNA from fibroblasts or from the FcR$^-$ A20/2J variant, IIA-1.6 (Fig. 3). To investigate the mechanism underlying the loss of FcR-specific mRNA from the variant cell line, a preliminary Southern blot analysis was performed. Using the 3′-end probe pFcRAb, single bands were detected in J774 and A20/2J DNA digested with *Eco*RI (15 kb), *Hin*dIII (10.5 kb), or *Xba*I (6.8 kb)

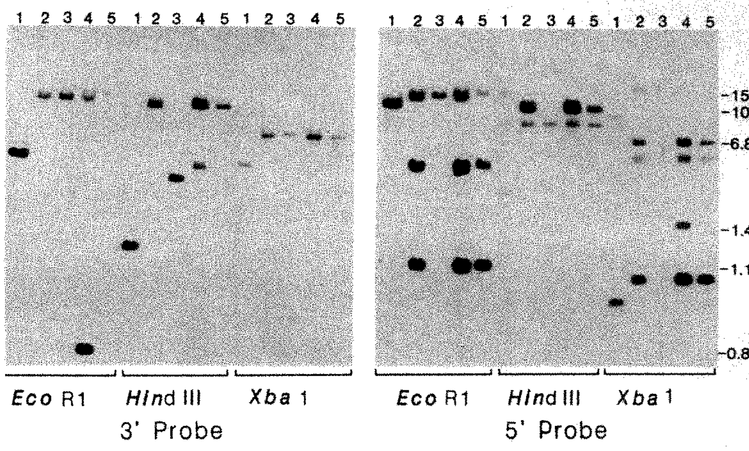

Fig. 4 Southern blot analysis of FcR-positive and -negative celllines. DNA isolated from: track 1, CHO cells (FcR$^-$); track 2, A20/2J; track 3, IIA-1.6; track 4, BW5147; and track 5, J774 cells was digested to completion with *Eco*RI, *Hin*dIII or *Xba*I, separated on a 0.8% agarose gel (10 μg per track) and transferred to nylon (Zetabind) membrane. The blots were then hybridized consecutively with the 3′ probe pFcRAb (left panel) or the 5′ probe pFcR11 (right panel) essentially as described[29]. Isolated inserts were labelled by nick-translation, filters washed with 0.2×SSC, 0.1% SDS at 55 °C, and the autoradiographs exposed overnight. Sizes of the major restriction fragments are shown in kb.

(Fig. 4, left panel). In contrast, *Hin*dIII digestion of IIA-1.6 DNA produced a single hybridizable fragment (4 kb), much smaller than that found in the A20/2J parent (10.5 kb). *Hin*dIII and *Eco*RI digests of the FcR$^-$ BW5147 DNA produced additional smaller bands (5.0 kb and 0.8 kb, respectively) not seen in FcR$^+$ cell lines. When the same blots were hybridized with the 5′-end probe pFcR11, 1-3 extra bands were detected in all cell lines except the receptor-negative variant IIA-1.6 (Fig. 4, right panel). In IIA-1.6 DNA, the 5′ probe even failed to detect the major 4 kb *Hin*dIII and 6.8 kb *Xba*I fragments seen with the 3′ probe (Fig. 4, right panel). As before, pFcR11 also hybridized with a unique low molecular weight band in BW5147 DNA. These data strongly suggest that the failure of the IIA-1.6 variant, and possibly BW5147, to express hybridizable FcR mRNA is attributable to deletions or rearrangements of the FcR gene.

Because the IgG_1/IgG_{2b} receptor studied here is only one of a large family of isotype- and cell type-specific FcRs[1], the existence of multiple FcR-related genes is not surprising. The availability of FcR cDNA clones and cell lines containing alterations in the receptor gene will now permit analysis of the distribution, structure and activities of these receptors, and the definitive establishment of their relationship to functionally-defined genetic loci of immunological importance, such as *Mls*[12-14,24].

We thank Adrian Hayday, Elisabetta Ullu, Chris Tschudi, Arthur Horwich, Saumyen Sarkar, Johanna Griffin, Christine Howe, Susan Froschauer and Heini Miettinen for their advice and assistance; Gary Davis and David Speicher for protein sequencing; Alan Williams and Gunnar von Heijne for help with sequence analysis; Christine Kozak, Dimi Prartcheva and Frank Ruddle for providing DNA from their chromosome panels; Alan Ezekowitz and Brigitte Huber for providing cDNA libraries; Barry Jones for providing the IIA-1.6 cell line and Pam Ossorio for photographic work. Supported by NIH grants and a Presidental Research Award from The Leukemia Society of America, Inc.

Note added in proof: During preparation of this manuscript, we learned that Ravage *et al.* (*Science*, in the press) have also cloned and sequenced FcR specific cDNAs. The sequence they obtained from a clone designated β-2 (isolated from a J774 macrophage cell line cDNA library) is identical to that described here (P388D1-derived cDNA). Although identical, the two sequences arise from mouse strains representing different *Mls* alleles (BALB/c: *Mls* b and DBA/2: *Mls* a, respectively). Therefore it is clear that the FcR cloned here, although immunologically identical to the Ly-17 alloantigen, cannot be the product of the *Mls* locus.

The phorbol esters in addition to being among the most potent mouse skin tumour promoters profoundly affect many different biological systems[1,2]. It is postulated that they act through activation of protein kinase C (ref. 3-5), but substantial heterogeneity in their pharmacological and binding behaviour in some systems[6] has caused concern about whether this is their only target. Evidence linking protein kinase C activation with biological responses to the phorbol esters includes similarity in structure-activity relations for binding and response[7]; *in vitro* phosphorylation of specific proteins by protein kinase C at the same sites at which phorbol ester treatment induces phosphorylation in intact cells[3]; and corre-

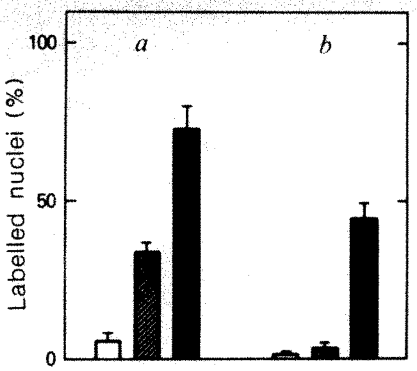

Fig. 1 Blocking of the mitogenic response of Swiss 3T3 cells to phorbol esters by pretreatment with phorbol ester. Control cells (*a*) or cells previously incubated with phorbol esters (*b*) were treated with no addition (□), 200 nM PDBu (▨) or 10% calf serum (■), and DNA synthesis measured by autoradiography. Data represent the mean ± s.e.m. for 5 experiments, with 200 cells counted for each experimental condition in each experiment.

Methods. Swiss 3T3 cells were plated at 1.2×10^5 cells per 35-mm tissue culture dish in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% calf serum (CS, Hyclone) and incubated at 37 °C in 95% air: 5% CO$_2$. Two days after plating, the cells were refed with fresh DMEM containing 10% CS. After an additional 2 days, the plates were washed 5× with DMEM, and DMEM containing 1% CS was added back in the presence or absence of 200 nM PDBu. Three days later all the cultures were washed 5 times with 1 mg ml^{-1} bovine serum albumin (BSA) in phosphate-buffered saline to remove residual PDBu. Conditioned DMEM containing 1% CS was added back together with 2 μCi ml^{-1} ^{3}H-thymidine (NEN) and 200 nM PDBu or 10% CS. After incubation for a further 24 h, the plates were washed and subjected to autoradiography as described[15,16], and labelled nuclei counted.

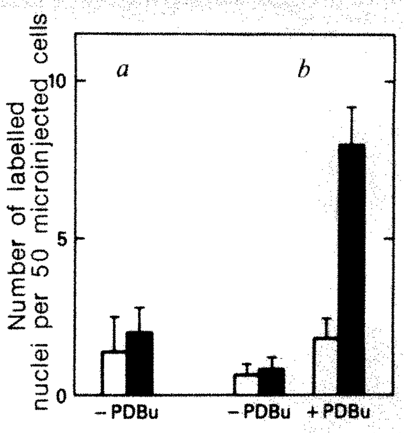

Fig. 2 Stimulation of mitogenesis by microinjected protein kinase C in phorbol-ester pretreated cells. Control cells (*a*) or cells pretreated with phorbol esters (*b*) were microinjected with protein kinase C(■) or with carrier solution (□). They were then incubated with ^{3}H-thymidine for 24 h in the absence or presence of 200 nM PDBu, and labelled nuclei in the microinjected area were counted. Data represent the mean ±s.e.m. for 5 experiments using two separate preparations of protein kinase C. In each experiment, 50–100 cells were microinjected under each experimental condition.

Methods. Swiss 3T3 cells were grown in 60-mm tissue-culture dishes and treated as described (Fig. 1 legend). Protein kinase C was purified to homogeneity as described by Jeng *et al.*[17]. After the final purification step the enzyme was concentrated in the presence of fatty acid-free BSA (Sigma), and the buffer was changed to 130 mM KCl. The final BSA concentration was 15 mg ml^{-1}. The concentrations of protein kinase C in the two preparations used were 2.2 and 4.1 mg ml^{-1}, respectively. The specific activities were 1.6 and 1.2 μmol ^{32}P transferred mg^{-1} min^{-1}, respectively. Activity in the absence of Ca^{2+} and phospholipid was <1% of that in its presence. The enzyme was stored for no more than 3 days at 0 °C before use. During this period, activity decreased no more than 20%. Volumes of 5×10^{-14} l were usually microinjected[16] using a Leitz micromanipulator coupled to a Zeiss IM35 microscope under a F-Achromat LD 32/0.4 PH1 lens (320× total). Pipettes were made from borosilicate glass tubes of 0.7–1 mm outer diameter (Kimble) using a vertical pipette puller Model 720 (D. Kopf Instruments, Tujinga, California). Treatment of tips and loading of pipettes by suction from the tips was as described previously[16,18]. Labelling of microinjected control cells incubated in the presence of PDBu was not determined because the results would have been obscured by the mitogenic response of uninjected cells within the microinjected area.

lation in certain cell types between down regulation of protein kinase C on chronic phorbol ester treatment and loss of cellular responsiveness to the phorbol ester[8–10]. Here we report that microinjection of purified protein kinase C into Swiss 3T3 fibroblasts pretreated with the phorbol ester phorbol 12,13-dibutyrate (PDBu) restores the mitogenic response of the cells to PDBu, directly establishing the involvement of protein kinase C in this response.

Quiescent cultures of Swiss 3T3 cells were obtained in the presence of low serum (Fig. 1 legend). Under these conditions addition of 200 nM PDBu stimulates DNA synthesis, measured by autoradiography, in 34 ± 3% (mean ± s.e.m.) of the cells compared with 83 ± 7% (mean ± s.e.m.) of cells stimulated with 10% serum (Fig. 1*a*). Pretreatment of the cultures for 3 days with 200nM PDBu markedly reduces the number of cells responding to PDBu (Fig. 1*b*). The number of cells responding to 10% serum was also reduced although by a smaller percentage perhaps because the phorbol ester pretreatment resulted in higher cell density (protein per plate = 144% of controls).

Similar results were obtained when DNA synthesis was measured by total ^{3}H-thymidine incorporation. In control cells, stimulation of ^{3}H-thymidine incorporation by PDBu was 35 ± 6% (mean ± s.e.m.) of that by 10% serum (5 experiments). In PDBu pretreated cells PDBu caused no stimulation, whereas 10% serum stimulated ^{3}H-thymidine incorporation to 78 ± 12% (mean ± s.e.m.) of the level for cells that were not pretreated.

To determine the effect of restoration of protein kinase C on the mitogenic response, cells were microinjected with $4\text{–}8\times10^5$ molecules per cell of active protein kinase C. This amount was comparable to the initial kinase levels in control cells of $3\text{–}6\times10^5$ (ref. 8). To control for effects caused by microinjection, results were compared with those for cells microinjected with carrier protein only. Microinjected protein kinase C mitogenically stimulates phorbol ester pretreated cells provided 200 nM PDBu was present (Fig. 2). No stimulation was seen in the absence of PDBu in either control or pretreated cells, confirming that the mitogenic effect is phorbol ester-dependent. The absolute level of mitogenic stimulation, 17% of nuclei labelled, was lower than that observed for stimulation of control cells by PDBu. This difference may be more apparent than real, however, because these results are normalized to the total number of microinjected cells. Swiss 3T3 cells are somewhat fragile to the microinjection procedure under our culture conditions and ~40% of the cells lysed after injection either with carrier protein or with enzyme. The number of labelled nuclei per surviving microinjected cell would therefore be larger.

These studies provide direct evidence for the role of protein kinase C in the mitogenic response of Swiss 3T3 cells to the phorbol esters. The role of protein kinase C in mitogenesis is of particular interest because there is evidence that some growth factors and oncogene products induce enhanced phosphatidylinositol turnover, activating protein kinase C (ref. 11), although apparently protein kinase C cannot account for all their mitogenic activity[10]. Our results do not support the suggestion of Collins and Rozengurt[10], based on the kinetics of recovery of response in the presence of cycloheximide, that phorbol ester pretreatment imposes an additional postreceptor block to responsiveness, but this difference may reflect the difference in stimulation conditions.

A similar strategy may be applicable to other systems, for example, cell-cell communication[12], in which desensitization is observed in response to chronic phorbol ester treatment. Microinjection has been used to demonstrate a role for protein kinase C in two other systems: enhancement of calcium current in neurones of *Aplysia*[13]; and K$^+$ ion conductance in photoreceptors of *Hermissenda*[14].

We thank Dr Stuart H. Yuspa for critical reading of the manuscript.

The v-*fms* oncogene induces factor independence and tumorigenicity in CSF-1 dependent macrophage cell line

Esther F. Wheeler, Carl W. Rettenmier,
A. Thomas Look & Charles J. Sherr

Department of Tumor Cell Biology, St Jude Children's Research Hospital, 332 N. Lauderdale, Memphis, Tennessee 38105 USA

The McDonough strain of feline sarcoma virus (SM-FeSV) transforms fibroblast cell lines in culture and produces fibrosarcomas in domestic cats[1,2]. SM-FeSV does not induce haematopoietic malignancies in spite of the fact that its viral oncogene, v-*fms*, codes for a glycoprotein related to the receptor for the mononuclear phagocyte colony stimulating factor, CSF-1 (refs 3, 4). The v-*fms*-coded polypeptide includes the complete extracellular domain of the c-*fms* proto-oncogene product[5,6] and retains the ability to bind CSF-1 specifically[4]. The two molecules have very similar sequences except at their extreme carboxyl terminal ends where 40 amino acids of the c-*fms*-coded glycoprotein are replaced by 11 unrelated residues in the v-*fms* product[5]. Autophosphorylation of the c-*fms* gene product on tyrosine is enhanced by CSF-1 addition[3], whereas phosphorylation of the v-*fms*-coded glycoprotein appears to be constitutive[4]. We now show that introduction of the v-*fms* gene into simian virus-40 (SV40)-immortalized, CSF-1 dependent macrophages renders them independent of CSF-1 for growth and tumourigenic in nude mice. These factor-independent cell lines express unaltered levels of the c-*fms* product which is down-modulated in response to either CSF-1 or the tumour promoter 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA). The induction of factor independence by a non-autocrine mechanism suggests that the v-*fms* product is an unregulated kinase that provides growth stimulatory signals in the absence of ligand.

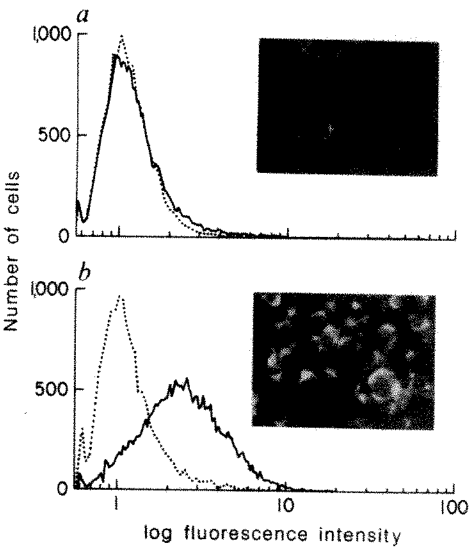

Fig. 1 Expression of v-*fms*-coded antigens in SM-FeSV-infected BAC1.2F5 macrophages. SM-FeSV-infected cells maintained for 5 passages in *a*, the presence or *b*, the absence of CSF-1 were tested for expression of v-*fms*-coded epitopes identified by the rat monoclonal antibody SM2.6.3[11,13]. Solid line, the flow cytometric fluorescence profile recorded after binding of SM2.6.3 to the surface of viable cells; dotted line, the control fluorescence profile obtained with an irrelevant isotype-matched rat myeloma protein. The insets in each panel show photomicrographs (400 × magnification) of fixed, permeabilized cells incubated with the same monoclonal antibody and subsequently reacted with an affinity purified, fluorescein-labelled goat antibody to rat immunoglobulin G (IgG). Note the single positive cell in the field of factor dependent cells shown in *a*. The frequency of positive cells in these cultures was <2% of the total population (see Table 1). BAC1.2F5 cells studied in parallel showed background fluorescence, similar to that observed for the majority of cells in *a*.

Methods. Indirect immunofluorescence labelling of viable cells and flow cytometric analysis were performed as described[11], except that cells scraped from culture dishes were preincubated in medium containing 100 mg ml^{-1} bovine IgG before staining, to prevent nonspecific binding of the monoclonal antibody to Fc receptors. Immunofluorescence staining of methanol-fixed cells was as described[13], except that the slides were pretreated with buffer containing 100 mg ml^{-1} of bovine IgG before reaction with the monoclonal antibody. The insets in *a* and *b* are matched exposures of SM-FeSV-infected FD and FI cells, respectively, photographed in the same experiment.

The murine macrophage cell line BAC1 was derived from adherent BALB/c × A.CA F$_1$ mouse spleen cells by transfection with origin-defective SV40 DNA[7]. The 2F5 subclone[8], chosen for its inability to grow in the absence of CSF-1, produces lysozyme, collagenase and esterase, secretes interleukin-1, expresses Fc receptors, and is capable of Fc-mediated phagocytosis. BAC1.2F5 cells were infected with high titre, helper-free SM-FeSV pseudotype virus[6] prepared by transfection of cloned, replication-defective SM-FeSV DNA[9] into the packaging NIH-3T3 cell line, Ψ2, which contains a defective Moloney murine leukaemia provirus that provides viral replicative functions but cannot package its own RNA[10]. No factor-independent colonies were obtained from mock-infected BAC1.2F5 cells. SM-FeSV-infected cells grown for seven days in the absence of CSF-1 gave ~0.1% factor-independent (FI) colonies. These were grown and maintained in the absence of CSF-1. Virus-infected factor-dependent (FD) cell lines were maintained in L-cell conditioned medium containing CSF-1 and passaged at 5-day intervals.

SM-FeSV-infected macrophages were plated in semisolid medium with or without CSF-1. Uninfected BAC1.2F5 cells formed colonies in agar only in the presence of CSF-1 (Table 1); FI cells formed colonies (6.9%) in the absence of CSF-1; as did FD cells at passage 3 and 5 after infection, but at low frequency (0.1–0.3%). The plating efficiency of FD cells was greatly increased (6.0%) after 14 passages. When factor-

Table 1 Efficiency of colony formation of SM-FeSV-infected BAC1.2F5 cells

	Colony forming efficiency (% of plated cells) +CSF-1	−CSF-1
Uninfected BAC1.2F5 cells	7.0	<0.01
FD cells:		
passage 3	6.8	0.1
passage 5	4.6	0.3
passage 14	10.9	6.0
FI cells:		
passage 5	9.3	6.9
passage 10	13.4	4.2

A plasmid containing biologically active SM-FeSV proviral DNA[9] was transfected into Ψ2 cells[10], and transformed Ψ2 subclones were derived from single cells by endpoint dilution in microtitre culture dishes. Supernatants from a subclone producing 2×10^7 helper-free SM-FeSV focus-forming units (FFU) per ml on NIH-3T3 cells[6] were used to infect 3×10^5 BAC1.2F5 cells at 10 FFU per cell. Cells were grown in Dulbecco's minimal medium containing 15% fetal calf serum and 25% murine L-cell conditioned medium containing CSF-1. Two days after infection the culture was divided and infected cells were continuously maintained in the presence or absence of CSF-1. In the absence of CSF-1 most of the infected cells failed to survive, but about 0.1% of the unpassaged cells gave rise to factor independent colonies which were grown up and maintained in the absence of CSF-1 (FI cells). Parallel cultures maintained in medium containing the growth factor (FD cells) gave rise to FI cells at a progressively increased frequency when shifted to factor-free medium. Cells from both infected populations were plated at various passage levels after infection in 60 mm culture dishes in 0.3% Noble agar containing complete medium supplemented with or lacking CSF-1. In each experiment duplicate sets of cultures were established containing 10^3, 10^4 and 10^5 cells per dish. The efficiency of colony formation was independent of the cell density and represents an average of triplicate determinations. Continuously growing colonies (>100 cells) were scored three weeks after plating. Colonies picked from SM-FeSV-infected cells plated in the absence of CSF-1 gave rise to cell lines which were indistinguishable in their properties from the original FI cell line derived in liquid medium.

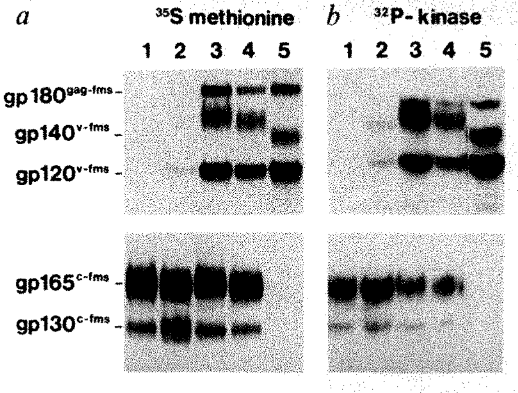

Fig. 2 Synthesis (*a*) and tyrosine kinase activities (*b*) of v-*fms* (top panels) and c-*fms* (bottom panels) gene products in infected mouse cells. The lanes are the same in each panel. Lane 1, uninfected BAC1.2F5 cells; lane 2, SM-FeSV-infected FD cells maintained in medium containing CSF-1 for 5 passages; lane 3, infected FD cells maintained for 14 passages; lane 4, SM-FeSV-infected FI cells at passage 5; lane 5, SM-FeSV-transformed mouse NIH-3T3 fibroblasts. The mobilities of the various forms of v-*fms* and c-*fms* gene products are noted at the left margins. Due to differences in oligosaccharide processing, the mature form of the v-*fms*-coded glycoprotein (gp140$^{v\text{-}fms}$) in the mouse macrophages has a greater apparent molecular mass than that expressed in NIH-3T3 cells. Matched exposures of the corresponding autoradiograms are shown in upper and lower panels.

Methods. To avoid down modulation of CSF-1 receptors[18] in cells grown in the presence of CSF-1, all cell lines were shifted to factor-free medium 18 h before the experiment. *a*, Cells were metabolically radiolabelled with ^{35}S-methionine for 90 min and then lysed in RIPA buffer (50 mM Tris HCl, *p*H 7.4, containing 150 mM NaCl, 20 mM EDTA, 1% Triton X-100, 1% sodium deoxycholate and 0.1% sodium dodecyl sulphate (SDS)) with 2% Aprotinin and 1 mM phenylmethylsulphonyl fluoride as protease inhibitors. Unlabelled cell lysates for protein kinase assays were prepared in parallel. The lysates were incubated first with antibodies that react with the v-*fms*-coded glycoproteins but do not bind the product of murine c-*fms* gene[13]. After recovery of the immune complexes using *Staphylococcus aureus* protein-A-Sepharose as immunoadsorbant, the cleared lysates were incubated with a rabbit antiserum to a recombinant v-*fms*-coded polypeptide expressed in bacteria that cross reacts with the murine CSF-1 receptor[3,14]. *b*, Unlabelled immune complexes were incubated in the presence of [γ^{32}P]ATP and divalent cation as described[16,17]. Radiolabelled products in washed immunoprecipitates were separated by SDS gel electrophoresis and detected by fluorography (*a*) or autoradiography (*b*).

independent agar colonies from FD cells at passages 5 and 14 were picked and cultured in liquid medium without CSF-1, the resulting subclones were indistinguishable from unpassaged FI cells directly after infection. Thus SM-FeSV-infected cells maintained in medium containing CSF-1 progressively gave rise to FI cells. Because the SM-FeSV was produced from the Ψ2 packaging cell line, this was not due to virus spread. No RNA-dependent DNA polymerase or focus-forming activity was found in the culture fluids, so no virus was produced by infected cultures.

From Southern blot analysis with a v-*fms* probe, early passage FD cells contained an average of 0.5–1.0 proviral DNA copies per cell, integrated polyclonally in host DNA, but late-passage FD cells, and FI subclones derived from single cells contained multiple (~2–4) proviruses per cell (data not shown). Most FD cells must have acquired proviral DNA after infection, but only those with multiple proviral insertions appeared to have a proliferative advantage, even in the presence of CSF-1.

Conditioned medium from FI cultures was tested using uninfected BAC1.2F5 cells to exclude the possibility that FI cells produced CSF-1. BAC1.2F5 cells die within 7 days in the absence of CSF-1. No CSF-1 activity was detected, so the proliferation of FI cells is not due to an autocrine mechanism. Northern blot analysis using a CSF-1 complementary DNA probe confirmed that BAC1.2F5, FD and FI cells did not express CSF-1 messenger RNA.

In fibroblasts infected with SM-FeSV the v-*fms*-coded glycoprotein, gp140$^{v\text{-}fms}$, is required at high levels on the cell surface for transformation[11,12]. Only a low percentage of unpassaged SM-FeSV-infected FD cells gave rise to FI colonies when CSF-1 was removed from the medium, suggesting that most of these cells produced insufficient amounts of the glycoprotein to become factor independent. We analysed the infected cultures by fluorescence-activated flow cytometry using a monoclonal antibody to the extracellular, amino-terminal domain of the v-*fms*-coded polypeptide[11,13]. FD cells at passage 5, like uninfected BAC1.2F5 cells, did not express the v-*fms*-coded glycoprotein (Fig. 1*a*). In contrast, FI cells at passage 5 expressed relatively high levels of the glycoprotein (Fig. 1*b*). The FI cells were uniformly fluorescence-positive when assayed for cytoplasmic fluorescence (Fig. 1*b*, inset), whereas less than 2% of FD cells were fluorescent (Fig. 1*a*, inset). Thus, only a small proportion of early passage SM-FeSV-infected BAC1.2F5 cells express sufficient v-*fms* gene product to become factor independent.

We also examined the expression of the feline v-*fms* and murine c-*fms* gene products in the various cell lines. Cultures were metabolically radiolabelled with ^{35}S-methionine, lysed with detergent and sequentially immunoprecipitated; the first antibody was specific for the v-*fms* gene product[13] (Fig. 2*a*, top), and the second, a rabbit antiserum to a recombinant v-*fms*-coded polypeptide, cross-reacts with the murine CSF-1 receptor[3,14] (Fig. 2*a*, bottom). Because v-*fms* sequences were inserted into the open reading frame of the SM-FeSV *gag* gene, the primary

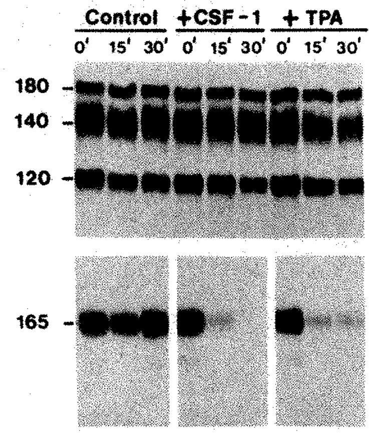

Fig. 3 Down modulation of the c-*fms* gene product in SM-FeSV-infected FI cells. Upper panel, v-*fms* gene products; lower panel, c-*fms* gene products. FI cells grown in factor-free medium were metabolically labelled for 15 min with ^{35}S-methionine and incubated for an additional 75 min in medium containing a 100-fold excess of unlabelled methionine. Following the 'chase' period, parallel tissue culture dishes were incubated in normal medium (control) or in medium containing either 3 nM CSF-1 or 1×10^{-7} M TPA for the indicated periods of time (0, 15, 30 min). Cells were lysed in RIPA buffer. The clarified lysates were incubated first with antibodies that react only with the v-*fms*-coded glycoproteins, and then with an antiserum to the c-*fms* product as in Fig. 2 legend. The immunoprecipitates were analysed by SDS gel electrophoresis. The sizes of the expected glycoproteins are given in kilodaltons (left). The figure gives data from quantitative sequential immunoprecipitations and shows matched exposures of the corresponding autoradiograms.

translation product is a glycosylated polyprotein of relative molecular mass (M_r) 180,000 (180K), (gP180$^{gag-fms}$) which is proteolytically cleaved, yielding an immature form of the v-*fms*-coded glycoprotein (gp120^{v-fms}), which undergoes processing and appears at the cell surface as a glycoprotein of greater M_r, gp140^{v-fms} (refs 13, 15). Uninfected BAC1.2F5 cells did not express v-*fms* gene products (Fig. 2*a*, top, lane 1). SM-FeSV-infected FD cells at passage 5 produced low levels of these glycoproteins (lane 2), but after serial subculturing in the presence of CSF-1, these cells (passage 14; lane 3) expressed comparable levels of the viral oncogene products to FI cells (lane 4) and SM-FeSV-transformed NIH-3T3 cells (lane 5).

Uninfected and infected BAC1.2F5 cells, whether CSF-1 dependent or not, expressed high levels of the murine c-*fms* gene product (Fig. 2*a*, bottom, lanes 1-4). The glycoprotein gp130^{c-fms} is an intracellular precursor of the mature 165K cell surface receptor, gp165^{c-fms} (ref. 14). SM-FeSV transformed NIH/3T3 cells did not express the c-*fms* product (lane 5). Immune complex protein kinase assays[16,17] show that the v-*fms* (Fig. 2*b*, top) and c-*fms* (Fig. 2*b*, bottom) glycoproteins were phosphorylated in ratios proportional to the expression levels detected by metabolic radiolabelling. Phosphoamino acid analysis confirmed that *in vitro* phosphorylation was exclusively on tyrosyl residues. Subculturing of SM-FeSV-infected FD cells yields a population expressing high levels of the v-*fms*-coded glycoproteins without affecting synthesis of the c-*fms* product.

Since both the v-*fms* and c-*fms* products were coexpressed in FI cells, we studied down-modulation of the c-*fms* gene product[18] after addition of CSF-1 or TPA. Cells labelled with ^{35}S-methionine were exposed to CSF-1 or TPA for brief periods, and the v-*fms* and c-*fms* products were immunoprecipitated from detergent lysates and analysed on gels. Turnover of gp140^{v-fms} was unaffected by CSF-1 or TPA, whereas turnover of gp165^{c-fms} was greatly increased by either compound (Fig. 3). Thus, both CSF-1 and TPA down-modulate gp165^{c-fms} but not the transforming glycoprotein.

Since the SM-FeSV-infected FI cells did not produce CSF-1 or show constitutive down-modulation of their CSF-1 receptors, their conversion to factor independence was directly mediated by the v-*fms*-coded receptor kinase rather than an autocrine mechanism. Thus, although the v-*fms* gene product includes the ligand-binding domain of the CSF-1 receptor, it can function as an unregulated enzyme without ligand. This has not been formally shown in fibroblasts, since fibroblast cell lines susceptible to transformation by SM-FeSV produce CSF-1 (ref. 4). The structural differences between the carboxyl termini of the v-*fms* and c-*fms* products could be responsible for the transforming activity of the oncogene product[5]. The carboxyl terminus of the v-*fms*-coded glycoprotein lacks a distal tyrosine residue found in the c-*fms* product, so it may be that phosphorylation of the c-*fms* product on this tyrosine decreases kinase activity, as observed[19] for pp60^{c-src}.

Late passage FD and FI cells both formed tumours when inoculated subcutaneously or intraperitoneally into nude mice (5×10^6 cells per animal), whereas uninfected SV40-immortalized BAC1.2F5 cells did not. Tumours appeared within 5 weeks after injection, spread haematogenously, and formed histiocytic sarcomas metastatic to liver, spleen, pancreas, lung and spinal cord. CSF-1 independent cell lines from tumour tissues had the histological appearance of macrophages, stained cytochemically for butyrate esterase, contained multiple copies of the integrated SM-FeSV provirus and expressed high levels of v-*fms*-coded glycoprotein at the cell surface. The v-*fms* receptor kinase therefore acts with a nuclear oncogene product to form tumours *in vivo*. Critical alterations in the kinase domain of the c-*fms* proto-oncogene might similarly contribute to haematopoietic malignancy.

Oncogenes encoding other tyrosine kinases, including v-*abl*, v-*src*, v-*fps*/*fes* and v-*erb*-B, can transform a variety of different cells of the myeloid and lymphoid lineages[20-27]. The normal physiological functions of the v-*abl*, v-*src*, and v-*fps*/*fes* gene products remain obscure, but the ability of v-*erb*-B (a truncated EGF receptor gene)[28,29] to transform erythroid progenitors suggests that viral tyrosine kinases can generate abnormal signals for cell proliferation. This raises the possibility that the v-*fms* gene product may convert other haematopoietic cell lines to factor independence, including those that do not express CSF-1 receptors.

We thank Dr E. Richard Stanley for BAC1.2F5 cells, Drs Ernest Kawasaki and Peter Ralph of Cetus Corporation for a CSF-1 cDNA clone and Shawn Kramer and Jean Elmendorf for technical assistance. Recurrent mutations in haemophilia A give evidence for CpG mutation hotspots

Haemophilia A is a common disorder of blood coagulation caused by a deficiency of factor VIII[1]. It is inherited as an X-linked recessive trait, and one-third of all cases are thought to result from *de novo* mutations[2]. The clinical severity of haemophilia A varies markedly among different families and a subset of the patients with severe disease develop antibodies against factor VIII, called inhibitors[3]. Because of this heterogeneity, it is likely that many different molecular lesions result in haemophilia A. Indeed, of the nine mutations described to date, all appear to be unique changes[4–6]. However in this study of 83 patients with haemophilia A we have identified two different point mutations, one in exon 18 and one in exon 22, that have recurred independently in unrelated families. Each mutation produces a nonsense codon by a change of CG to TG, and each occurred *de novo* on the X-chromosome donated by the maternal grandfather. These observations strongly support the view that CpG dinucleotides are mutation hotspots.

Recent reports have described the isolation and partial sequence of the factor VIII gene and its expression *in vitro* from recombinant DNA clones[7–10]. The gene is 186 kilobases (kb) long and is divided into 26 exons, encoding a protein of 2,351 amino acids. The availability of cloned factor VIII gene fragments has made possible the study of molecular defects in patients with haemophilia A. Because of the clinical heterogeneity of the disorder, the large size of the factor VIII gene, and the pool of new mutations, it has been suggested that the number of genetic lesions producing haemophilia A may be very large[4,5].

We have analysed the genomic DNA of 83 unselected patients with haemophilia A who were referred to us for carrier detection and prenatal diagnosis. Our screening strategy for factor VIII mutations involved restriction analysis with *Taq*I, *Sst*I and *Eco*RI, and successive hybridizations with two complementary DNA probes that span exons 1–12 (probe A) and 14–26 (probe BC) of the factor VIII gene. We detected 6 deletions and 10 point mutations using this strategy (ref. 5 and manuscript in preparation); 9 of the 10 point mutations were detected with *Taq*I, which has the dinucleotide CpG in its recognition sequence.

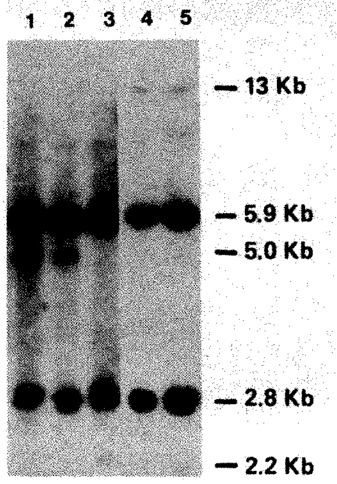

Fig. 1 Autoradiogram of DNAs from members of family K and family T digested with *Taq*I and hybridized to probe BC. Family K: lane 1, subject III-1; lane 2, subject II-2; lane 3, subject I-2; family T: lane 4, subject III-2; lane 5, subject II-2.

Methods. Genomic DNA was isolated from 10–15 ml of peripheral blood by standard techniques. DNA (5 μg) was digested to completion with *Taq*I. Gel electrophoresis, transfer to nitrocellulose filters, and hybridization with a ^{32}P-labelled cloned factor VIII DNA fragment (probe BC) were performed as previously described[5]. The following cloned factor VIII DNA fragments were used as probes: (1) probe A, a 1.7 kb *Kpn*I cDNA fragment that spans exons 1–12; and (2) probe BC, a 6.5 kb *Eco*RI cDNA fragment that spans exons 14–26. These probes were kindly provided by Drs J. Toole and J. Wozney of Genetics Institute, Inc. The 2.2 kb fragments of subject II-2 (family K) and subject III-2 (family T) are difficult to see on this autoradiogram. Sizes of fragments are given in kb.

In an earlier study from our laboratory[5], a patient with severe disease (factor VIII titre <1 U per 100 ml) and factor VIII inhibitors was shown to have a point mutation in exon 18 of the factor VIII gene, where a change of C to T in a CpG dinucleotide led to the generation of a nonsense codon. That family was of Anglo-Saxon origin, and the mutation was present in at least four generations. Upon screening the DNAs of our more recent patients, we observed a *Taq*I site alteration in an unrelated Greek family (family K) where the two affected brothers (subjects III-1 and III-2, Fig. 2*a*) had severe haemophilia A (factor VIII titre <1 U per 100 ml) and were inhibitor-negative. This change appeared identical to the mutation described previously.

Figure 1 shows a representative restriction analysis of genomic DNA from various members of this family digested with *Taq*I. Hybridization with probe BC revealed a new 5.0 kb fragment and absence of a 2.2 kb fragment in an affected male (subject III-1). The DNA of the mother, an obligate heterozygote (Fig. 2*a*, subject II-2), contained the 5.0 kb fragment as well as the 2.2 kb fragment. The patient's father, maternal grandfather and maternal grandmother (Fig. 2*a*; subjects II-1, I-1, and I-2, respectively) displayed the normal *Taq*I pattern, indicating that this mutation appeared *de novo* in one of the mother's X-chromosomes. No variant fragments were detected when the DNA was digested with *Sst*I, *Eco*RI, or *Bam*HI, or when probe A was used for hybridization (data not shown).

To determine the precise nature of the mutation responsible for the altered *Taq*I site, we used oligonucleotides to detect single base mismatches[11,12]. A pair of oligonucleotides were made, each 18 nucleotides long, one having the normal sequence flanking the exon 18 *Taq*I site, the other differing from the normal by the substitution of a T for C in the *Taq*I site, the presumed mutant sequence. Digestion of genomic DNA with *Hin*dIII normally produces a 2.7 kb fragment which contains

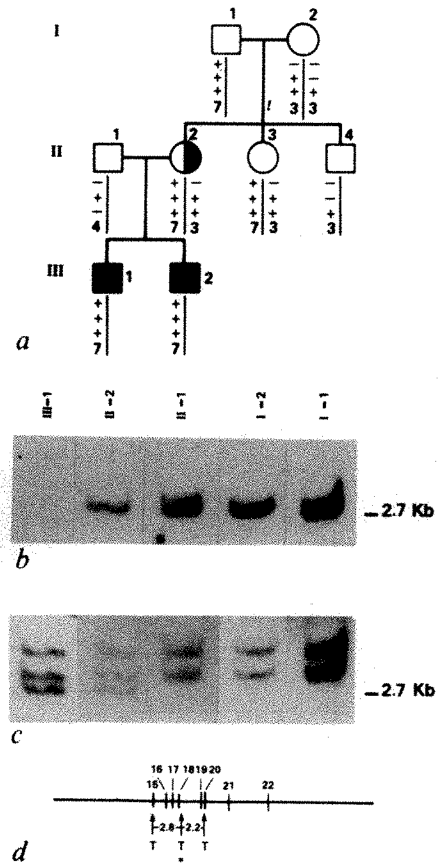

Fig. 2 Analysis of the factor VIII exon 18 mutation. *a*, Pedigree of family K (□, normal male; ■, haemophilic male; ○, normal female; ◑, carrier female). Haplotypes of polymorphic restriction sites are indicated below each subject, in the order (top to bottom) *Bcl*I-factor VIII, *Bgl*I-factor VIII, *Bgl*II-DXS15, *Taq*I-DXS52. The presence or absence of a polymorphic restriction site is shown as + or −. In one case (DXS52) the alternative alleles are arbitrarily numbered. *b*, Oligonucleotide analysis of genomic DNA from members of family K digested with *Hin*dIII and hybridized to the normal exon 18 probe (GATTCGATGGTATCTGCT). *c*, Hybridization of the same gel with an oligonucleotide corresponding to the mutant exon 18 probe (GATTTGATGGTATCTGCT). *d*, Partial restriction map of factor VIII DNA cleaved with *Taq*I (T). Asterisk, location of the absent *Taq*I site in exon 18.

Methods. DXS15 cloned DNA was kindly provided by Dr K. Davies and DXS52 cloned DNA by Dr J. L. Mandel. Oligonucleotides (18 bases long) were chemically synthesized by Dr C. Riley of the Johns Hopkins University School of Medicine, end-labelled using T_4-polynucleotide kinase and ^{32}P-ATP, further purified by electrophoresis on a 20% polyacrylamide sequencing gel, and the labelled probe extracted by the crush and soak method[11,12]. Hybridization to dried agarose gel was performed at calculated melting temperature (T_m minus 4 °C for 3 h, washed in 2× SSPE/0.1% SDS, then washed further in 2×SSPE at 2 °C below T_m for 2 min), and autoradiographed. The agarose gel was re-used after stripping off the first probe by denaturation in 0.5 M NaOH/0.15 M NaCl for 30 min, and neutralization.

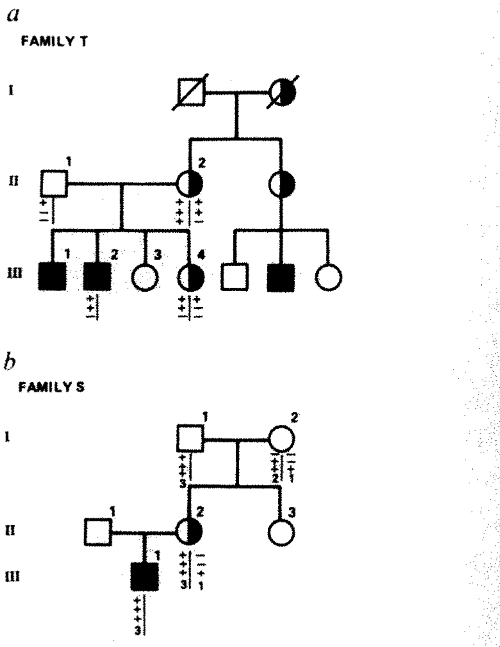

Fig. 3 Pedigrees of *a*, family T; *b*, family S. Both families show the factor VIII exon 22 mutation. Symbols as for Fig. 2*a*.

exon 18 of the factor VIII gene. The normal probe did not hybridize to the 2.7 kb fragment in *Hin*dIII-cleaved DNA from the affected male (Fig. 2*b*, subject III-1), although it did hybridize to the DNAs of unaffected family members. By contrast, the mutant probe hybridized to the 2.7 kb factor VIII fragment from the DNA of the affected male (subject III-1) and his mother (subject II-2), but not to that of the normal members of the family (Fig. 2*c*). Constant hybridizing sequences that were not factor VIII were seen in all individuals. We have thus shown that the basis of the exon 18 *Taq*I site mutation is a C to T change producing a nonsense codon, TGA, at position 1,960 in place of the normal CGA, which codes for arginine. The factor VIII protein produced by this mutant gene is presumably a truncated, inactive molecule.

To determine the parental origin of the new mutation in the patient's mother, we performed DNA polymorphism analysis on various family members. The DNA polymorphisms used were: *Bcl*I and *Bgl*I sites in the factor VIII gene; a *Bgl*II site adjacent to DXS15; and *Taq*I polymorphic alleles detected by probe DXS52[5,13-15]. Analysis of these sites suggested that the X-chromosome of the patient was inherited from the maternal grandfather (Fig. 2*a*), and, therefore, the mutation to an abnormal factor VIII gene occurred in a germ cell of the maternal grandfather. The grandfather was 32 years old at the time his carrier daughter was conceived.

A different *Taq*I site alteration was found in both of two other unrelated families. The haemophilic subjects from each family have severe disease (factor VIII titres <1 U per 100 ml) but are inhibitor-negative. *Taq*I digestion of genomic DNA from subject III-2 of family T (Fig. 1) and subject III-1 of family S (data not shown) and hybridization to probe BC showed an abnormal 13 kb fragment and the absence of the normal 5.9 kb fragment that includes exon 22 sequences[4]. Female carriers of the mutation from family T (subjects III-4 and II-2, Fig. 3*a*) and subject II-2 from family S (Fig. 3*b*) also contained the 13 kb fragment in their DNA, but normal males from either family did not. Neither the maternal grandfather nor the maternal grandmother (subjects I-1 and I-2, respectively) of family S contained the abnormal fragment in their DNA, indicating that the mutation arose *de novo* within two generations.

We determined the precise nucleotide change by making a pair of oligonucleotides, each 18 nucleotides long, flanking the exon 22 *Taq*I site which differed in a single substitution of a T for C in the *Taq*I site. *Hin*dIII digestion of genomic DNA normally produces a 13 kb fragment which contains exon 22 sequences. The normal oligonucleotide probe failed to hybridize to the 13 kb fragment from the affected males (Fig. 4*a*) of family T (III-2) or family S (III-1), but the oligonucleotide bearing the mutant sequence showed specific hybridization to DNA of each affected individual (Fig. 4*b*) as well as to female carriers from each family (subjects II-2 and III-3 of family T and subject II-2 of family S). Therefore, the exon 22 mutation in both these

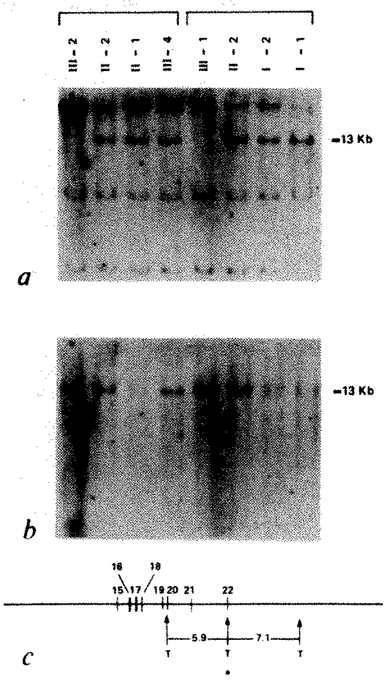

Fig. 4 Analysis of the factor VIII exon 22 mutations by oligonucleotide hybridization to *Hin*dIII-cleaved DNA from members of family T and family S. *a*, Hybridization with an 18-base long oligonucleotide corresponding to the normal exon 22 sequence (CTTATÇGAGGAAATTCCA). *b*, Hybridization of the same gel with an oligonucleotide corresponding to the mutant exon 22 sequence (CTTATŢGAGGAAATTCCA). *c*, Partial restriction map of factor DNA cleaved with *Taq*I (T); asterisk, location of the absent *Taq*I site in exon 22. See Fig. 2 (legend) for methods.

families is due to a CGA to TGA change at codon 2,135 of the factor VIII gene, generating a nonsense codon.

By analysis of polymorphic restriction sites in the factor VIII gene and flanking it, we showed that the *de novo* mutation in family S arose on the X-chromosome of the maternal grandfather (subject I-1, Fig. 3*b*) who was 34 years old at the time his carrier daughter was conceived. It is interesting that both *de novo* mutations were associated with advanced paternal age; further data are needed to determine the significance of this observation.

In all four families, the haplotype of the two intragenic polymorphic sites (*Bcl*I and *Bgl*I) happened to be the same for chromosomes bearing the mutant gene. To confirm that these mutations were independent in origin and to exclude the possibility that the stated parentage was not correct in either family K or family S, we examined multiple, highly polymorphic loci that lie outside the factor VIII gene[15,16]. We examined four such loci; in no case did the mothers in family K (Fig. 2*a*, subject II-2) or in family S (Fig. 3*b*, subject II-2) show a DNA fragment which was not consistent with stated parentage. The probability of the stated parentage being correct is estimated for each patient's mother as 1×10^5 to 1.

These cases are two instances of recurrent mutation in man. The previously reported presence of a particular mutation in two very different ethnic groups and in two or more different β-globin gene frameworks provides strong circumstantial evidence for recurrent mutation in various β-globin gene alleles, including β^S, β^E, and certain β-thalassaemia alleles[17]. Chehab *et al.* have also presented strong evidence for recurrence of a common Mediterranean β-thalassaemia allele[18]. However, unlike β-thalassaemia, there is no positive selection for mutations that produce haemophilia A and the life of each mutation is estimated to be two to four generations in a stationary population[2]. Thus, without positive selection for such mutations, each new mutation would be expected to last 100-150 years. This means that every unrelated affected family should have a different mutant allele (barring recurrent mutation) and that study of these alleles should give an unbiased observation of mutation hotspots.

There is strong circumstantial evidence that CpG dinucleotides are hotspots for mutation in man. The proportion of CpG in sequenced genes is 37% of that expected[19]. Several authors have postulated that methylated cytosines could be mutation hotspots because 5-methylcytosine can spontaneously deaminate to thymine resulting in a C-T transition in DNA[20-22]. Barker *et al.*[23] found an unusually high frequency of polymorphism at a number of loci in human DNA using restriction enzymes whose recognition sequences contain a CpG dinucleotide. Significantly, of the four point mutations producing haemophilia A reported before this study, three were CG-TG changes and one a CG-CA mutation[4-6]. The latter would result from a C-T transition at the CpG on the anti-sense strand of DNA. Our observation of recurrent CG-TG mutations strongly supports the view that these dinucleotides are mutation hotspots. One can estimate the number of recurrences of the codon 1,960 or codon 2,135 mutations in human history given that (1) their recurrence frequency is comparable to that observed in our studies (about 1 in every 50 affected males); (2) the incidence of haemophilia A is 1 in 10,000 males in all racial groups; and (3) each mutation persists for an average of 100-150 years in the population. Using these assumptions, we estimate that over 1,000 individuals are alive today with different recurrent origins of the C-T mutation at codon 1,960 or of the C-T mutation at codon 2,135 of the factor VIII gene, and that the total number of recurrences of each type of mutation in man is perhaps 10,000. Even if this is an overestimate by a factor of 10, it is in striking contrast to recurrence frequencies of 5-10 predicted for the β-globin alleles mentioned earlier, β^S, β^E, and certain β-thalassaemia mutations[17].

We thank Drs J. Toole and J. Wozney for the factor VIII clones, K. Davies for the DXS15 clone, J. L. Mandel for clone DXS52, Drs A. Chakravarti and H. Donis-Keller for helpful discussions, Ms C. E. Dowling for technical assistance and Ms E. Pasterfield for assistance in the preparation of this manuscript. This study was supported by NIH grants to S.E.A. and H.H.K. and a Johns Hopkins Institutional Grant to S.E.A.

Since its first isolation[1], bovine β-lactoglobulin (BLG) has been an enigma: although it is abundant in the whey fraction of milk, its function is still not clear. The results of the many physico-chemical studies on the protein need a structural interpretation. We report here the structure of the orthorhombic crystal form of cow BLG at pH 7.6, at a resolution of 2.8 Å. It has an unusual protein fold, composed of two slabs of antiparallel β-sheet, which shows a remarkable similarity to plasma retinol-binding protein. A possible binding site for retinol in BLG has been identified by model-building. This suggests a role for BLG in vitamin A transport and we have discovered specific receptors for the BLG–retinol complex in the intestine of neonate calves.

BLG is found in the milk of many animals including bovine species, sheep, deer, horse, dog, pig, dolphin[2] and possibly man. Usually the protein exists as a dimer and many species appear to possess genetic variants. In ruminants, the relative molecular weight of the subunit is ~18,000 corresponding to a polypeptide of ~162 residues. There are two disulphide bridges and, in the cow protein, a free cysteine in the sequence Cys-Gln-Cys- (119–121)[3], variously reported as 119[4], 121[5,6] or an equal mixture of the two[7]. The properties of the protein have been reviewed[4,8–10]. It is remarkably acid-stable, resisting denaturation at pH 2[11] and remaining intact until after passing through the stomach[12]. As the pH is raised, it undergoes several conformational changes observed by optical rotatory dispersion, perhaps the most interesting occurring at about pH 7.5[13]. BLG is known to bind a variety of hydrophobic molecules[14–16].

Of the abundant crystal forms of BLG[17,18], four salted-out forms have been studied by X-ray crystallography at low resolution[19]. A preliminary report has been given[20] of higher resolution work on one, lattice Y, crystallised at pH 7.6 We now discuss the similarity between BLG and plasma retinol-binding protein (RBP), which has suggested a function for BLG.

RBP is the protein that transports retinol from its storage in the liver. It is secreted into the plasma where it binds to transthyretin (formerly prealbumin). The transfer of retinol from plasma to retina is mediated by a specific surface receptor[21,22]. Human RBP contains 182 amino acids; the 2 Å resolution structure of the RBP-retinol complex has recently been solved[23] and refined[24].

We have determined the structure of BLG by standard crystallographic techniques (Fig. 1). We are confident that the strands are accurately positioned in our map, although one external loop and the N- and C-terminal residues remain poorly defined. Higher resolution data now being processed should reveal the remainder of the molecule. The molecule consists of anti-parallel β-sheet, formed by 9 strands wrapped round to form a flattened cone or calyx. The core of the molecule, an eight-stranded, antiparallel β-barrel, is an unusual structural motif which has been observed previously only in RBP[23], although catalase[25] has a barrel of similar topology, one connecting loop of which forms a separate domain. The strands A–I comprise residues 16–27, 39–44, 47–58, 62–76. 80–84, 89–97, 102–109, 115–124 and 145–150. Strands E,F,G,H,A and I are flanked by a 3-turn helix (130–140). The strands of the two sheets that form opposite sides of the calyx are orthogonal (ref. 26 and Fig. 2). Reverse turns occur at residues 44–47, 59–62, 78–81 and 84–88 but the turns at 98–102 and 111–115 are not true β-bends. Strand I is involved in the formation of the dimer by making anti-parallel interactions with the dyad-related strand. The interface between monomers also involves hydrophobic interactions between Ile 29 and Ile 147, and stacking of the imidazoles of symmetry-related His 146 residues. The free sulphydryl, at position 121, is buried at the sheet-helix interface. The disulphide bond at 106–119 is clearly resolved and shows

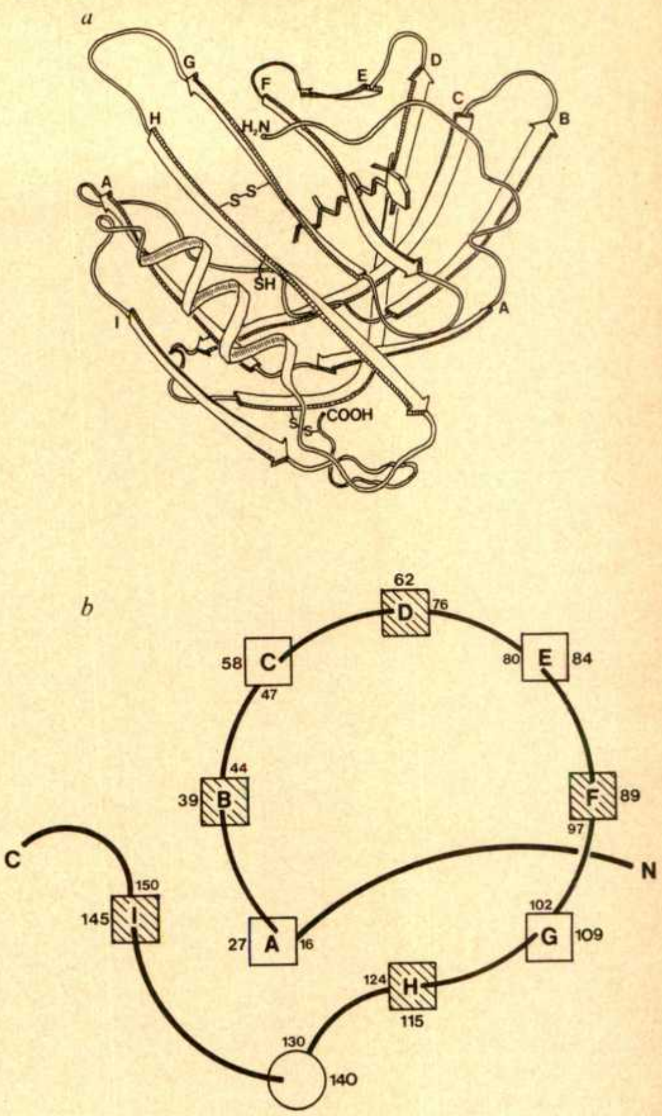

Fig. 1 *a*, Drawing of the β-lactoglobulin fold showing the position at which we propose that retinol binds. The arrows indicate the strands of β-sheet. The axis of the calyx runs approximately parallel to the extended isoprene chain with the far tip lying at the entrance from the solvent. *b*, The topology of the protein with the N-termini of the strands hatched to emphasize their antiparallel nature. A preliminary account of the preparation and crystallography of BLG is given in ref. 20.

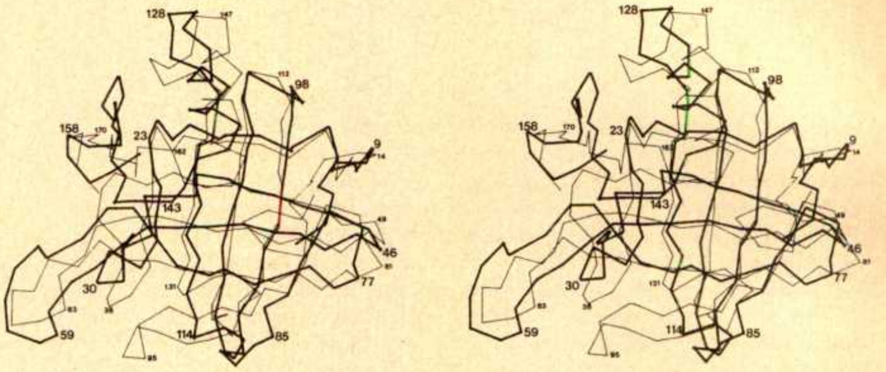

Fig. 3 Stereoscopic diagram of retinol (Rtl) model-built into β-lactoglobulin as described in the text. The side-chains of the BLG residues referred to are also shown as is the position of the retinol molecule (dotted) in RBP.

no evidence of equimolar amounts of cystine 106–119 and 106–121[7]. As the distance between the S_γ atoms of Cys 119 and Cys 121 is 10.5 Å, any interchange would be impossible without significant conformational flexibility. The other disulphide, 66–160, is not clear although it appears to be on the outer surface linking strand D to the C-terminal region.

BLG shows limited sequence homology to RBP, and human α_1- and rat α_2-microglobulins (refs 2, 27 and L. Rask and P. A. Peterson, personal communication). The sequence alignment of BLG and RBP, obtained with the program GAP[28] using a gap weight of 1 and a gap length of 0.1, shows 42 identities when 9 insertions or deletions are allowed. Only two pairs of regions have 4 consecutive identical residues (17–20 in BLG and 22–25 in RBP; 96–99 in BLG and 108–111 in RBP), and a third pair (79–83 in BLG and 83–87 in RBP) has 4 out of 5. However, the spatial similarity of the two structures is striking (Fig. 2) and when the backbone C_α coordinates were superimposed by the program HOMO[29,30], 129 out of the 162 residues were closely aligned, with an r.m.s. error of 2.76 Å. The greater length of the RBP chain is accommodated in larger surface loops, while the regular cores of the molecules are similar and in each case form a pocket open to the surface in which retinol binds in RBP.

Futterman and Heller[15] studied the binding of retinol to BLG and RBP by fluorescence spectroscopy and suggested that the retinol binding site in RBP was non-polar. In RBP the fluorescence remained constant with time whereas BLG showed a slow decline. The retinol was fully protected against oxidation by liver alchohol dehydrogenase in the complex with RBP but not in that with BLG. It has been suggested[31] that the BLG binding site makes the retinol more rigid than in free solution by encompassing the β-ionone ring and one or more adjacent carbon–carbon double bonds and that a tryptophan residue helps to form the binding site for the β-ionone moiety. Binding studies of retinylidene amine[32] suggest that both BLG and RBP protect the retinyl Schiff's base from hydrolysis and that in BLG there is a positively charged group near the carbon–nitrogen double bond. Interestingly, the dissociation constant, K_d, for the retinol-BLG complex[31] is 2×10^{-8} M whereas that for the RBP complex[33] is only 1.7×10^{-7} M.

These studies are in agreement with our structural models. In RBP[24], the retinol molecule is surrounded by the protein except for the very tip of the hydroxyl group. We modelled the retinol–BLG complex, first transforming the coordinates of retinol from RBP to the BLG coordinate system. Interactive graphics[34,35] gave a model in which the isoprene tail of retinol is fairly accessible to solvent because the loop at positions 83–85 in BLG is shorter than the corresponding one (at positions 91–98) in RBP. No tryptophan residue is close to the retinol although Trp 19, at the bottom of the calyx, lies at a distance of about 10 Å. Lys 70 may approach the retinol hydroxyl group. However, in BLG there appears to be an empty space further into the calyx and inaccessible to solvent, owing to changes from the residues that block this end of the cavity, in RBP. In particular, of 5 phenylalanine residues in RBP (at positions 15, 20, 45, 77 & 86) there are 3 (at positions 15, 20 and 45) that are replaced by smaller ones in BLG (Leu 10, Val 15 & Val 41); in addition, RBP Met 53 is changed to Thr 49 in BLG, RBP His 104 to BLG Val 92, RBP Ile 106 to BLG Val 94 and RBP Gln 117 to the larger Phe 105 in BLG. These changes allow the β-ionone ring of retinol to be fitted more deeply after minor conformational adjustments to some protein sidechains. The new binding site is partly formed by the sidechain of Trp 19. Most of the retinol is as well protected from the solvent in this conformation of BLG as in RBP, although the tip of the isoprene tail remains more exposed. It seems reasonable to imagine that some exchange is possible with the hydrophobic substrate binding pocket of ADH[36], which in the presence of NAD^+ could lead to oxidation. The retinol hydroxyl group is still within reach of the N_ζ of Lys 70. Energy minimization of the retinol in this deeper position reveal a better fit when the conjugated π-system is fully planar than when rotation is allowed about the 6-7 bond to permit closer approach to Trp 19. The fine structure in the UV spectrum of retinol when bound to BLG has been interpreted[37] as indicating a fully planar π-system. Thus, this model (Fig. 3) accounts for all the available chemical evidence, although details of the interactions between BLG and retinol will have to await the high resolution refined structure.

The fact that retinol binds to BLG with greater affinity than to RBP and our demonstration that it can be neatly accommodated within the BLG structure, prompted the speculation[20] that the biological function of the milk protein is involved with vitamin A transport. We monitored [^{3}H]-retinol bound to BLG using both gel filtration and a transthyretin-affinity resin, but found no detectable interaction between BLG and transthyretin. However, [^{125}I]-labelled BLG-retinol complex binds specifically to purified microvilli prepared from one-week-old calf intestine. Total binding of [^{125}I]-labelled-BLG (5 nM) was reduced by 70% in the presence of 5 μM unlabelled BLG. Specific binding was observed only in the lower segments of the small intestine and was not present in six-month old animals. The binding is dependent on both pH and ionic strength, and shows optima in the region of 6.8 and 0.1 M respectively. These observations are still preliminary, but they suggest that specific receptors for BLG which may be important in vitamin uptake are present in the small intestine of the neonate calf. The mechanism of uptake remains to be established. Neither RBP nor BLG inhibits the binding of the other to its specific receptor.

We thank Professor Sir David Phillips for drawing our attention to the similarity between β-lactoglobulin and RBP, Dr C. Holt for help with protein purification, Drs H. Muirhead and H. C. Watson, Bristol University, for use of X-ray photographic facilities, the Physics Department, Edinburgh University for use of their diffractometer and computing facilities and the SERC for financial support. E.E.E. thanks the University of Leeds for a studentship.

DNA conformation is determined by economics in the hydration of phosphate groups

Mixed sequence DNA can exist in two right-handed and one left-handed double helical conformations—A, B and Z[1–3]. Under conditions of high water activity the B conformation prevails. If the water activity is reduced on addition of salt or organic solvents, transformation occurs to A-DNA or, in DNAs with alternating purine-pyrimidine sequences, to the left-handed Z-DNA. In crystal structure analyses of oligonucleotides, the free oxygen atoms of adjacent phosphate groups along the polynucleotide chain in B-DNA are found at least 6.6 Å apart and individually hydrated[4] whereas they are as close as 5.3 Å in A-DNA and 4.4 Å in Z-DNA, and bridged by water molecules[5–7]. We suggest that this more economical hydration in A- and Z-DNA compared with B-DNA is the underlying cause of B → A and B → Z transitions.

To learn about possible driving forces for conformational transitions of DNA, we have investigated in detail the hydration of crystalline DNA fragments in the A, B and Z forms. The bases and sugars are equally well hydrated in all three forms. Ordered patterns of hydration have been observed in several oligonucleotide crystal structures, including the spines of hydration in the minor groove of the Z-hexamers with alternating G-C sequence[6–9], in the centre AATT part of the B-DNA dodecamer[4,10–13], and the fused pentagons within the TATA region of the A-DNA octamer[5]. These ordered structures are base-specific and are important elements in stabilizing regions of DNA with particular base sequences, and in influencing

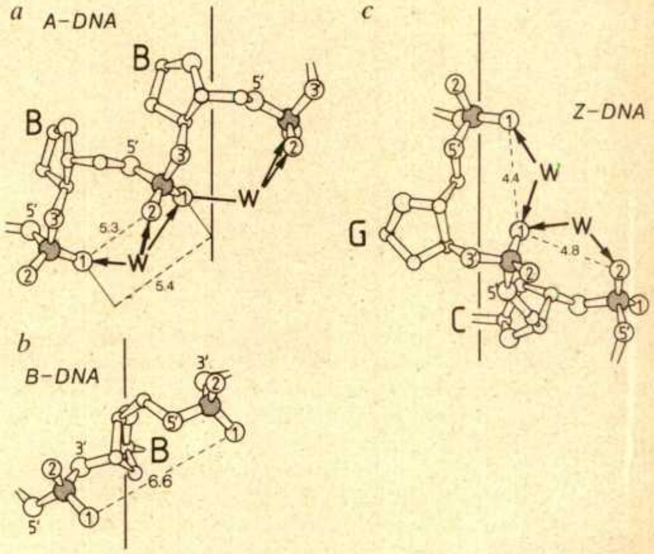

Fig. 1 Comparison of deoxyribose-3′, 5′-diphosphate fragments in *a*, A-, *b*, B- and *c*, Z-DNA. Redrawn from corresponding figures in ref. 1. Vertical lines represent helical axes; phosphorus atoms indicated by shading, phosphate oxygens by numbering. Shortest distances between free phosphate oxygen atoms are given in Å units (see Table 1), W represents water molecules that bridge free phosphate oxygens in A- and Z-DNA. Capital letters B in A- and B-DNA and G, C in Z-DNA indicate C(1′) sugar atoms where bases are attached.

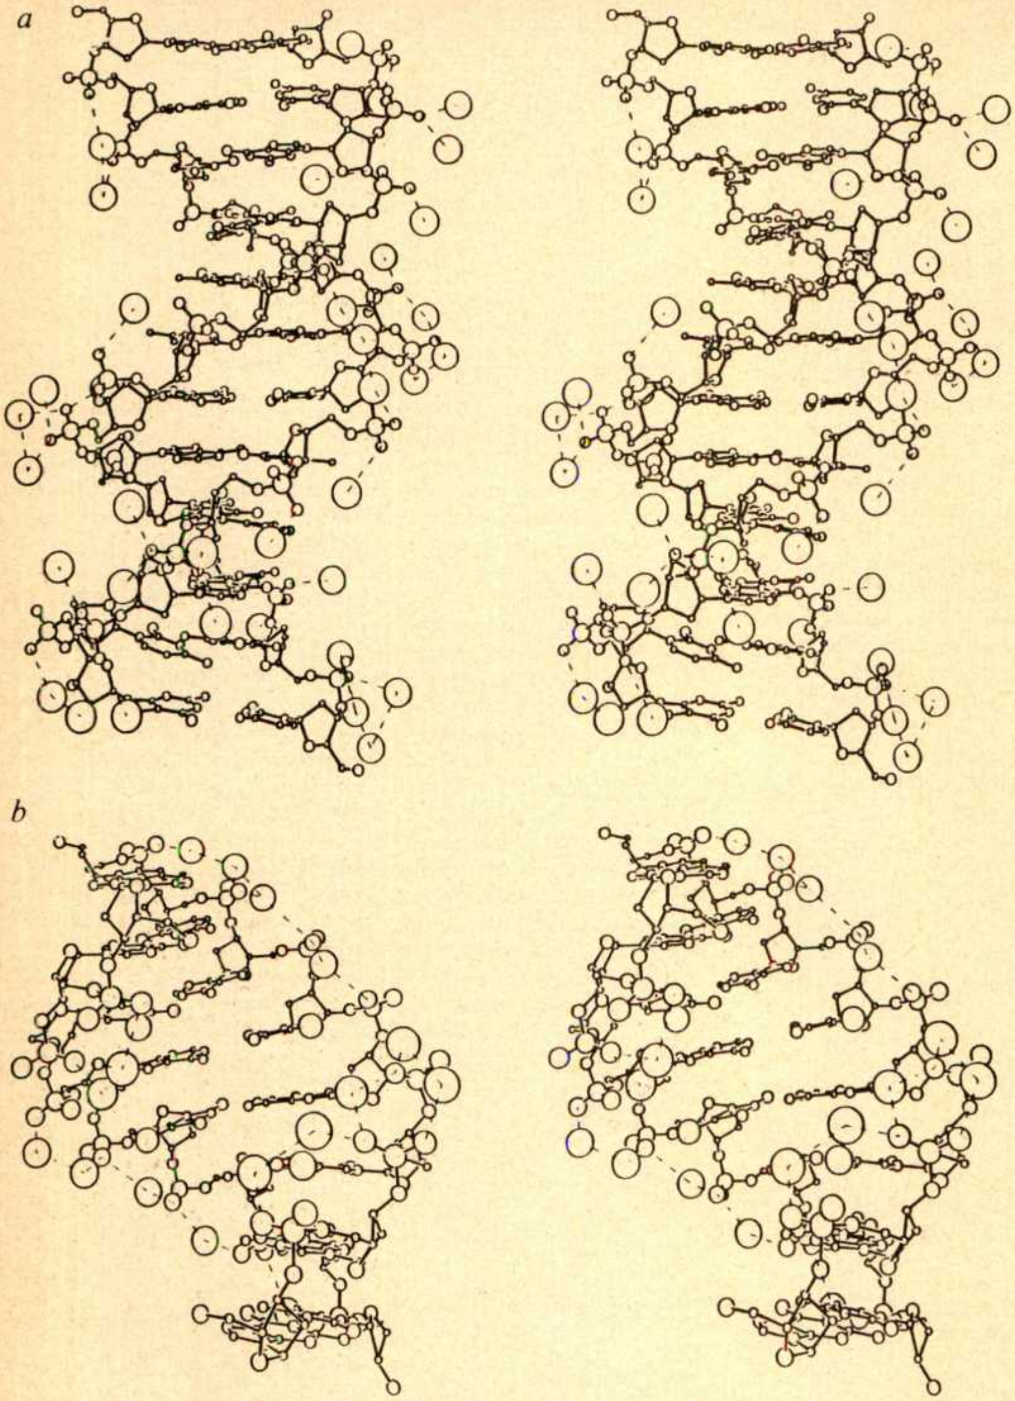

Fig. 2 *a*, *b*, DNA stereoviews. *a*, Stereoview showing the hydration of phosphate groups in the B-DNA dodecamer d(CGCGAATTAGCG) (ref. 10). Atoms are shown in order of size: water oxygen, P, O, N, C. Dashed lines, hydrogen bonds. Note the clustering of solvent molecules around phosphate groups and the lack of continuous water bridges. *b*, Hydration of phosphate groups in the A-DNA fragment d(GG$^{\mathrm{Br}}$UA$^{\mathrm{Br}}$UACC) (ref. 5). Of the 12 possible water bridges between free oxygen atoms of adjacent phosphate groups, 7 are actually formed within the cutoff limit of 3.5 Å for O–O separation in water. In one strand of the duplex, the water bridges are nearly continuous. The stereoview is into the major groove.

conformational transitions of DNA with non-random sequence, such as the B → A transitions of DNA fibres with high A+T content[14], and the B → Z transition[15] of poly [d(G-C)]. However, it is not yet possible to extrapolate from these sequence-dependent ordered patterns to the more general mechanisms of conformational transitions in mixed-sequence DNA.

The most relevant difference between A-, B- and Z-DNA lies in the conformation of the sugar ring, which is related to the distance between the phosphate groups at the 3′ and 5′ ends of each nucleotide, and to the displacement of base pairs relative to the helical axis. The sugar pucker in B-DNA is 'soft' and extends beyond the O(4′)-*endo* to C(1′)-*exo* to C(2′)-*endo* range or, in terms of pseudorotation phase angle[16], from east to south, with the majority of sugars in C(1′)-*exo* to C(2′)-*endo*. These sugar puckers give rise to a wide phosphate–phosphate separation of 6.6 Å on average (Table 1 and Fig. 1). In contrast, in A-DNA the sugar conformation is much more narrowly confined to C(3′)-*endo*, and the distance between the phosphate groups is reduced to an average of about 6 Å. In Z-DNA, the sugar pucker alternates, with C(2′)-*endo* for the pyrimidine nucleotides in *anti* conformation, and with O(4′)-*endo* to C(1′)-*exo* for the *syn* purine nucleotides. The resulting interphosphate distances differ considerably for the sequences listed in Table 1, but are comparable to A-DNA in the idealized Z-DNA, 5.9 Å for the pCp step and 6.0 Å for the pGp step.

Associated with the differences in phosphate–phosphate separation in A-, B-, Z-DNA are differences in distances between the successive free phosphate oxygens O(1) and O(2), that are further influenced by right- and left-handed helical twist, as shown in Table 1 and Fig. 1. On average, all interphosphate O–O distances exceed 6.6 Å in B-DNA. In A-DNA (omitting the very short sequence containing an iodinated cytidine residue d($^{\mathrm{I}}$CCGG)), they are considerably smaller; 5.4–5.7 Å for O(1)–

Table 1 Average intra-strand separations (Å) between free oxygen atoms O(1), O(2) in adjacent phosphate groups in A-, B-, Z-DNA

In A- and B-DNA, O(1) is that atom which is closer to the major groove side. Numbers give the spread of distances and the geometrical mean with standard deviation in parentheses. In the DNAs with base pair mismatches, the backbone geometry is virtually unchanged compared with all-Watson-Crick base pairs.

* Oxygen-oxygen contacts which are so close that they are most frequently (and almost systematically) bridged by water molecules. See also Fig. 1.

Table 2 Statistics of water binding to free phosphate oxygen atoms O(1), O(2) in different DNA fragments

Sequence*	I	II	III	IV	V	VI	VII
Helix type	A	A	B	B	B	Z	Z
Number of water molecules:							
Bound to O(1), O(2)	40	34	22	35	32	37	35
Forming bidentate intra-phosphate bridges	1	0	1	2	2	1	1
Forming monodentate interactions with O(1), O(2)	31	30	21	33	30	34	31
In one-water inter-phosphate bridges	7	4	0	0	0	5	3
In two-water inter-phosphate bridges	4	1	1	2	1	2	2
Inter-phosphate gaps bridged by one water (%)	58	33	0	0	0	63	38

The cutoff limit for O-O distances to water is 3.5 Å.

* I is d(GG^{Br}UA^{Br}UACC), ref. 5; II is d(GGGGCCCC), ref. 24; III is native d(CGCGAATTCGCG) ref. 11; IV is d(CGCGAATT^{Br}CGCG), MPD 7, ref. 4; V is d(CGCGAATTAGCG), ref. 10; VI is d(^{Br}CG^{Br}CG^{Br}CG, ref. 7; VII is d(^{Br}UGCGCG), ref. 28.

O(1), and 5.3 Å for 3′-O(1)-O(2)-5′, compared to the other two distances O(2)-O(2) and 3′-O(2)-O(1)-5′. For Z-DNA in the idealized form, O(1)-O(1) distance for pGp (4.4 Å) and 3′-O(2)-O(1)-5′ distance for pCp (4.8 Å) are short; O(2)-O(2) for pCp (5.5 Å) is intermediate; and all other O-O distances exceed 6.4 Å.

When the hydration schemes of the phosphate groups in the three different DNA conformations are compared, it is evident that in B-DNA the average oxygen-oxygen separation of about 6.6-8.1 Å is so large that each phosphate group can be surrounded by its own sphere of water molecules, and displays an independent hydration[4]. With a cutoff of 3.5 Å for O-O$_{water}$ distances, one or two water molecules cannot bridge adjacent phosphates for the sequences given in Table 2. In contrast, in A- and Z-DNA, the oxygen atoms of adjacent phosphate groups are so close together (Table 1) that they can be bridged by one or two water molecules[5-7], as shown in Figs 1, 2 and in Table 2. The single water molecule bridges are always oriented in the same direction; in the 3′ to 5′ direction in A-DNA, the O(1) of the 3′-phosphate being linked by a water molecule to either the O(1) or O(2) oxygens of the adjacent 5′-phosphate, as these O-O distances are the shortest. In crystal structures the former is preferred because only in this case can the water molecule also interact with the functional groups of the bases in the major groove. For Z-DNA, the reverse direction of the bridges is found in the pCp step, O(2)-O(1) (Fig. 1). This directionality of water bridges is a result of the right- and left-handed twists of the respective DNA conformers, which determine the separations between phosphate oxygens.

B-DNA occurs under conditions of high water activity, and

A- and Z-DNA at low water activity; it appears that the hydration of A- and Z-DNA, where adjacent phosphate groups along the polyphosphate backbone are bridged by water molecules, is more economical and efficient than that of B-DNA, where each phosphate group is individually hydrated. As indicated by gravimetric[17] and infrared spectroscopic[18] studies and by crystal structure analyses of hydrated nucleotides[19], the binding of water molecules to the charged phosphate oxygen atoms is energetically more favoured than binding to base and sugar atoms. Therefore, the phosphate hydration will have a substantial influence on the structure of DNA. If the water activity is high, the number of water molecules available for hydration of DNA is high, and the phosphate groups will be fully and individually hydrated. If salt or an organic polar solvent is added, water molecules are withdrawn from the DNA and hydration consequently becomes more economical. Economy is achieved by water molecules bridging adjacent phosphate groups, following a change in conformation of the sugar residues that results in the phosphate groups moving closer together. This transition between conformational states is cooperative, as is the formation of the bridges, which run along the entire sugar-phosphate backbone in A-DNA[5]. A comparable situation is seen in Z-DNA[6,7] and we assume that this transition has the same basis as the B → A transition. Additionally, in Z-DNA the metal ions appear to play a significant role as in the crystal structures magnesium hexahydrate, cobalt hexammine, and sodium ions were found tightly coordinated with N(7) and O(6) of guanosine[7,9,20].

The concept of hydration economy finds further support if we consider the water content per base pair in the DNA double helices. It has been suggested, on the basis of gravimetric studies[21] and theoretical considerations[22], that an A · T base pair binds one more water molecule than a G · C base pair. This was confirmed in the crystal structure of the B-DNA dodecamer where water molecules are systematically trapped between the thymine methyl groups and one of the free oxygens of the 5′ phosphates[23]. Such an interaction can only occur if the nucleotide adopts a sugar conformation typical of B-DNA because then the base and the 5′-phosphate are farther apart than when the sugar is in the C(3′)-*endo* conformation found in A-DNA. Therefore, DNA at high water activity adopting the B-type conformation is able to bind one additional water molecule at each thymidine, which confers additional stabilization. If the water activity is lowered, this (weakly) bound water molecule will be removed, and the transition from the B-type sugar puckering mode to the C(3′)-*endo* form can take place. This again has to occur under cooperative control because otherwise the DNA would have both random B-DNA type and C(3′)-*endo* puckers which would be unfavourable for the double helical structure.

Hence, it appears that the conformational transitions of mixed sequence DNA from B to A or B to Z are associated with the hydration of the phosphate groups which is less economical in B-DNA than in the A and Z forms. It is clear that other factors such as the spine of hydration in the minor groove of B-DNA and Z-DNA and the ordered water pentagons in the major groove of A-DNA also play a role, particularly in stabilizing specific base sequences.

A protein on *Plasmodium falciparum*-infected erythrocytes functions as a transferrin receptor

Mario H. Rodriguez* & Michele Jungery†

Department of Tropical Public Health,

Several observations suggest that iron is essential for the development of malaria parasites[1-6] but there is evidence that the parasites in erythrocytes do not obtain iron from haemoglobin. The total haemin level in parasitized erythrocytes does not vary during parasite development[7], indicating that the iron-containing moiety of haemoglobin is not detectably metabolized. Although parasite proteases can degrade the protein part of haemoglobin in red cells[8,9], no parasite enzymes that degrade haemin have been identified. In mammalian cells, haemin is degraded to carbon monoxide and bilirubin by the enzyme haeme oxygenase[10]. This enzyme has not been found in malaria parasites[11]. In fact haemin has been found to be toxic to parasite carbohydrate metabolism[12]. Thus, iron apparently cannot be liberated from haemin and instead is sequestered in infected red cells as haemozoin, the characteristic pigment associated with malarial infection[13,14]. If iron bound to transferrin is the source of ferric ions for malaria parasites within mature erythrocytes, then the parasite must synthesize its own transferrin receptor and localize it on the surface of the infected cell, because the receptors for transferrin are lost during erythrocyte maturation[5,16]. Our results here suggest that *Plasmodium falciparum* synthesizes its own transferrin receptors enabling it to take up iron from transferrin by receptor-mediated endocytosis.

To determine whether human ferrotransferrin binds to parasitized cells, we conjugated this ferrotransferrin with fluorescein isothiocyanate (FITC) and observed the movement of the ligand from the cell surface to the parasitophorous vacuole inside erythrocytes for 30 minutes (Fig. 1). The transferrin was initially found in small vesicles in the cytoplasm of infected cells but within 30 min these fluorescent vesicles concentrated around the

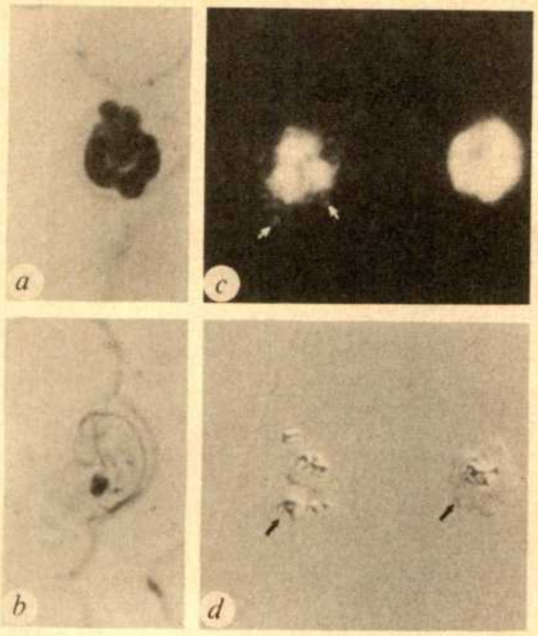

Fig. 1 Uptake of FITC-labelled ferrotransferrin by malaria parasites. Erythrocytes infected with *P. falciparum* (Palo Alto, Uganda strain) young trophozoites were obtained from cultures[26] by sedimentation on plasmagel[27]. The infected cells were washed twice with RPMI 1640 (GIBCO) and 25 μl of these cells were cultured in 100 μl of complete culture medium (10% human serum, 0.4% glucose, 0.2% $NaHCO_3$, 0.3% TES (*N*-Tris[hydroxymethyl]methyl-2-aminoethanolsulphonic acid), 0.004% gentamycin in RPMI 1640 medium) with ~1 mg ml^{-1} of FITC-ferrotransferrin. Transferrin (Calbiochem) was saturated with iron[28] and coupled to FITC (isomer I-Sigma) as described[29] with a final ratio FITC/protein of 2:1. Every 15 min cells were removed from culture, washed three times with cold RPMI and examined in a Zeiss ICM microscope with an epifluorescence condenser. Fluorescent transferrin was observed initially in small vesicles in the cytoplasm of the infected cells (*a*, arrow *b* and *c*). After 30 min at 37 °C fluorescent material accumulated around the parasitophorous vacuole surrounding the parasite (*d* and *e*, arrows). Fluorescence was not evident on uninfected cells on the same slide. The specificity of FITC-transferrin uptake was further tested by showing competititve inhibition of uptake in the presence of an excess of unlabelled transferrin (a 1:100 dilution of the labelled transferrin): only a pale surface-fluorescence was observed (*f*).

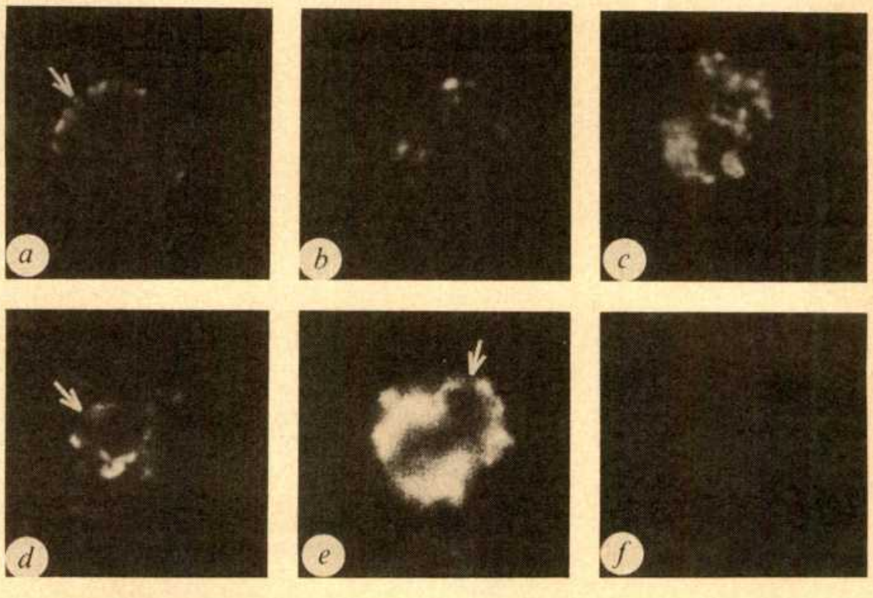
parasitophorous vacuole surrounding the parasite in all the parasitized cells (Fig. 1*d*, *e*, arrows). Such fluorescence in parasitized cells was observable over a wide range of FITC-transferrin concentrations. When FITC-ferrotransferrin was diluted with an excess of unlabelled ferrotransferrin, little fluorescence was observed on the infected cells (Fig. 1*f*) indicating selective competition for this receptor. K562 cells, which carry transferrin receptors, were used to show the specificity of binding of FITC-transferrin. FITC-transferrin could be detected at concentrations from 1 mg ml^{-1} to less than 1 μg ml^{-1} except in the presence of unlabelled transferrin. Finally, iron-free apotransferrin, which has no affinity for transferrin receptor at neutral *p*H, did not bind to any of these cells.

We confirmed the presence of transferrin in vesicles and in or around the parasites in similar experiments using either peroxidase (Fig. 2*a*, *b*) or rhodamine (Fig. 2*c*) immunostaining of fixed parasite-infected cells treated with an anti-transferrin rabbit antibody. Most of the fluorescence was in or around the parasites or in vesicles (Fig. 2*c*, arrows) and not at the surface. These results agree with observations in mammalian cells that about 75% of the transferrin bound to receptors is found intracellularly[17]. Studies at the ultrastructural level to determine the precise location of the ligand and the receptor are in progress (D. Titus, M. Neutra, M. Jungery).

We used affinity chromatography and binding assays to identify the receptor(s) for transferrin in malaria-infected cells. Two different types of affinity chromatography were used to isolate the transferrin receptor. First, a ^{35}S-labelled parasite extract was passed through a column of anti-transferrin immunoglobulin coupled to Sepharose 4B. The SDS-polyacrylamide gel electrophoresis(PAGE) profile of parasite proteins from this column reveals a prominent band with relative molecular mass (M_r) of approximately 93,000 (93K), and a series of minor bands (Fig. 3, lane 2). In the second isolation procedure, ferrotransferrin was coupled to Sepharose 4B and washed in a way that releases the receptor from the transferrin/receptor complex in mammalian systems[18]. After incubation with the labelled parasite extract, the eluates contained few counts, indicating that most of the bound parasite material was not released. The major parasite protein that bound to the transferrin affinity column was again the 93K protein (Fig. 3, lane 4). The 93K protein did not bind to control columns coupled with either bovine serum albumin or ethanolamine. Therefore the most likely candidate for the parasite-derived transferrin receptor is the 93K transferrin-binding protein.

Fig. 2 *a*, *b*, Immunoperoxidase detection of transferrin on *P. falciparum*-infected erythrocytes; *c*, *d*, rhodamine-conjugated immunostains of *P. falciparum* infected cells. *P. falciparum* was cultured in complete medium containing 1 mg ml^{-1} ferrotransferrin. Infected cells were washed three times with RPMI and thin smears prepared. After fixation with 10% methanol in acetone, the slides were washed with 0.5% H_2O_2 to inactivate endogenous peroxidase[30], and treated with rabbit anti-transferrin serum and a peroxidase-labelled goat anti-rabbit IgG (Cappel). After development with aminobenzidine-H_2O_2, a red-brown stain was observed in infected erythrocytes around the parasitophorous vacuole (*a*). Specific anti-transferrin stain was seen on all infected cells. No stain was seen on non-infected cells or on infected cells treated with non-immune rabbit serum (*b*). *c*, *d*, Parasites were fixed and incubated with anti-transferrin antibody as in *a*. Slide 5 was washed in PBS with gelatin, then rhodamine-conjugated goat anti-rabbit serum was added. *c*, Anti-transferrin binding to vesicles (arrow) and accumulating around the parasite. *d*, A light-field (Nomarski optics) photograph of the same cells as in *c*. Only faint background fluorescence can be observed on normal erythrocytes seen in *c*.



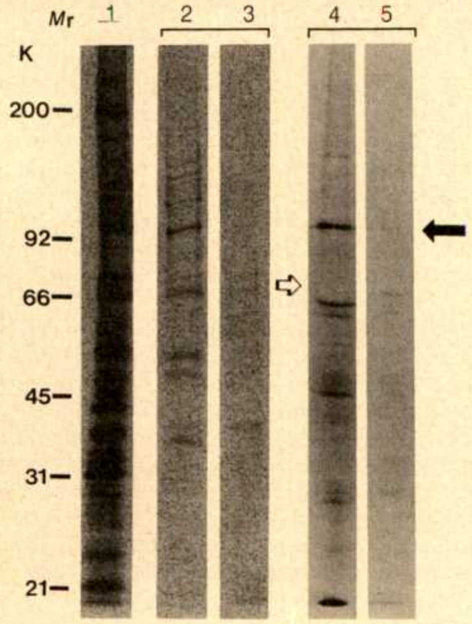


Fig. 3 Affinity chromatography of ^{35}S-methionine-labelled *P. falciparum* protein preparations on anti-transferrin-antibody bound to Sepharose or Fe-transferrin-Sepharose columns. *P. falciparum* trophozoites were metabolically labelled with ^{35}S-methionine for four hours. The parasites were harvested, solubilized in 0.15 M NaCl, 0.1 M PO$_4$, *p*H 7.4 in phosphate-buffered saline (PBS) with 100,000 U ml^{-1} aprotinin, 1 mM iodacetic acid, 5 mM TPCK, 5 mM TLCK and 2.0% Triton X-100. The preparation was incubated either with affinity purified rabbit anti-transferrin-antibody bound to Sepharose 4B or with Fe-transferrin-bound Sepharose 4B beads. Control columns included Sepharose 4B beads coupled with purified rabbit Ig (lane 3) or blocked with ethanolamine or bovine serum albumin (lane 5). Open arrow, location of the transferrin that was removed from the transferrin affinity Sepharose columns during boiling of the beads in SDS sample buffer.

Methods. The affinity column beads were incubated at room temperature for 3 h and then washed. The antitransferrin-Sepharose beads were washed with phosphate-buffered saline (PBS), 0.25% Triton X-100 until no counts were obtained from the washings. The Fe-transferrin beads were washed first with PBS, 0.5% Triton X-100, followed by 0.15 M Na acetate, 0.5% Triton X-100, *p*H 5, then 0.1 M Na citrate, 0.5% Triton X-100, 50 μg ml^{-1} Desferrioxamine, *p*H 5, and finally by 0.1 M NH$_4$HCO$_3$, 0.5% Triton X-200, 50 μg ml^{-1} Desferrioxamine, *p*H 7.8. Beads from both columns were then boiled for 5 min in sample buffer, (0.1 M Tris-HCl, *p*H 7.5, 2% SDS, 10% mercaptoethanol, 2 mM ethylenediamine-tetraacetic acid (EDTA), 2 mM phenyl methyl sulphonyl fluoride (PMSF), 30% glycerol) and the supernatants analysed by SDS-PAGE[31] and fluorography. Lane 1, the initial ^{35}S-methionine-labelled parasite preparation; lane 2, parasite proteins bound to and eluted from the anti-transferrin Ig-beads. The most prominent protein obtained has a molecular weight of 93K. Lane 4, parasite proteins that bind to the transferrin beads. The 93K protein is the most prominent protein binding to transferrin. Though it cannot be seen directly in this autoradiograph, the large amount of transferrin in lane 4 produced a displacement of other radiolabelled proteins in the 70K M_r (open arrow) region. The presence of transferrin was confirmed in Coomassie blue stain of this same gel. Lanes 3, 5 control affinity columns. Although there is some non-specific binding of parasite proteins the 93K protein is not present. Both affinity procedures identify a major protein band of M_r 93K (solid arrow) which binds to transferrin as the parasite transferrin receptor.

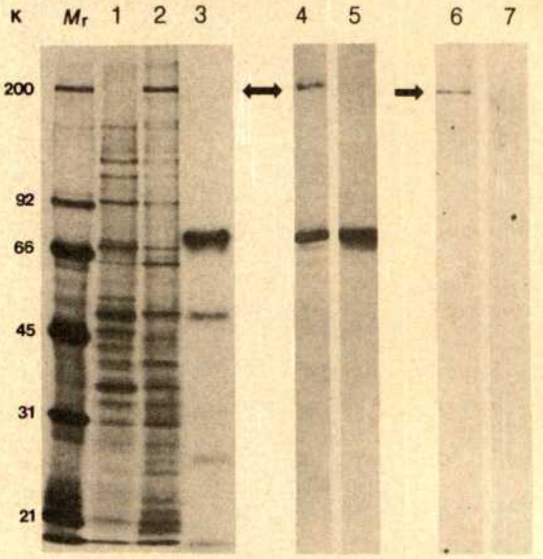

Fig. 4 Incorporation of ^{125}I-Fe-transferrin by *P. falciparum* in culture. Fluororadiograph of reduced SDS-PAGE of *P. falciparum* parasite preparations. *P. falciparum* trophozoite-infected erythrocytes were cultured in complete medium with 7 μCi ml^{-1} of ^{35}S-methionine (Amersham, 332 MBg ml^{-1}) for a total period of 4 h. After 3 h in culture, the preparation was divided into two aliquots, (samples 1, 2). A third was cultured for 3 h without ^{35}S-methionine. ^{125}I-labelled Fe transferrin was added to samples 2 and 3. The three cultures were incubated for a further hour at 37 °C. The parasites were harvested and washed three times with cold RPMI 1640. The parasitized red cells from samples 1 and 2 were lysed with 0.01 M Tris/HCl, *p*H 7.4 and spun at 10,000 r.p.m. for 30 min. This lyses the erythrocyte plasma membrane but leaves the intact parasites surrounded by the parasitophorous vacuole. The parasites were washed with 0.1 M Tris HCl *p*H 7.4 and extracts were prepared by adding solubilizing buffer (10 mM HEPES, 2.0% TRITON-X100, 2 mM PMSF, 5 mM L-1-tosylamide-2-phenylethyl chloromethyl ketone (TPCK), 5 mM *N*-α-p-tosyl-L-lysine chloromethyl ketone (TLCK), 50 μg ml^{-1} leupeptin, 50 μg ml^{-1} chymostatin). The extract was clarified by centrifugation at 100,000 *g* for 1 h. Supernatants containing extracted proteins were added to sample buffer (as described in Fig. 3 above) and run reduced conditions in SDS-PAGE gels. Lane 1, ^{35}S-methionine-labelled trophozoites from sample 1; lane 2, labelled trophozoites cultured in medium with ^{125}I-transferrin, sample 2; lane 3, ^{125}I-labelled Fe-transferrin. (Breakdown products were sometimes present in SDS gels.) ^{125}I-labelled ferrotransferrin alone was also added to sample 3, (young trophozoites in culture) for 1 h. Intact infected erythrocytes from sample 3 were harvested, washed, and dissolved in solubilizing buffer. The extract was clarified by centrifugation at 100,000 *g* for 1 h. The supernatant with the extracted proteins was added to sample buffer and resolved by SDS-PAGE. A 200K protein is present in both lanes 2 and 4), samples 2 and 3 to which ^{125}I-ferrotransferrin M_r 73K was added. The ^{125}I-ferrotransferrin (73K band, lane 4) is distinct from the ^{125}I-label which is present in a 200K protein band. We cannot at present explain how the 73K transferrin is associated with other molecules in SDS to give a 200K band. (Several procedures using different gel conditions are in progress.) Lane 5, the ^{125}I-labelled transferrin added to cells in lane 4. Arrows, ^{125}I-labelled F-transferrin-parasite protein complex (200K). The presence of transferrin in this 200K protein band was confirmed by immunoblotting the isolated parasite preparation from sample 2 (shown in lane 2) with purified rabbit anti-transferrin antibody and alkaline phosphatase-coupled goat anti-rabbit[32]. The result of this blot (lane 6) indicates that there was transferrin in the 200K protein. A control of non-infected mature erythrocytes cultured in medium with transferrin showed no reaction (lane 7).

We next determined the stage in the parasite's life-cycle where maximum uptake of ^{59}Fe bound to ^{125}I-labelled transferrin took place. By monitoring *P. falciparum*-infected cells from ring to schizont stages we found that the young trophozoite stage is most active, internalizing both radioactive labels which then accumulated in or around the parasite within the red cell. Further, after the erythrocyte membrane was removed from the infected cell by immune lysis, we found that both ^{59}Fe and ^{125}I-transferrin were still associated with the parasites isolated from the host cell.

In an effort to monitor changes in the presence of parasite proteins which might bind to transferrin, young trophozoites of *P. falciparum* were divided into two samples and metabolically labelled for four hours with ^{35}S-methionine. ^{125}I-transferrin was added at the end of three hours to sample 2. The parasites in samples 1 and 2 were collected at the end of four hours, then isolated from their red cells; this process was found to retain much of the parasite transferrin receptor. Solubilized parasite proteins from each sample were resolved by SDS–PAGE (Fig. 4). Lanes 1 and 2 show protein extracts from samples 1 and 2, (young trophozoites separated from the erythrocyte membranes); lane 3 shows the ^{125}I-transferrin used in sample 2. It was not possible to determine major differences in levels or the metabolically labelled protein between samples 1 and 2, but we did observe a 200K band in sample 2, suggesting that the ^{125}I-transferrin added to sample 2 was bound to a parasite protein, presumably the parasite transferrin receptor. This 200K transferrin complex is not present in quantities sufficient to be detectable in samples labelled only with ^{35}S-methionine but it must be different from the 195–210K protein seen in late stage *P. falciparum*-infected cells[19] because that protein does not contain transferrin. To confirm the existence of a 200K band in sample 2, we incubated parasites (sample 3) for one hour with only ^{125}I-ferrotransferrin, after which the erythrocytes were collected intact. When the infected cells in sample 3 were solubilized and resolved by SDS–PAGE, we observed a ^{125}I-labelled 200K protein band distinct from the 73K transferrin band (Fig. 4, lane 4). Lane 5 shows the ^{125}I-transferrin which was added to sample 3. The 200K protein band was not seen when ^{125}I-ferrotransferrin was added to control cultures of uninfected mature erythrocytes.

The presence of transferrin in the 200K band was confirmed by immunoblotting the parasite-solubilized protein preparations with purified anti-transferrin immunoglobulin, then alkaline phosphatase conjugated anti-rabbit antibody (Fig. 4, lane 6). No reaction product was seen in the control normal erythrocytes solubilized and treated in the same way as infected cells (Fig. 4, lane 7). The control red cells were identical to those used in the parasite culture. We pretested these control red cells in several ways to ensure that they did not contain reticulocytes, and used the red cells (blood bank blood) in the *in vitro* culture of *P. falciparum* after two weeks storage at 4 °C. We found that these cells did not take up FITC-transferrin or ^{125}I-transferrin, did not bind anti-transferrin antibodies on Western blots or on fixed smears, and did not immunoprecipitate with antitransferrin antibody. Further, these red cells did not take up ^{35}S-methionine above background levels.

Mammalian transferrin receptors are composed of two disulphide-linked 93K proteins that, in turn, bind two molecules of transferrin[20]. We do not yet know the nature of the parasite transferrin receptor/transferrin association. Based on the fact that a parasite derived transferrin receptor must bind mammalian transferrin and, consequently, may resemble the mammalian counterpart, we believe that the 93K protein synthesized by *P. falciparum* is the parasite's own transferrin receptor. It is, however, also possible that the 50K protein seen in the SDS–PAGE gels of affinity-purified parasite proteins is either a fragment of the 93K protein or perhaps functions together with this protein as a part of the receptor. Polyacrylamide gel electrophoresis of purified infected erythrocyte membranes, under nonreducing conditions, suggests such an association of these proteins (data not shown).

In each of the techniques used, we always found the 93K protein associated with or binding to human ferrotransferrin and not apotransferrin, strongly suggesting that this protein serves as a receptor for transferrin. We are now producing antibody to the 93K protein in mice following the procedure of Tung *et al.*[21]. This antibody will be used to determine whether the 93K protein, together with transferrin, is part of the 200K band. Preliminary Northern blot analysis of genomic *P. falciparum* DNA with the complementary (c)DNA clone of the human transferrin receptor indicates that the parasite has genes that code for this protein and that they are different from the human gene[23].

Several different approaches suggest that a *P. falciparum* parasite-derived molecule has transferrin receptor-like behaviour: (1) this molecule binds ferrotransferrin but not apostransferrin on parasitized erythrocytes; (2) FITC-transferrin uptake can be completely inhibited by an excess of unlabelled transferrin; (3) affinity chromatography with antitransferrin antibody or with transferrin reveals the presence of this specific parasite protein, and (4) the molecular weight of the complex of parasite receptor and transferrin from parasitized red cells is different from the transferrin/transferrin receptor complex described for reticulocytes[15,16]. More importantly, our results indicate that malaria parasites transport proteins to the surface of the infected cells (see also refs 23, 24, 25), and use these proteins to obtain nutrients and other elements from the plasma. The parasite within the erythrocyte is in contact with macromolecules in its extracellular environment and is thus exposed to attack by immunological and pharmacological means.

Arc minute gravitational lenses and cosmic strings

PACZYŃSKI has suggested[1] that several large separation gravitational lens candidates could be explained by the existence of cosmic strings. These lens candidates are quasar pairs with separation between 1 and 4 arc min. Paczyński states that arc minute separation quasar pairs, which are lensed by long straight strings, are a prediction of cosmic string theory. Paczyński's work received a great deal of attention when preliminary evidence for a gravitational lens with a 2.6 arc min separation was published by Turner *et al.*[2]. Because a lens with such a large separation is difficult to explain with unseen conventional objects and requires a large mass-to-light ratio for the lens, this lens candidate has been reported[3] as evidence for a cosmic string. Subsequent observations suggest that the quasar pair is not lensed[4]. We point out here that such large separation lenses are not predicted by cosmic string theories.

The typical separation of the images of an object that is lensed by a cosmic string[5-7] is $4\pi G\mu$ where $G\mu$ is the dimensionless mass parameter of the string. A gravitational lens with a separation of 2.6 arc min corresponds to $G_\mu \approx 6\times10^{-5}$. While it is possible for a string configuration to produce gravitational lenses with image separations $>4\pi G\mu$ with favourable geometry, to increase the image separation by more than a factor of two or three above this value seems to require very unlikely conditions. While it was originally suggested[8-10] that a valve of $G\mu \approx 10^{-3}$-10^{-5} might be useful for galaxy formation, further work has shown that these valves are too high, and probably already excluded by observation. Arc minute separation lenses are thus not a prediction of cosmic string theories. If some of these objects were lensed by long straight strings, it would create other cosmological problems, or suggest a basic misunderstanding of how cosmic strings should behave.

We now list the evidence against valves of $G\mu > 10^{-5}$. Models where galaxies or clusters accrete around loops[11,12] have obtained $G\mu \approx 2\times10^{-6}$. Thus the prediction of cosmic string models is that $G\mu \approx 10^{-6}$ not 10^{-5}. More serious problems for large values of $G\mu$ come from nucleosynthesis and anisotropy of the microwave background radiation. The most stringent limit on $G\mu$ comes from the requirement that the strings do produce so much gravitational radiation as to interfere with the successful primordial nucleosynthesis scenario[13-15]. This bound is stringent, $G\mu < 4\times10^{-6}$, but it can also be avoided by some types of cosmic strings that predominantly radiate massless goldstone bosons rather than gravitational waves[16]. However, these strings are not as attractive as seeds for galaxy formation, nor do they appear in any attractive particle physics models. A completely model-independent limit has been obtained by Kaiser and Stebbins[17] who showed that $G\mu < 10^{-5}$ is required by the observed isotropy of the microwave background. Similar limits come from anisotropy due to string loops and the gravitational waves they produce[18,19]. While estimating the errors on these theoretical limits is difficult, we feel that at least the limit of Kaiser and Stebbins is actually conservative. As they stated, the limit given is for a "minimal model" which, for example, does not include the increase in the r.m.s. temperature fluctuation due to the superposition of strings which will occur in any model. Thus, the limit $G\mu < 10^{-5}$ is quite firm, so the predicted separation of images lensed by a cosmic string is definitely <1 arc min.

PACZYŃSKI REPLIES—In my letter[1] I intended to emphasize two issues. Firstly, it is unlikely that cosmic strings could be discovered by finding pairs of images. I pointed out that there is a more striking effect of a string lensing: the images of some galaxies would appear as if they were cut with a sharp edge. Secondly, I pointed out that with the images separated by a few arc minutes the expected difference in the light travel time between the two images may be a few hundred or even a few thousand years. We do not know how stable are the broad line spectra of quasars, and I presented some observational reasons why they may, in fact, be variable. Therefore, I proposed that the forbidden lines in the spectra of pairs of quasars may help to decide between a cluster of quasars and a gravitational lens hypothesis. I quoted some papers (not mine) that suggested that strings may produce pairs of images separated by up to a few arc minutes, but this was just one of the many possibilities I listed. Therefore, it is surprising that Bennett and Stebbins give me so much credit for the cosmic string as the cause of the 2.6 arc min lens candidate.

I would like to take this opportunity to re-emphasize the same two points. Figure 1 shows a computer-generated field with about 700 'stars' randomly placed in a flat three-dimensional space, with a broad luminosity function. Half-way between us and the 'horizon' there is a straight 'cosmic string' that produced 27 pairs of images. Readers are encouraged to find the pairs and the string. This can be done, but the presence of the 'string' is not striking. That was my first point[1].

I do not think that it is possible to prove or disprove the gravitational lens hypothesis for the 2.6 arc min candidate of Turner *et al.* by analysing their spectra, as the forbidden lines are too weak to be seen. Fortunately, the quasars (or the quasar) are relatively close, with redshift, $z = 1.01$. With present technology it is possible to see, although with some difficulty, galaxies at this redshift and beyond. Galaxies have two obvious advantages over quasars for our purpose: their space density is much higher, and they do not vary on a timescale shorter than a few billion years. Therefore, if there is a giant gravitational lens then we should be able to see many multiply-lensed galaxies. If these are discovered we shall know there is a lens, and we shall be able to study the lens structure. If the multiply-lensed galaxies are not found then we shall have to conclude that there is no lens. The task is obviously difficult, and it may take years to complete, but I think that any proof may come only from studies of far away galaxies in the field of the 2.6 arc min lens candidate.

'Capture' of stereopsis by illusory contours

Ramachandran and Cavanagh[1] reported an interesting effect in which disparate subjective contours capture regions of zero disparity enclosed within these contours but not regions that lie outside the contours. They suggest that this phenomenon challenges the current computational models of stereo matching. However, the effect is not as general as their article implies: it occurs only in the presence of ambiguity posed by periodic structures. When non-periodic backgrounds are used the stereo capture does not occur (Fig. 1 bottom). This suggests that the phenomenon may have something to do with the treatment of periodic structures by the visual system[2].

Most current computational models of stereo matching[3–5] are based on point-by-point matching of features and use a set of assumptions or constraints (based on some very general properties of the environment) to ease the computational burden associated with solving the often massive local ambiguity problem. Surfaces containing periodic texture cannot be successfully matched locally. For example, a periodic texture on a frontoparallel plane will produce a set of peaks in the cross-correlation surface, each corresponding to a possible match. Locally, there is not enough information to decide which of these possibilities is the correct one. True correspondences can be obtained only by using more global information or by incorporating information originating outside the stereomatching system. This is true for any matching mechanism relying on local computations.

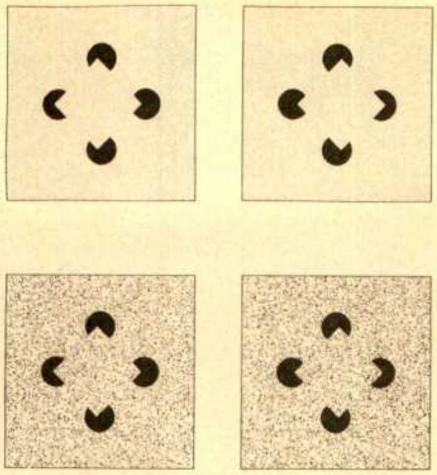

Fig. 1 Depth carried by disparate subjective contours is attributed to periodic (top) but not to non-periodic (bottom) texture elements enclosed by these contours. The stereograms were constructed for viewing with free fusion by crossing the eyes in front of the displays.

The problem of multiple 'local maxima' has been often attacked by invoking multiresolution strategies in which low spatial frequency matches are used to disambiguate the high frequency ones[4]. However, such strategy is not of much use in the case of extended periodic structures. Another, more general, way to solve this problem is to use other cues, for example, accommodation[6], to bias disparity. The idea of a set of depth maps cooperating to converge on a state in which all maps agree and present sharp and accurate three-dimensional localization of features is a powerful notion, the potential of which has yet to be fully explored in the machine vision research.

Current computational theories of stereopsis do not address the qualitative or quantitative aspects of binocular depth perception. Rather, they attempt to understand only its first step: the detection of binocular disparities. Not all of them assume that binocular disparities are directly linked to our perception. That is to say, not all of them assume that our perception of depth from stereograms are isomorphic to the state of the neural disparity network. It is possible, to use an analogy, that binocular disparities are to the stereoscopic depth perception what the output of retinal receptors is to the perception of brightness.

Rather than challenging current computational models of stereomatching, stereoscopic capture illuminates, I believe, mechanisms underlying more cognitive or configurational aspects of stereoscopic processing.

Ramachandran replies—in our article on stereoscopic capture[1] we argued that existing stereo-algorithms could not account for our findings although it is possible that some of them could be modified to do so. This is quite consistent with Prazdny's interesting suggestion. Since disparity of illusory contours can influence the matching of finer elements in a stereogram (Fig. 1, top), we concluded that monocular contours are involved in stereopsis[1,2]. Contrary to Prazdny's suggestion, however, we believe this to be a very general effect and 'capture' happens to be just one way of demonstrating their role. Prazdny also suggests that the effect is specific to 'periodic' patterns, a possibility that we ourselves consider (page 528) when discussing the phase sensitivity of stereo-capture. However, it is almost certainly the lack of ambiguity (not lack of periodicity) that prevents capture in Prazdny's Fig. 1 (lower).

Furthermore, there are also three other aspects of our effect that are not easily handled by existing computational models. First, stereo capture can be seen even in rivalrous displays[1,2] (especially when flashed briefly) and not just in peri-

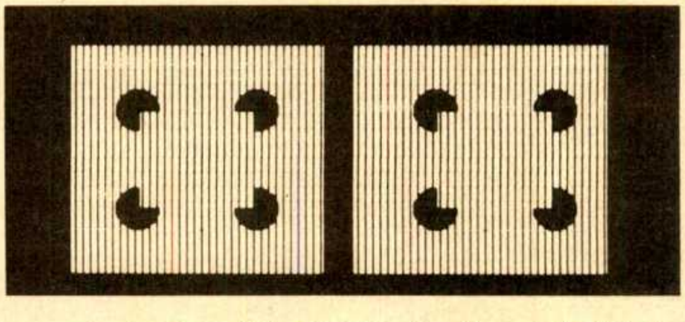

Fig. 2 Stereo capture is not seen if disparity is introduced between the disks themselves.

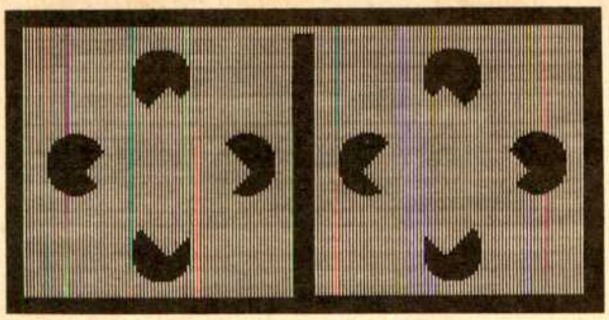

Fig. 3 Occlusion must be an inherent part of the stereoscopic matching process. The four black disks now become 'holes' through which one can see the four deep corners of a partially hidden diamond and the corners pull the corresponding lines of wallpaper with them.

odic displays. Second, Prazdny suggests that disparity signals from the 'unambiguously matched borders' help obtain true correspondences. This conjecture cannot be valid, at least in its simple form, as Fig. 2 does not yield stereo capture. (Here the disparity is between the disks themselves and not just between the cut sectors.) Hence construction of a three-dimensional surface and the presence of a steep disparity gradient are prerequisites; the mere propagation of depth signals will not suffice. Third, we find that reversing the sign of disparity does not simply reverse perceived depth. When the pictures of the two eyes are interchanged to convey uncrossed disparities (Fig. 3), a qualitatively different percept emerges. The black disks now look like holes through which one can see the four corners of a partially occluded square (diamond) and these deeper corners pull the corresponding lines with them. The illusory contours are now seen to complete the holes rather than the square. Here, the illusory contours are created after stereo matching and must, in their turn, influence the subsequent stereo matching of finer elements.

Effects similar to stereo capture can also be observed in apparent motion (motion capture)[3] but the effect is not phase sensitive and has a much higher tolerance for uncorrelated textures.

Any visual process can in principle be simulated in a computer but our results suggest that the brain solves the correspondence problem (in motion and stereopsis) by using a set of short cuts[4] rather than elaborate computation of the kind implied by artificial intelligence researchers. During phylogeny the visual system may have acquired many such tricks which were adopted not for their aesthetic appeal, versatility or mathematical elegance but simply because they worked—an idea that we call the utilitarian theory of perception[5]. Artificial intelligence can be useful in rigorously reformulating[6,7] perceptual problems, but the mechanisms used by the brain to solve these problems are best revealed by old-fashioned psychophysics and neuroanatomy[5,8]. Capture probably results from the fact that the motion (or depth) of certain salient image features is first extracted by the magnocellular pathways and then attributed to finer features that excite the parvocellular pathways. The nature of this interaction merits further attention.

Is the Gulf of Tadjoura a platelet boundary or complex rift zone?

CHOUKROUNE *et al.*[1] have provided new data for the structure of the Gulf of Tadjoura (central Afar), which supposedly separates the Danakil and Somali platelets. Their observations (orientation and activity of a NW–SE fault set) made during dives with the *Cyana* submersible, are at odds with the model of orthodox plate-tectonics boundary, which had been developed in the central Afar and in the Gulf, and was previously widely accepted. Choukroune *et al.* question the westwards opening of the Gulf by rifting: their new interpretation of the Arabia and Africa plate-tectonics relationship does not imply that the Afar triangle is a multi-platelet building, but that it could represent a diffuse relay zone between the Aden Rift and the Red Sea Rift.

The new data support observations (unpublished) made during earlier cruises by Boucarut *et al.* Their complete tectono-bathymetric chart of the Gulf of Tadjoura shows that the Maskali–Obock trough and the Tadjoura trough are located on either side of a subcontinuous tectonic lineament (major fault zone), running ENE–WSW (N 60°) from 43°20 to 43°. Both troughs are delineated either by ENE–WSW, NW–SE, or EW fault zones, which form some important (Recent) submarine cliffs. Moreover, the presence of active (NW trending) extensional fault zones, some of them crossing the Gulf and cropping out on both sides[2], and of faulted Middle Pleistocene sediments in the Obock trough and on the northern side of the Gulf[3] had been mentioned.

Continuation of the major structures on land into the Gulf suggests that the Gulf floor is composed mainly of broken continental crust, separated by relatively narrow and irregular shaped rift zones filled with young volcanics[2].

The various orientations of the fault sets in the Gulf should be compared with those of the nearby land area, whose successive motions and combinations with volcanic occurrences during Plio-Pleistocene times are well known[4]. On land, the structural dominance of the 'Aden type' fractures (N 80°–100°) diminishes westwards: likewise, in the Gulf, it is taken over by that of the NW–SE and ENE–WSW faults. This explains the zigzag shape for the (supposed) boundary.

So, even if the platelet sketch for the central Afar has to be reviewed, various data indicate that the westwards tearing interpretation of the Gulf of Tadjoura[5–7] should not be eliminated.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 500 words and the briefest of replies, to the effect that a point is taken, should be considered.

nature

Europe runs before it walks

The European Commission threatens dire consequences if it is not given a bigger budget for research. But its case is fragile, at best

THE European Commission seems to be heading for a fruitless confrontation with its sponsors, the twelve governments now members of the European Communities. Although this will not be the first time that the Commission has been at loggerheads with the governments of which it is the titular servant, and although there will be general sympathy with the Commission's frustration at the slow pace of change in Europe, it is a pity that the Commission has picked on the research budget on which to do battle. The difficulty is that the Commission is talking as if it might tell member governments that if it cannot have $8,000 million (over five years) to spend on its "framework programme" of largely applied research, it will let the European research enterprise go hang (see *Nature* **324**, 291; 1986). European researchers will be the chief losers, but the Commission's own European ideals will also take a bashing. The best hope now is that the Commission is merely bluffing. Otherwise, it should think again.

The nature of the row is best understood and is only understandable in terms of the Commission's own constitution. Those who wrote the Treaty of Rome which legitimized the European Economic Community and Euratom (there was previously the Iron, Steel and Coal Community) believed that their ultimate goal of a united Europe would come about only as member governments were given proof that Europe would work in small ways. Ingeniously, the founding fathers legislated for a kind of government-in-waiting (the Commission) whose immediate function would be to formulate policies for approval by member governments. In the short run (which is now), the Commission would propose and member governments would dispose, by the agency of what is called the European Council. But in the long run, the calculation ran, member governments would be so content with the developing idea of Europe that they would cede more and more executive power to the Commission and would use the European Parliament as a common legislative body that would also breathe down the Commission's neck. This dream is still a very long way from fruition. The Commission, understandably, is frustrated at being kept a dogsbody for quarrelsome governments, and this frustration has now spilled over onto its policy for research.

Discontents

If discontent with the snail's pace of change were the only touchstone, the Commission would be surrounded by friends. One prominent companion in discontent, but not necessarily an ally, is President François Mitterrand of France, who has been pressing for the past five years for more technical collaboration within Europe and, for the past eighteen months, for a substantial move towards European integration on a wider front. The Commission now seems to regard President Mitterrand's more recent initiative as a licence for insisting that member governments must at last be forced to collaborate on something, and has picked out research. For the time being, it seems prepared to overlook the more glaring of the defects of its enabling treaty — the assumption that little would happen in foreign affairs where, in the event, members' interests most often coincide and the legal provisions that compel collaboration in agriculture to the great cost of European consumers and cheaper food producers elsewhere in the world. Two-thirds of Europe's energy in the past 30 years, and a great deal of mutual recrimination among the Communities' members, have been occasioned by the unkeepable promise to 1950s' farmers that they would be protected from the discomforts of clearly impending technical change. The Commission knows (it has tried) that reforming the Common Agricultural Policy would do more to liberate European energies than a coordinated policy on applied research, however well conceived the programme. Yet the Commission is so exercised about the budget for its framework programme that M. Jacques Delors has thrown his reputation behind the campaign for $8,000 million.

Misunderstanding

The Commission's pitch for a larger research programme would be more telling if its record on the conduct of scientific affairs were more convincing. Unfortunately, its record is poor, to say the best of it. Throughout the long argument on regulations on environmental pollution in the 1970s, the Commission too obdurately clung to the notion that pollution must be controlled by emission standards, so as to be fair to manufacturers of the same kind wherever they might be located, and obscurantistly resistant to the notion that what matters is the degree to which the environment is polluted. On many occasions, it seemed that the difficulty was the Commission's failure to understand the difference. More recently, the Commission has been responsible for two quite shocking assaults on good sense in its handling of essentially technical issues. Thus, in the days after the nuclear accident at Chernobyl in April, the Commission hurriedly organized a meeting to agree on common standards of when it would be prudent to ban radioactively contaminated food and concluded that food should not be sold with more than 1,000 Bq per kg—a standard roughly an order of magnitude more stringent than necessary. Worse still, the Commission has decided to use its powers for the regulation of agricultural produce to ban the use by European farmers of natural growth hormones (bovine growth hormone, perhaps manufactured synthetically, to make more beef, for example). It is generally agreed that such a practice would damage consumers, the people who might eat meat grown in such a way. The Commission's motives have simply been to restrict the embarrassing productivity of European farmers. When the ban was declared (it comes into effect this month) the commissioner responsible for agriculture said that there were occasions when "politics must take precedence over science". Is that the kind of organization to which people will willingly entrust $8,000 million for research?

The Commission will no doubt complain that these administrative matters have nothing to do with its reputation for the conduct of research, but even that is only half true. In its administration of the Communities' four research centres, the Commission has been over-sensitive to political (especially Italian) objections to the suggestion that some of them might be closed. The Commission's sponsorship of fusion research, on the other hand, is admirable. There is no suggestion that the major programmes in applied science have been tainted by political considerations, but the most interesting of them, that called ESPRIT (where the last two characters stand for information technology) is too young for its benefits to be properly evaluated and costed. Most probably, the Commission is right to think that there are good works it might perform in fields like this, but little would be lost and much might be gained if it set out to foster collaboration in research with much more deliberation.

This is not to say that the Commission must forever drag its feet on research. Curiously, there are many causes that the Commission has itself in the past espoused that could benefit from encouragement — and a little money. Only three weeks ago, the annual general assembly of the European Science Foundation was wringing its hands over the poverty of its plan to build 'networks' of European scientists, ironically stimulated by a study sponsored by the Commission a few years ago. The Commission could also usefully (as it may yet) listen to appeals such as that from the group of European radioastronomers who seek a modest 16 million European Currency Units (roughly £11.4 million) over five years to establish a centre for the analysis of data gathered during very-long baseline measurements. Such projects are not, of course, alternatives to a programme of applied research, but the fact that they go begging is a sign that the Commission has not yet begun to work effectively on the common ground where success would come most easily and bring the greatest benefits — the effective integration of the technical community without which a common research enterprise will have little purpose. □

Licensing the spooks

The British and US governments are both embarrassed by the doings of their undercover people.

WHO would have known, until the British government's attempt to prevent in the Australian courts the publication of a book on its security service that Lord Rothschild, the embryologist and merchant banker, was once a member of that same service, called MI5? This is nevertheless what has emerged from the embarrassing (for the British government) disclosure that Rothschild acted as the intermediary in bringing together Mr Peter Wright, once also a member of MI5 and now living in Australia, and Mr Chapman Pincher, who published a racy account of Wright's tale three years ago. Few will think the worse of Rothschild now; some will now put him in the same daredevil category as Colonel Oliver North, the staff member of the US National Security Agency dismissed last week for alleged gun-running (to Iran) and now described by President Reagan as a national hero.

Popular heroics apart, there is nevertheless a case for believing that spying and spy-catching have got out of hand. Every few months, there seems to be either a serious international incident or a serious domestic crisis in some major capital because of spooky doings (Auckland Harbour, for example). Then there are retaliations (the name of Daniloff refers). The obvious difficulty is that espionage and counter-espionage are unregulated. The obvious solution is that governments employing secret agents should be required to register all salaried agents' identities with an international authority, which would keep the information secret unless asked by the registrant to disclose it (perhaps secretly) to a third party. That way, it would be possible for governments more easily to arrange swaps for agents or even to find out whether people arrested in foreign capitals were in their employ or were merely innocent visitors. By becoming licensed in this way, secret agents would be able to trade self-esteem for the dare-devilry that now sustains them, and would be less inclined to write their memoirs. So long as the international authority were not itself penetrated by agents, the whole business would be made less serious a threat to international good relations; international spy crises might, for example, be defused by mutual consent. Would not such a scheme be worth a trial? □

Action against AIDS

Governments are moving quickly on publicity about AIDS; should they be doing more?

BOTH the British and the French governments have responded well to the latest alarm about the spread of AIDS (acquired immune deficiency syndrome). In both countries, the governments have decided that public education must take precedence in any serious attempt to break the chain of infection by the virus. Plainly that makes sense. Unless people know which features of their personal behaviour expose them to the risk of infection, their self-interest will not coincide with the needs of programmes of public health aimed at averting what could be a cataclysmic infection. One of the several haunting aspects of the problem is that there remain so many features of the natural history of AIDS that are, as yet, unknown. It is not yet known when and for how long, in the course of an infection, a person is capable of infecting others. Whether all those infected, or only a proportion of them, eventually develop AIDS, is another imponderable for the time being. Little is known about the relative risks of transmission in different sexual acts. The case for acting now is that, if all the answers to such questions were gloomy, large proportions of us or our successors would be killed.

It is a pity that young people, at the beginning of their sexual lives, must be the chief targets of public education, but that, too, makes sense; it is not, as usually the case, that young people are especially deserving of consideration (true though that remains) but that they could be especially effective agents for the transmission of a socially damaging and usually venereal disease. To say the least, a young person, during the remainder of his or her lifetime, will on the average have more sexual partners than an older person and will therefore, on the average, be a potential source of infection for a greater number of people. It is also possible that some young people may be unusually promiscuous. To their credit, both governments appear to have faced this part of the problem that confronts them squarely. The British government, with its reputation for being careful about money, has surprised its taxpayers by deciding to spend twice the sum it first thought of (£20 rather than £10 million) on immediate publicity. The French government is wisely emphasizing the need that people should have a ready opportunity of a test for antibodies.

None of this, unfortunately, will throw light on the present incidence of the infection (as distinct from the disease it may ultimately cause). Those who voluntarily seek an antibody test will often be people who suspect they may have run a particular risk. The routine testing of blood offered at transfusion clinics may similarly, as in the United States, be biased by people's recognition that a blood transfusion is the most convenient way of being tested. That is why some means of random testing would, in present circumstances, be beneficial; it would then be possible to tell objectively how great is the present pool of infection, a necessary starting point in estimating more accurately the rate at which infected people progress to overt disease. Schemes for the anonymous testing of pregnant women at antenatal clinics have similarly been advocated as ways of monitoring the spread of AIDS through heterosexual intercourse. The snag is that, in these enlightened days, it is unethical for physicians to test a person's blood without telling him or her what is afoot, whereupon it would be unethical not to disclose the results. The result is that information that would be invaluable for an assessment of the present problem, and which could be collected easily, is not available. The reasons for this self-denial are admirable, but the outcome is ignorance on an important point. If the AIDS problem becomes more serious, societies will find themselves considering a variety of illiberal measures to protect themselves against the pool of those infected; on the face of things, anonymous testing whose results are not disclosed might be a lesser evil that should be more quickly allowed. □

French universities

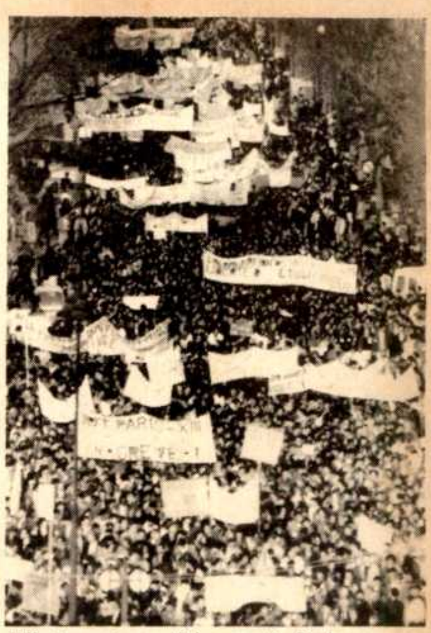
Student protests succeed in postponing new law

For 1986 read 1968 — the year of revolution in French universities which led finally to the resignation of General de Gaulle as President of France. Last week, more than half a million French students and schoolchildren were on the streets to protest against a new law for the universities which, students claim, will tighten up entry requirements, reverse the right of free entry to universities that was won so bitterly by, in many cases, the demonstrators' parents nearly 20 years earlier. Right-wing Prime Minister Jacques Chirac, who dealt with the events in 1968 as a protégé of de Gaulle's prime minister and later president, Georges Pompidou, this time had no stomach for a fight. He told his minister for the universities and research, Alain Devaquet to withdraw the bill for revision.

Resignations do not seem to be in order this time, however. Chirac is not going to see the fall of himself or his government over the issue when the national budget and the economy is his main theme; and the socialist President, François Mitterrand, who might be contending with Chirac in the presidential elections of 1988 and had no involvement in the preparation of the bill, must be laughing up his sleeve. Furthermore, Devaquet, whose law was a compromise between various pressure groups, is said to have many sympathies with the students, and may see the demonstrations as giving weight to his own position. The losers so far in the battle would appear to be *'les emigrés'*, that group of university staff which was silent, or powerless, during the previous socialist administration but which now that a right-wing government is in power has been calling for much greater power for the university professors in France, both in the selection of students and over the control of research funds. In the latter case this would have entailed the dismemberment of the French national research council, CNRS, a battle the *emigrés* recently lost; now, it seems, their battle for more control over their students, 40 per cent of whom leave after one year in university, has also gone against them.

There is thus a good deal of despondency among the rightist camps in French universities this week — if this government cannot help them none can. On the other hand, French natural scientists, who number few of the *emigrés* among them, are more cheerful. Many deplored yet another attempt to reform the universities, and most thought the new bill's efforts to divide departments into single-subject faculties retrogressive, likely to reduce interdisciplinary research and to recreate the pre-1968 professional fiefdoms.

Another common complaint of researchers about the new bill was that it threw away the fledgling French PhD, just two years old, to put back the old system of multiple theses and doctorates of various levels which was incompatible with research qualifications outside France and reduced international mobility. The bill before parliament last week, which resulted in the student demonstrations, had been improved in this respect by amendments in the French Senate, but many researchers are still unhappy.



Associated Press.

Effective yet peaceful protest in Paris.

ADEMAST, the Association Nationale Pour le Développment et la Maîtrise des Sciences et des Techniques, an association of scientists that grew up after the epoch-making 1982 national colloquium on science and technology in Paris has also strongly criticized the bill, now withdrawn after the protest. In a report published just before last week's demonstrations, ADEMAST admitted deficiencies in the universities but rejected the constant politicization of university reform.

Governments "must work with what exists" rather than attempt in each parliament to recreate the universities anew, said the scientists' associates. And it gave a strong endorsement to the system of multiannual contracts, by which the ministry of education in the previous administration was guaranteeing extra funds to universities.

These funds were available only to establishments which put in place a serious research and training policy to meet local and national needs. These multiannual contracts changed the distribution of university funds from what had been uniform "sprinkling" to real selectivity, the association claimed. But the new bill appeared to be weakening this kind of selection rather than strengthening it.

The scientists' association recommends the creation of an agency to distribute university funds selectively. The agency would be indepedent of the ministry, and similar to the British University Grants Committee; but again the new law moved in the opposite direction in the name of autonomy. According to ADEMAST members, French universities are still immature after the revolution of 1968; and the new law would have led to a mere counter-revolution rather than an improvement. Whether any changes at all will now occur is yet to be seen.

Robert Walgate

Hermes to win approval soon?

Britain's space industry was earlier this weeks still awaiting government approval of a proposed multimillion dollar contribution to the European space shuttle project, Hermes. The approval, due last Monday (1 December), is for about 10 per cent, or $4 million, for the first phase of the space project. The preparatory phase, which began in the autumn and will take a year to complete, will cost $40 million. The complete programme, geared to a launch in 1995–96, will cost $1,200 million, of which France and West Germany will provide 39 and 30 per cent, respectively.

But a great deal of research is needed in the preparatory phase to tell how companies with expertise in space technology will benefit. Nearly 30 submissions on how the technology can be advanced and exploited are with the European Space Agency, which is coordinating the project.

The British National Space Centre, formed about a year ago to coordinate the British space effort, awaits a response from the government to its 15-year plan, which includes the Hermes project. The centre wants an early decision so that preparations can be made for a ministerial meeting of agency members next June.

The Hermes is a space aeroplane to be launched aboard the new European rocket Ariane V, which will be ready for its first flight in about 1994–95. The research on Hermes is expected to inspire applications in other military and civil aviation fields. New types of wings and flight systems would be two possible areas of research.

Bill Johnstone

Chemical weapons

Study reflects Atlantic divisions

Washington

EUROPEAN and US perceptions of the value of North Atlantic Treaty Organization (NATO) chemical weapons are still very much at odds, to judge from a new joint study* by independent strategists. The Aspen Strategy Group in the United States and the European Strategy Group failed to find common ground on the key question of whether NATO's policy of modernizing chemical weapons while removing them from Europe is justifiable. And both are pessimistic about a total ban.

Chemical weapons remain a source of deep divisions within the NATO alliance; although European countries want a treaty banning them, the United States is keen to preserve the chemical option as a means of countering Soviet first use and to decrease reliance on nuclear weapons.

Under NATO rules of engagement, chemical weapons would be used only if Warsaw Pact countries used them first. The Soviet Union has more advanced chemical capabilities than NATO, and opinions differ over their importance to Soviet war plans.

The Aspen/European study believes that chemical weapons are probably not a Soviet "weapon of choice". But it could not agree on the wisdom of the planned modernization of the NATO chemical weapons stockpile.

Many, not least the US government's General Accounting Office, have serious reservations about the likely usefulness of the 'Bigeye' binary chemical bomb now being developed (see *Nature* **321**, 717; 1986). Binary weapons are in principle safer than the single-agent weapons now in storage, because two relatively non-toxic agents do not become lethal until mixed during flight. But the Bigeye has had severe technical problems.

Unable to reach joint agreement on NATO strategy, the Aspen/European study settled instead on the face-saving formula that chemical weapons should not be a cause of alliance disunity in deterring conventional or nuclear war in Europe. The group almost tries to have it both ways by saying there is no justification for NATO acquiring a large-scale chemical war-fighting capability, but also that few believe NATO policy should allow nuclear deterrence to be the only means of deterring possible Soviet use.

The compromise seems to be that a small offensive capability would be prudent, which is what NATO has. Given that, the group could find no rational reason for removing them from Europe to the United States. The NATO plan to airlift chemical weapons across the Atlantic in a time of crisis is seen by the group as substantially limiting their deterrent value; the logistical burden in a military crisis would be very substantial.

Negotiations for a comprehensive chemical weapons ban have been in progress for nine years, with little sign yet of agreement. Verification is, of course, the stumbling block, with the United States and the Soviet Union deadlocked mainly over the question of on-site inspections.

The Soviet Union has accepted the principle that destruction of chemical weapons stocks should be monitored continually by on-site inspectors, and appears to be moving towards accepting the need for a quota of on-site inspections to verify compliance. But the United States recently hardened its position, arguing the need for a short notice (48-hour) mandatory challenge procedure.

The Soviets so far reject anything but voluntary inspections, although there is a British proposal that might break the deadlock. Under the proposal, an on-site inspection could be legally refused if the accused party provided evidence that the inspection was unjustified. The proposal fails, however, to specify the type and standard of "evidence of innocence" that would suffice. **Tim Beardsley**

* *Chemical Weapons and Western Security Policy*, Aspen Strategy Group and European Strategy Group, 1986.

National Science Foundation

New centres for biotechnology

Washington

THE US National Science Foundation (NSF) plans to spend more money on shared instrumentation and multidisciplinary basic research related to biotechnology. The new programme has two strands — facilities centres to be set up in 1987 and research centres to follow a year later.

Eight million dollars have been appropriated for the development of multi-user instrumentation facilities, or 'mini-centres', in 1987. The foundation expects to make 10–15 two-year awards averaging $500,000 each for these centres, which are being developed to meet the demands of the "consistent lobby of people [doing basic biological research] who need access to sophisticated instruments for less than full-time use", according to Thomas Quarles at NSF.

The instruments NSF has in mind include costly items such as DNA or protein synthesizers, peptide sequencers and the new nucleotide sequencers developed earlier this year. Prices vary, with the DNA machines costing between $30,000 and $90,000, and the peptide machines ranging between $85,000 and $160,000. These prices are prohibitive for many research laboratories, especially if they need the machines only occasionally.

The instrumentation sharing programme has two objectives. The first is to maximize the return on investment by attempting to ensure nearly full-time use of expensive equipment by combined groups of researchers. The second is to stimulate multidisciplinary exchanges through the common use of equipment.

The centres are not, however, designed to be regional facilities located equidistant from the researchers who will use the instruments. David Kingsbury, the assistant director for the directorate administering the programme at NSF, says he sees the instrumentation awards in 1987 going to single departments or groups of investigators in one area.

According to Kingsbury, the success of previous regional shared instrumentation centres has been mixed, depending on the users' location. Often, the institution physically housing the equipment has received the greatest benefit, with little regular sharing with researchers elsewhere. To qualify for support under the research centre scheme in 1988, laboratories will need to demonstrate the quality of their research programme as well as their need for equipment. The aim is to encourage people from various disciplines to work together on important problems in biotechnology. The money is expected to establish, modify or support existing multidisciplinary biological research centres, and the grants will be structured to fill gaps not financed by industry, universities or other government entities.

Kingsbury expects "everyone under the Sun" to apply for the research centre grants, and foresees joint proposals from, for example, ecologists and microbiologists and from chemists and biologists. These awards will depend on the treatment by Congress of the NSF budget for 1988, not yet published, but may be as large as $2–4 million per centre.

NSF says that it has no preconceptions of the topics these centres should deal with except that they should be within the field of biotechnology and should not be related to diseases or the development of drugs, which are the responsibility of other agencies.

Proposals for the 1987 facilities centres are due by 1 April 1987, and those for the 1988 research centres by 1 August 1987. Awards will be made after the deciding panel meets in May or June. James Brown, the division director at NSF, says it will be "nip and tuck" to make the facilities awards within the 1987 fiscal year, which ends next September. **Carol Ezzell**

Telecommunications

Fight for Japanese network

Tokyo

As Tokyo is one of the three principal financial centres of the world and growing the world's telecommunications giants are fighting to plug their cables into Japan. But an attempt by Britain's Cable and Wirelss to tap Japan's lucrative international telecommunications market has met with a solid wall of resistance.

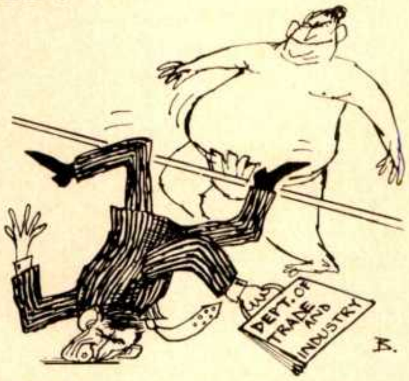
Following last year's liberalization of Japan's telecommunications law, a consortium headed by Cable and Wireless and C. Itoh, a major Japanese trading house, declared its intention to set up an international telecommunications company that would break the monopoly held by Kokusai Denshin Denva (KDD).

But Mitsubishi Corporation, Mitsui and Co. and Sumitomo Corporation beat the C. Itoh/Cable and Wireless consortium to establish a feasibility study company, International Telecom Japan (ITJ), in July (see *Nature* **321**, 803; 1986).

Whereas ITJ plans to follow established telecommunications routes — Intelstat satellites and a submarine trans-Pacific cable (TPC-3) due to be laid by KDD and American Telephone and Telegraph in 1988 — the C. Itoh/Cable and Wireless group was expected to link up with Cable and Wireless' global digital highway, a network of submarine and transcontinental optical fibre cables connecting Western Europe, the United States and the Far East. But there has been strong opposition to the C. Itoh/Cable and Wireless plan.

Both the Ministry of Post and Telecommunications and KDD maintain that there is not enough room for a third company, and KDD says there is no need for an extra trans-Pacific submarine cable. But the most conservative estimates of Japan's international telecommunications market forecast a tripling in size to Y600,000 million (£2,600 million) by the mid-1990s.

Taking heed of the ministry's pronouncements, the C. Itoh/Cable and Wireless group approached the major shareholders of ITJ in October and suggested a merger but their offer was turned down. And in mid-November the group formed International Digital Communications Planning Co. (IDC) with Cable and Wireless and C. Itoh the major shareholders. No sooner had staff set up its new office than Japan's minister of Post and Telecommunications, Shunjiro Karasawa, let drop a bombshell. In discussions with British Trade Secretary Paul Channon last week, Karasawa announced that although Cable and Wireless could keep its 20 per cent share in IDC (under Japanese law a foreign company can hold up to 33 per cent of a telecommunications company), the British company would be barred from management decisions "because international communications are relevant to national security in emergency situations" and thus a foreign company could not have an influential voice or power in a "second KDD".



DEPT. OF TRADE AND INDUSTRY
B.

With ITJ expected to apply for a licence from the Ministry of Post and Telecommunications by the end of this month, Karasawa's statement could not have come at a worse time for IDC. And although one of IDC's managing directors insists that the matter is by no means closed, he also emphasized that Cable and Wireless's trans-Pacific cable is only one of the options currently under consideration by his company. **David Swinbanks**

India creates biosphere reserve

Bangalore

INDIA's first biosphere reserve, patterned after the guidelines in UNESCO's Man and Biosphere Programme, has been inaugurated at Nilgiris in South India, one of twelve biosphere reserves suggested by the Department of Environment (DOE).

It covers an area of 5,520 km^2 comprising the famous Silent Valley, a region with 1,500 plant species and virgin forests of western ghats spanning the states of Kerala, Tamil Nadu and Karnataka. The Nilgiris biosphere reserve, classified as a Malabar rain forest, includes 2,020 km^2 of minimally disturbed forests in which about 20 tribal groups have been identified.

The reserve is cooperatively managed by the three states under existing state and central legislation on conservation and preservation of forests, wildlife and environment. India has 53 national parks and 247 wildlife sanctuaries covering 100,000 km^2.

According to Mr Z.A. Ansari, Union Minister of State for Environment, a comprehensive national conservation strategy is being formulated and steps are being taken to improve the living conditions of tribals in the biosphere reserves.

Radhakrishna Rao

Hepatitis B

Cheap vaccine for wide use?

Washington

AN international "task force on Hepatitis B immunization" has announced plans to use a new vaccine costing as little as $1 per dose in mass immunization demonstration projects in four developing countries. The nine-member task force, which includes several recognized authorities on the disease, aims to convince governments of countries where the disease is endemic that mass immunization, previously considered too expensive, is economically feasible.

Hepatitis B is most common in Asian countries. It causes 80 per cent of the world's liver cancer, and may be second only to tobacco as a cause of world cancer mortality, acccording to one task force member, Dr Richard Mahoney. As little as a year ago, a dose of vaccine cost $30, with three doses needed for a protective course, but Cheil Sugar and Company of Korea has now undertaken to produce it for $1.

The Cheil vaccine is of the conventional plasma-derived type and is made under licence from the New York Blood Center. The new process increases by a factor of ten the number of doses obtained for each cubic centimetre of starting plasma, by reducing the number of harsh purification steps and starting with more potent plasma. According to Dr Alfred Prince of the centre, another task force member, the vaccine has been tested in more than 1,000 volunteers for safety and immunogenicity, and long-term effectiveness trials are, at present, under way in several countries.

Demonstration programmes will be mounted in Indonesia, Thailand, Brazil and one African country. Over three years the group expects to vaccinate 1.2 million newborn babies. Vaccinating babies is most effective because those infected before the age of three are far more likely than others to become infectious carriers.

The task force includes members coordinated by a non-profit organization, Program for Appropriate Technology in Health, which will also help governments and international organizations to implement their own programmes.

Costs for the three-year demonstration programme are estimated at $12.5 million; a substantial part has already been promised by charitable foundations, and the health programme is "confident" that the remainder will be found.

US biotechnology

Research centre gets fixed home

Washington

ON an unseasonably cold, blustery day last month in the Washington suburb of Rockville, the proud parents of the Center for Advanced Research in Biotechnology (CARB) held a ceremonial groundbreaking of what will some day be CARB's new home. A joint venture of the National Bureau of Standards, the University of Maryland and the local county government. CARB will focus initially on protein engineering and rational drug design.

For now, CARB is housed in temporary quarters in Gaithersburg, Maryland, on the campus of the Bureau of Standards. CARB director Kevin Ulmer says the centre will take advantage of the bureau's expertise in fine measurement technologies, essential to making detailed protein structural determinations. The bureau also possesses a CYBER 205 supercomputer needed to make calculations for modelling of atomic interactions in protein molecules. Ulmer says that CARB will provide the bureau with a window into biotechnology, an area in which it has not traditionally had a very large presence.

For the University of Maryland, CARB is only one aspect of a major thrust in the realm of biotechnology. The Maryland Biotechnology Institute includes centres devoted to marine biotechnology, agricultural, medical and ethical aspects of biotechnology in addition to CARB. The university's 1987 budget allots $5.6 million to these institutes, including provision for 75 full-time positions. Rita Colwell, university vice president for academic affairs, says Maryland is a logical place to house these centres, because the 50-mile corridor between Washington and Baltimore is rich in biotechnology companies and government research laboratories.

Montgomery County, where CARB is located, is also trying to take advantage of the population characteristics of the Baltimore–Washington corridor. The county has created the Shady Grove Life Sciences Center, and is providing funds and space to both the University of Maryland (50 acres) and John Hopkins University (35 acres) for new campuses, has begun work on what will be a teaching facility for high-technology graduate programmes, and the University of Maryland has begun CARB. County officials say the idea is to compete with the San Francisco Bay area and the Boston area for biotechnology companies. Montgomery County is home for the National Institutes of Health, the National Bureau of Standards and the Food and Drug Administration. Some four dozen biotechnology companies have already located in the county.

CARB's major initial thrust — protein structure — has in just the past two years been an area of intense interest. Thomas Steitz of Yale University calls the resurgance of structural biology "spectacular". Steitz attributes the renewed interest to strides in molecular biology that have provided large quantities of molecules of interest for study. Ability to perform site-directed mutagenesis has spurred efforts to derive a theoretical understanding of how DNA sequence changes would affect the structure of the resulting protein.

But the increased interest in structural biology means that CARB will face stiff competition for personnel and funds. CARB has offered positions to seven scientists to form its senior staff, but so far only one has accepted. Ulmer admits it is hard to persuade industry to enter collaborative projects without a full staff on board. The National Bureau of Standards and the University of Maryland will together provide CARB with about $3 million annually, but Ulmer hopes to increase that figure several-fold through contracts and grants from both government and industry.

Raymond Salemme, who directs Du Pont's efforts in protein structure, says

Information technology

New institute

FINAL preparations are being made for the opening of Britain's first higher education institute devoted to the research and teaching of information technology (IT), the marriage of telecommunication and computer disciplines, supported entirely by industry and by its users.

The new institute, to be based in Milton Keynes in Buckinghamshire just north of London, has been possible through an initial tranche of £3.5 million from more than 25 companies in the IT field, in an attempt to reduce the growing shortage of IT skills in the United Kingdom.

The institute has been created in partnership with the Cranfield Institute of Technology in Bedfordshire, whose vice-chancellor, Sir Henry Chilver, has been the chief driving force behind the project.

The institute is a new dimension in British higher education and one that has provoked detectable hostility from some in established academic institutions who suspect that industrially-funded education, the preference of the Prime Minister Mrs Margaret Thatcher, will undermine the already shaky finances of the British educational establishment.

Supporters of the institute, however, consider that its curriculum will be more appropriate to the needs of an industry already desperately short of key skills, and that its existence will lighten the burden now falling on traditional education institutions, which have been unable to satisfy the appetite of industry.

The future of the institute will depend on whether it proves to be commercially viable, which is reflected in the management structure. A managing director, Dr Allan J. Fox, reporting to a board, replaces the conventional hierarchy of vice-chancellor and senate. Fox was previously deputy director (applied physics) at the Royal Signals and Radar Establishment at Malvern.

Initial areas of research are to include software engineering, parallel processing, artificial intelligence in computers and the communications of computers linked through networks. **Bill Johnstone**

Alaskan environment

Long row ahead

Washington

THE first salvo in what is likely to be the major energy debate of 1987 was fired last week when the Department of the Interior recommended leasing 1.5 million acres of the Arctic National Wildlife Refuge in Alaska for oil and gas exploration. The government believes the land lying along the northern Alaska coast could be "the most outstanding oil and gas frontier in North America". But environmental groups call the same land a unique treasure house of wildlife, and doubt whether the area can be developed without severe ecological disruption.

Since 1980, when Congress set aside 17.9 million acres of Alaskan land for a wildlife refuge, the government has been struggling over what to do about its coastal plain. Environmental groups wanted the land declared a national wilderness, putting it off limits for oil and gas exploration. But the Interior Department's report proposes a full leasing plan, arguing that industry can conduct its operation in a way that will minimize environmental damage.

The report argues that the national need for oil and gas makes development of the coastal plain essential. A 150-mile pipeline would carry oil from the eastern boundary of the coastal plain to the head of the trans-Alaska pipeline at Prudhoe Bay.

Alaskan politicians are enthusiastic about the Interior Department's plans. The Alaskan economy is in the doldrums. The government's report maintains that oil exploration in the coastal plain will reduce US dependence on foreign oil, enhance national security and bring a more favourable balance of trade.

The coastal plain is inhabited by a wide variety of fauna, including bears, polar bears, musk oxen, foxes, sheep and migratory birds. But development will have the greatest impact on the Porcupine herd of some 180,000 migratory caribou. Appromost industries have been disinclined to contract with start-up operations, choosing instead to launch in-house divisions. Salemme believes the interest now being shown by the Howard Hughes Medical Institute in structural biology will create academic laboratories that will compete with CARB.

Interest in protein structure is not limited to the United States. Japan has created the Protein Engineering Research Institute that Ulmer says will have an annual budget of $10 million. In Europe, John Tooze of the European Molecular Biology Organization says that more attention will be directed towards structural work at his facility. **Joseph Palca**

---

on oil leases

ximately 272,000 acres, or 78 per cent, of the herd's core calving area lies within the section of the refuge proposed for leasing. The report acknowledges that the impact on caribou number is "uncertain" even if care is taken to avoid disrupting the herd's movements. The report cites successful industry wildlife management at nearby Prudhoe Bay as evidence that the caribou population will not be decimated.

But Susan Alexander of the Wilderness Society says the experience at Prudhoe Bay is not relevant to the coastal plain. She argues that the principal herd at Prudhoe Bay, the Central Arctic herd, is resident, whereas the Porcupine herd is migratory. The Porcupine herd is also much larger than the Central herd but has a relatively small core calving area. Both factors, Alexander says, make the Porcupine much more susceptible to environmental change. Although assistant Interior secretary William Horn has proposed leasing the calving area last, Alexander says the damage will already be done if leasing is permitted on the range.

There is a 60-day public comment period for the report that expires on 23 January, after which it will go to Congress, sometime in the spring. Congress must approve the plan, and will probably hold its own hearings.

Representative Morris Udall (Democrat, Arizona) is likely to reintroduce legislation that would convert the land from wildlife refuge to wilderness, forestalling energy exploration. Similar legislation died earlier this year. As chairman of the Interior committee, Udall will have a powerful voice in the ultimate disposition of the land.

Alexander says a "suck-America-dry-first" policy is folly, because even Alaskan oil reserves will run out eventually. The coastal plain is a unique place, she says, one "we can afford to leave until the end". **Joseph Palca**

Laboratory fraud

Another damned by publications

San Diego

THE University of California is still trying to pick up the pieces after what appears to have been an extensive scientific fraud which has left the medical school at the campus here (UCSD) severely shaken. Although the case has nothing in common with that which came to light two weeks ago at the Dana-Farber Cancer Institute of the Harvard Medical School (see *Nature* **324**, 197; 1986), scientists are asking if the two cases may have been caused by pressure on investigators to publish.

The now-published report of the university's investigating committee, chaired by thoracic surgeon Richard Peters, into the San Diego fraud has revealed that as many as 68 papers published by former UCSD cardiologist Robert A. Slutsky must be considered questionable. Some of them contain fabricated data.

One of the distinctive features of the Slutsky case is Slutsky's use of what the committee calls "gift authorships", the practice of listing as co-authors colleagues who had made little or no contribution to the work, who could not vouch for its accuracy and who, in some cases, were not aware that their names had been used until the papers carrying them had been submitted for publication.

According to the committee, in the period 1983–84 Slutsky (then 37) was averaging one published paper every 10 days. The committee notes that this pace of publication went unremarked.

Although some of the co-authors were at the outset unaware of the 'gift' of co-authorship, the committee says that others questioned during its year-long investigation freely admitted to the practice of listing as co-authors senior scientists who had contributed nothing more than equipment or laboratory space to the work reported. This practice, it says, is "commonplace and condoned".

As a remedy, the committee recommends that each university department should take responsibility for specifiying the participation of each faculty author in the work described in every paper submitted for publication. It says that co-authors should be responsible for reviewing all manuscripts carrying their names and should be able to vouch for the accuracy of the work. During the investigation, the committee says, it summoned Slutsky's co-authors to defend the papers on which their names appeared, but some of those concerned objected. Peters says that the notion of "innocent until proven guilty" does not apply in science.

Peters also says that the problems at the San Diego medical school could and should have been discovered earlier. The failure, he says, is less in the research enterprise than in the senior scientists who lead it. Paul Friedman, the medical school's dean for academic affairs, said that some of Slutsky's colleagues had been suspicious of the quality of his work but that they "were simply bowled over by his energy, his enthusiasm and the size of his bibliography".

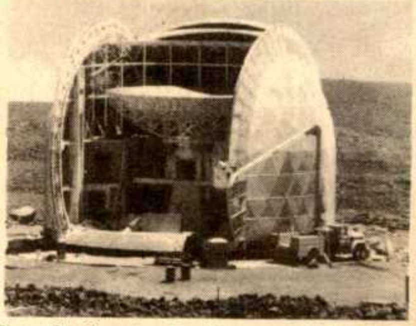
Slutsky's fabrications were apparently uncovered when he was being considered for possible promotion. Radiologist Elliot Lasser set two Slutsky papers side by side and noticed that, in two overlapping data tables dealing with control animals, the numbers of animals were different but the standard deviations were identical.

In retrospect, it has emerged that Slutsky's earlier work shows small discrepancies, as when the same data have been reused or the statistical significance of a result exaggerated. In the end, says Friedman, it emerged that the experiments simply had not been done.

Friedman says that Slutsky was caught because he did not understand statistics, and that he had survived for so long only because journals' reviewers also lack statistical expertise. Slutsky seems to have been successful because he stuck to experiments that he knew would work.

But Slutsky regularly ignored requests for supporting data, for which reason Friedman suggests that the retention of raw data should be a university requirement. He also says that young researchers should be given an estimate of what would be a realistic output of publications.

Friedman is concerned that Slutsky's unsound papers may be only the tip of an iceberg. He says that only the blatant fabrications are usually caught, so that nobody knows how many more cautious investigators cook their data in ways that escape detection. He says that the familiar use of expressions such as "dry-labbing" suggests that fraud is "not an extremely rare phenomenon" **Robert Locke**



THE California Institute of Technology (Caltech) Submillimeter Observatory (shown during construction), a 10.4 metre dish that will operate at wavelengths down to 200 micrometres, was dedicated on 22 November on Mauna Kea, Hawaii. ☐

Science teachers

British attempt solutions

The shortage of teachers of science, technology and mathematics in British schools prompted last week a string of proposed remedies, including the appointment of retired engineers and scientists to teaching posts, dropping the entrance requirements of universities and increasing the pool of supply teachers.

These proposals emerged at a conference in London, where representatives from 51 universities, polytechnics and colleges responded to the British government's consultation document on the shortage of specialized teachers. The government paper, *Action on Teacher Supply in Mathematics, Physics and Technology*, published in August, took the gloomy view that the present crisis will deepen as a technologically based society demands more from its workforce.

Britain needs more than 2,500 physics teachers alone to make up the shortfall, claims the Association of Science Education. At least 20 per cent of physics teaching is done by the unqualified. It is the same in mathematics and technology, where nearly a third of mathematics and a half of technology teachers are inadequately trained.

A statement signed by the universities, polytechnics and colleges says that "shortages of well qualified mathematicians, physicists, computer specialists, engineers and technologists are acting as a brake on economic growth, pushing up pay above the level of inflation and sucking the best staff out of teaching jobs in schools and higher education." The situation is aggravated by very few students applying for courses in these subjects.

The University Grants Committee, which controls the purse strings of the British universities, suggested that universities should be able to lower their admission requirements for courses for teachers in mathematics and physics; £1 million will be available in 1987–88 "for increasing the supply of mathematics, physics and CDT teachers in schools".

The Treasury announced last week that companies who second professionally qualified employees to assist education will qualify for tax relief. Industrially based mathematicians, physicists and engineers near retirement age should be encouraged to retire early and switch to teaching, says the council. **Bill Johnstone**

- British teaching problems are but a reflection of those in the United States. Last week, 90 of 126 invited research universities joined the Holmes Group; while 25 rejected the invitation. The group calls for more graduate teachers and stronger links between schools and universities.

Biotechnology companies

One falters, another forms

Despite its recent successful sale of stock worth $40 million, Biogen, one of the first and best-known biotechnology companies, is not sitting pretty. Indeed, it has decided that it can no longer keep the Geneva end of the business going. Bryan Sautelle-Smith, managing director of Biogen SA in Geneva says that he is in discussion with a number of companies that might become joint partners in his company. The alternative is that Biogen SA is sold.

The financial results for the third quarter of 1986 illustrate the problem faced by Biogen NV, the parent company of both Biogen SA and Biogen Inc. in Cambridge, Massachusetts. Biogen NV has already accumulated a net loss of $20.5 million this year, having lost almost as much in the whole of 1985. Worse still, 1986 revenue so far amounts to only $8.5 million, half the figure of this time last year. Jim Vincent, who replaced Walter Gilbert as chief executive of Biogen just over a year ago and who is now also chairman of the company, says that the decline is mainly due to the scheduled end of payments from collaborators and to fluctuations in revenues from licensing agreements. Vincent is determined to break even as soon as possible and with few prospects of greatly increasing income in the immediate future his only option is drastically to cut costs.

Like most biotechnology companies, Biogen is faced with the fact that its revenues from sales are still small. It receives some income from the sale of hepatitis B core antigens for diagnostic test kits. And it is expecting to receive increasing royalty income from the sale of alpha interferon by the Schering Corporation, for which it developed the product. (Schering, like Monsanto, has recently sold its substantial shareholding in Biogen.) Alpha interferon received UK approval for use in hairy-cell leukaemia this year and is approved in some countries for use in the treatment of multiple myeloma and Kaposi's sarcoma, a condition often found in patients suffering from AIDS (acquired immune deficiency syndrome).

Hopes for increased sales revenue hinge in particular on the use of gamma interferon in the treatment of rheumatoid arthritis. Trials in West Germany are claimed to show its therapeutic value. Bioferon, a company jointly owned by Biogen SA and Rentschler Arzneimittel GmbH, is hoping soon to receive approval for the sale of gamma interferon for use in rheumatoid arthritis in West Germany where it has patent protection.

While Biogen savours the problems of adolescence, a new biotechnology company is launched this week in Britain. Rising like a phoenix from the ashes left behind when Monsanto decided to axe the UK laboratories of its subsidiary G.D. Searle almost a year ago, British Biotechnology Limited starts with £2.5 million venture capital, about twenty ex-Searle staff and more than a touch of patriotism.

Fundamental to the hopes of the new company, situated in Cowley on the outskirts of Oxford, is the expertise in gene synthesis built up at Searle. Most of modern biotechnology is built on the isolation of genes and their manipulation, but British Bio-technology will synthesize and assemble parts of genes from scratch, enabling the production of hybrid proteins designed to have improved therapeutic properties. Dr Brian Richards, chairman of the new company, says that he has been careful to ensure that the patents for specific aspects of gene synthesis held by Searle do not preclude the pursuit of the general approach. A more enterprising plan is to synthesize a variety of carbohydrate groups that can be attached to the proteins, again in the hope of improving their therapeutic value.

Collaboration with established pharmaceutical companies is the initial goal of British Bio-technology. Two major projects are under discussion. One is for a novel thrombolytic agent, produced via a synthetic gene. The other is for an enzyme inhibitor made by organic synthesis, the other general technique on which the company is founded. With the help of an advisory board that includes leading British experts on AIDS, the company will examine the design of drugs against the disease and antiviral agents in general. Arthritis and bone disease are two other major targets.

The initial £2.5 million, which buys 45 per cent of the company's shares, will support the growth to about 80 staff in the next 18 months or so. Apart from the additional income from contract research, British Bio-technology also expects considerable income from the sale of their synthetic genes and carbohydrates to customers in industrial and academic laboratories.

Both Richards and Dr Keith McCullagh, the company's chief executive, are keen to tap British expertise, not least around the corner at the University of Oxford, and are proud of the 'British' in the company's title. To use it, they had to satisfy the government-run Companies Regulation Office that they were both British and pre-eminent. They will now be flying the flag alongside their neighbours in Cowley, British Leyland, the ailing remnant of the UK car industry.

Peter Newmark

Eastern Europe

Widespread shortage of energy

THE Soviet Union and its European Comecon allies face considerable problems with energy supplies this winter. This is, in part, due to the loss of generating capacity following the Chernobyl disaster. The damaged reactor No.4 is now permanently 'entombed' in concrete, reactor No.3 is still out of service and, throughout the Soviet Union, RBMK reactors have had to be temporarily withdrawn from service to make them 'operator-proof', a process which, according to Dr Valerii Legasov, will not be completed until 1987.

But Soviet hydroelectric generating capacity is also down because of a water shortage in Central Asia. Furthermore, there are shortfalls in oil, gas and coal production, due to lack of maintenance and repair work.

Last month, it was reported at a meeting of the Supreme Soviet's Commission on the Fuel and Energy Complex that the "energy shortage" due to Chernobyl and the lack of hydroelectric power would be "met" by increased efforts from the thermal generating sector. Just what "met" means in this context is not entirely clear, as Yurii Semenov, deputy chairman of the Fuel and Energy Complex Bureau of USSR Council of Ministers, predicted that electricity supplies would be "particularly difficult" in Ukraine, Central Asia and the Transcaucasus.

There are already difficulties with heat supplies in Moscow and Tashkent. Comecon countries that import electricity from the Soviet Union have had their quotas cut. In the case of Hungary, which normally imports almost 30 per cent of its electricity from the Soviet Union, instead of the hoped for 10,500 million kWh this year, there will be a cut of 500 million kWh, of which 280 million will come in the winter months. To replace this, the Soviet Union has offered 168 million m^3 of natural gas, but the Hungarians are not entirely happy about the substitution. At the Comecon summit in Bucharest last month, the Hungarian Prime Minister, Gyorgy Lazar, spoke critically about "occasional disorders in the unified system" of energy supply "in the recent period" — a remark widely interpreted as referring to shortfall in natural gas supplies either due to production difficulties in Siberia, or to supplies earmarked for the Soviet bloc being diverted to Western Europe to earn hard currency.

Restriction of supplies from the Soviet Union has led to some squabbling among the Comecon partners. In Bucharest, Lazar accused unspecified "partners" of the "unsystematic acquisition" of electricity, to the danger of Hungarian supplies. This statement was taken by the Hungarians as a reference to the Romanians, who, the Hungarians say, in early 1985 almost blacked out the entire "integrated Comecon grid" (Eastern Europe plus the Soviet Union west of the Urals) by attempting to draw more electricity than their entitlement.

Romania has recently come under fire from several East European countries on energy issues. Last year, according to the Yugoslavs, the Romanians drew too much generating capacity from the joint Yugoslav–Romanian Iron Gates hydroelectric station. More recently, the Czechoslovak party daily *Rude Pravo* accused the Romanians of failing to supply power station parts which, the paper said, will cause delays in refitting Czechoslovak power stations and cause electricity shortages well into 1987. Despite draconian restrictions on domestic use (only one bulb, maximum 40 W per room, and no heating of rooms or water in the morning or the evening) there are still regular lengthy power-cuts in Romania.

Other Comecon countries have also announced rationing. In Bulgaria, there is a limit on the number of kilowatt-hours allowed per household per month, and a new crime, "theft of electricity", has been defined. In Poland, a major coal-producer, there is said to be "chaos" at the coal shops, and the radio carries daily announcements as to which enterprises may expect energy supplies that day.

The preferred solution to the energy problems of the Comecon bloc is nuclear energy. Chernobyl has not changed this; the only difference is that there has been a major effort by the nuclear authorities in the member countries to assure the public that the VVER reactors they use are of different type from the RBMKs used at Chernobyl, and that, in any case, additional safety measures are being taken.

A new programme of nuclear energy cooperation in the Comecon countries has now been completed, and is awaiting ratification. This will include the construction of nuclear power stations and nuclear district heating stations for cities. Twelve such heating stations are now under construction in the Soviet Union. **Vera Rich**

US defence

Biological war still a threat

Washington

A PENTAGON report* released earlier this month on the threat of biological war from the Soviet Union reflects the growing interest in the subject in US military circles. The report reiterates claims that the Soviet Union is violating the terms of the Biological and Toxin Weapons Convention of 1972. It also provides the most comprehensive evidence so far released supporting the US contention that the release of anthrax in Sverdlovsk in 1979 was related to weapons research.

Without explaining how the evidence was gathered, the report says that as much as 10 kg of dry anthrax spores was released into the atmosphere in Sverdlovsk. The report says that the scope of the clean-up, the number of victims and the involvement of the military conflict with the Soviet explanation that contaminated meat was the source of the outbreak.

The report follows the regular five-year review of the 1972 Convention that took place in September in Geneva. Pentagon spokesman Major Randy Morger says the current report has been in preparation for some time, and had been intended to coincide with the Geneva meeting but was delayed at the printing stage.

According to Brad Roberts of the Center for Strategic and International Studies, the renewed interest in biological weapons issues can be traced to a presidential commission on chemical warfare chaired by former under secretary of state Walter Stoessel. The commission said last year that the United States could not afford to ignore Soviet activities on biological weapons, and should embark on comprehensive defensive research on biological agents. This strategy, the Stoessel commission argued, would deter the use of biological arms.

Although the Pentagon report concludes that the Soviet Union is developing biological weapons, it admits that violations of the 1972 Convention are difficult to identify. Research done for medical, biological and public health reasons is "also relevant to developing disease agents for warfare purposes". But the Sverdlovsk incident, the report claims, indicates activities that cannot be justified as prophylactic, protective or for peaceful purposes as permitted by the convention.

The report offers no further data on the yellow rain controversy, explaining in a footnote that its purpose is to focus on agents of disease rather than toxin weapons. **Joseph Palca**

Nuclear risk assessment

Sir—I write about the letter of S. Islam and K. Lindgren[1]. Exposure to nuclear accidents and the question whether nuclear engineering is safe or not, and to what degree, is not a question to be answered by sterile theory. The life, health and general well-being of many depend on the availability of cheap and comparatively safe energy. If silly calculations exaggerate the problems caused by mass hysteria, this is not in the best interest of an advanced technological society.

The conclusions reached by Islam and Lindgren are not only wrong but, worse, misleading for those such as the Greens in West Germany. Here are some obvious flaws.

(1) The authors write that "risk assessments which use data from operating experience are a must". I wish they had followed their own advice. What did they do? They inserted the operating experience (reactor years) of a very mixed sample and two accidents (Three Mile Island and Chernobyl) into some formulae. On such a basis, a hypothetical assessor of earthquake catastrophes would have entered an observation period of 10 years at the time when Shakespeare wrote *King Henry VI*, ten to eleven years after the "London Earthquake", Isaac Newton would have used 107 years when his *Philosophiae naturalis principia mathematica* was published and R.A. Fisher would have taken 470 years in 1950. One may repeat this *Gedankenexperiment* in relation to the catastrophic earthquakes of 1811–12 south of St Louis, Missouri. The authors should also ask themselves what their exposure calculations would have produced had the London or the Missouri earthquakes not occurred.

Backed by decades of risk assessment and using the very extensive data of the two largest reinsurance companies, I can assure the authors that a realistic probabilistic evaluation of the catastrophe potential is possible only if one has plenty of information on all accidents, from the smallest to the very largest; only then can reliable probability distributions be inferred.

(2) The authors have (generously) not counted the Windscale accident of 1957 "because it was a military reactor". What matters is the type and the parameters of a reactor, not whether it is a private or a military reactor.

(3) It is obviously unknown to the authors how large the difference is between Soviet RMBK-1000 reactors, light-water moderated reactors and other types. Accident probability depends not only on such basic differences but on engineering details, quality control and on hazards such as fire, explosion, earthquake, flood and so on, and on human parameters. No greengrocer would conclude from an observational sample of thousands of banana and strawberry-years that he must also sell his coconuts and almonds within a day or so to reduce loss from deterioration. Calculations that lump all types of reactors into one sample are not worth taking seriously.

Risk assessment segregates the total exposure according to parameters controlling accidents, when it is possible to correlate actual damage experience with individual parameters to find out which of them appears to be important, whether the list is complete and how much information on accidents is available. More advanced methods (*cf.* ref. 2) but even comparatively simple stochastic calculations, will show that a very large number of observations is necessary per subsample to produce reliable results.

Regretfully, I must add that I know of only a few cases where planners, designers, engineers or contractors of large and risky projects have consulted those with the largest collection of data on accidents and damage (such as specialized insurers and reinsurers).

Unfortunately, it is not generally realized that mathematical models, hypothetical reasoning or thinking carefully about accidents, using logically plausible scenarios[3] and subtleties such as wondering whether to use Poisson, Pearson, Weibull or Gumbel III, are no cheap substitute for difficult, time-consuming and costly compilations of information on actual failures. The observed failure frequency of civil engineering structures, for example, is several orders of magnitude greater than the safety to be expected from calculations[4]. How large is the error margin if far more exotic projects are designed according to logical, albeit theoretical scenarios?

Avalanche dowsing

Sir—I am grateful to *Nature* for publishing accounts of the scientific status of the shadowy field of paranormal phenomena, an area most serious scientists deliberately ignore.

The Norwegian Red Cross Mountain Rescue Organization officially advocates dowsing as an effective method for finding victims of avalanches. This voluntary organization has about 5,000 members in the mountains during the Easter skiing season. Dowsing has been taught for more than 10 years, under the pretence that the technique is accepted by mountain rescue organizations in other countries. Dowsing exercises have been part of the avalanche safety course taught to career officers of the Norwegian Army, and dowsing rods are part of the Army equipment for avalanche rescue.

On 5 March 1986, 16 young Norwegian soldiers died in an avalanche at Vassdalen in northern Norway. Dowsing was attempted by an Army officer in an area where seven or eight soldiers were later found dead. He got between 20 and 30 signals, of which one or possibly two pointed to a victim. He attributes the poor result to the presence of water and vegetation under the snow but is convinced the technique would work under other conditions. A central representative of the Red Cross has expressed the opinion that the dowser was not sufficiently familiar with the technique. The two positive finds made by dowsers at accidents in snow can both be associated with external visual clues. The results are thus in line with those presented, for example by Foulkes[1] and Marks[2], that in the absence of such clues the outcome of dowsing is no better than a series of guesses.

Fortunately, dowsing at the Vassdalen catastrophe did not interfere with the regular search activities which took place simultaneously.

Dowsing is not accepted by the Norwegian police and the Norwegian Geotechnical Institute, responsible for scientific studies of avalanches in this country, has taken a firm stand against the technique.

Wrong dose

Sir—In your recent article "Occupational radiation: British nuclear workers cleared" (*Nature* **323**, 481; 1986), there was a major error. It was reported that for Sellafield workers, "the average radiation dose for those for whom film badge records are available is given as 124 mSv (12.4 mrem) accumulated until the end of 1983". Which dose is correct? A dose of 124 mSv is equal to 12.4 rem. 12.4 mrem is equivalent to a dose of 124 μSv. There is a large difference between 12.4 mrem and 12.4 rem.

- The smaller dose was that intended. Editor, *Nature.*

Images in and of the brain

It is beginning to be possible to produce images of the brain in action, but interpretation of the pictures obtained remains uncertain.

DRAMATIC pictures of the brain in action are now being obtained by optical recording using voltage-sensitive dyes and by positron emission tomography. Some of them have been published in *Nature* (Blasdel, G.G. & Salama, G. **321,** 579; 1986 and Fox, P.T. *et al.* **323,** 806; 1986); last week, A. Grinvald *et al.* (*Nature* **324,** 361; 1986) reported an optical method for recording cortical activity without the use of dyes, at least when the surface of the cortex can be made accessible.

Producing these images requires sophisticated computer processing; understanding them needs tutored interpretation, involving some of the same neural mechanisms that are the subject of the images. Problems such as these were discussed at a recent symposium* on images and understanding, which brought together people who generate images, from the arts and computer graphics, together with neuroscientists and artificial intelligence people who seek to understand the mechanisms by which the brain analyses images.

The conundrum of how the brain interprets images of the brain was illustrated by Horace Barlow (Cambridge) and Marcus Raichle (St Louis), but the implications were left unexplored. The advantage of the new cortical imaging techniques is that the activity of many neurons can be monitored at once, in the intact brain, so as to give a much more complete picture of the spatial organization of neuronal responses to particular stimuli than could previously be had by painstaking reconstruction, and, with some guesswork, from single-unit recordings. Microelectrode recording is, of course, not superseded by the glamorous new technology, for it remains the best way of characterizing the responses of individual neurons. Rather, the synoptic methods add a new dimension by making it possible to see all the neurons activated at once by a particular stimulus; they provide functional maps of the brain.

What do such maps reveal? It has long been known that the brain itself contains a map of the external world — in several areas of the cortex, there are detailed point-to-point, though not necessarily proportional, representations of sensory fields or of the body surface. A consistent finding is that the world is represented many times over, both within a single area and in several regions; different aspects of the same information are then processed in parallel channels.

Colin Blakemore (Oxford) suggested that one reason for such maps is to bring common functions to adjacent points for efficient processing of information. This may be true for orientation and ocular dominance (the basis of depth perception) in the striate area of the visual cortex, as Blasdel and Salama's voltage-sensitive dye maps suggest. But in the same region, cells responding to colour and direction of movement are physically intermingled yet functionally quite separate and they project to separate secondary visual areas (Hubel, D.H. & Livingstone, M.S. *Nature* **315,** 325; Shipp, S. & Zeki, S. *Nature* **315,** 322; DeYoe, E.A. & Van Essen, D.C. **317,** 58; 1985). The organization at these relatively low levels in the processing hierarchy is probably a sorting process through which the correct combinations become addressed to multimodal processing centres higher up the system.

All the maps of the world are symbolic, the maps of the brain included. Reading them must be learned, just as people must learn to interpret geographical maps. Because it is still early in the development of the new imaging technology, the symbolic conventions are not well established and the viewer has to work hard to translate grey-scale or false-colour images into patterns of cortical activity. What is more, the published images are static snapshots of activity patterns at different times.

One of the most difficult features of the brain to capture and analyse is the pattern of dynamic change in the activity of and interaction between its constituent neurons. Because animals and the world around them are rarely still, the sensory input to the brain is constantly changing. Even when one looks at a static image, the attention shifts to focus on different aspects — and appreciation of the same image on different occasions is tempered by physiological and psychological states.

Others know of the difficulty. The art historian, Ernst Gombrich, pointed out how difficult it is to represent a sequence of movements pictorially without recourse to symbols or verbal explanation. Pictorial instructions are therefore rarely universally comprehensible. A clear example of how the interpretation of symbols depends on cultural context and hence on learning was provided by Monica Parker, choreologist to the Royal Ballet, London. In the Benesh notation for recording movements, a basic diagram representing a simple position with arms outstretched at shoulder height would look very different if adopted by an Indian classical dancer rather than by a Western dancer. The details that give the position its character will depend on the form of expression inherent in the tradition of the interpreter.

Although many of the visual images we create and enjoy are static, the perception of movement is a basic and important aspect of visual analysis. In primates, the motion-processing channel starts in the retina but directional sensitivity is first displayed by neurons in area V1 of visual cortex and further elaborated in the motion-analysing area, called MT.

Neurons in MT project to association areas including temporal cortex where, in monkeys, David Perrett and colleagues at St Andrews have recorded from many visually driven cells selective for aspects of body movements. Their results begin to give a glimpse of how the brain reconstructs complex images. Each cell responds to limited views of the body and limited sets of movements, for instance, to a body facing and moving towards the viewer or to a particular articulation of a limb. Many do not depend on absolute form, but respond similarly to a monkey, a human being or with a pattern of dots, as long as it is moving correctly. Although these higher-order cells combine information about motion, form, colour and depth, each still responds only to selected features of the object. Specific recognition or perception of the body as a whole must be the product of collaboration between many cells. Where and how this occurs for any image, simple or complex, is one of the unsolved mysteries of neuroscience.

As a highly visual species, how human beings perceive the world is bound to be a challenging subject; most research on sensory processing and perception has focused on the visual system. But it was for an artist, Liliane Lijn, to point out that ultimately our perception of the world is multisensory; visual images are reinforced by sound, smell and touch. How and where in the brain all the parallel channels carrying the various aspects of all the stimuli converge are unanswered questions. Beyond that still are our conceptual capabilities, defined by Richard Gregory (Bristol) as the marshalling of ideas on a long timescale to develop long-term strategies, generalizations and abstractions.

Mathematics

One hundred per cent proof

Ian Stewart

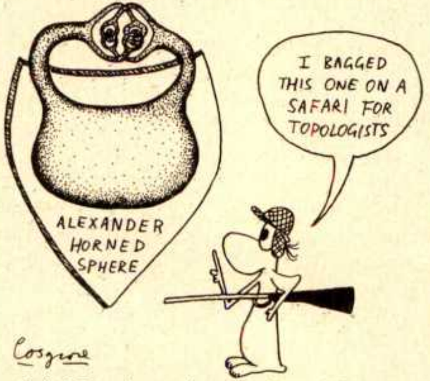
MATHEMATICIANS are a funny lot. They operate in a world of mental abstractions, and many of them appear to have little interest in anything outside it. They pursue abstruse problems on a basis of aesthetic taste, rather than directing their attention at explicit practical goals. Despite this otherworldliness, the results of their deliberations can have enormous practical impact, but that is not my target here, which is the following. To the eternal frustration of their colleagues in neighbouring disciplines, mathematicians are without exception obsessed by the belief that nothing in mathematics is true unless it has been proved, not just beyond reasonable doubt, but beyond unreasonable doubt. Why?

The seamen of ancient Corinth knew that if you tie an overhand knot in a rope, then it cannot be removed except by untying it. Mathematicians remained unconvinced until 1926, when Kurt Reidemeister came up with with an argument that went beyond mere plausibility and established as a mathematical fact the existence of knots that cannot be untied.

Nobody in his right mind would deny that a closed curve in the plane, which does not cross itself, divides the plane into two pieces — the inside and the outside of the curve. Mathematicians were sufficiently sceptical that the question was for many years a well-known and important unsolved problem, stated explicitly by Camille Jordan in 1887, who gave a lengthy, intricate proof. Several other distinguished mathematicians, unhappy with the details, gave their own proofs, but they all contained gaps or mistakes, and the first rigorous proof was given by Oswald Veblen as late as 1905.

In 1852 Francis Guthrie, a student at University College London, wrote to his brother Frederick about a tantalizing little conundrum that he had stumbled across while colouring a map of England. "Can every map drawn on the plane be coloured with four (or fewer) colours so that no two regions having a common border have the same colour?" Experiment rapidly suggests that the answer is yes. But can it be proved? At first this four-colour problem looked fairly easy, the kind of thing that any competent professional ought to be able to polish off with one hand tied behind his back. In 1879 Arthur Kempe, a barrister who belonged to the London Mathematical Society, published a clever argument that seemed to settle the matter. But the problem turned out to be rather more subtle. In 1890 Percy Heawood found a mistake in Kempe's argument, and showed that the best that could be salvaged was a proof that five colours suffice. For almost a century this tiny gap, between five proved and four conjectured, remained unbridgeable. Finally Kenneth Appel and Wolfgang Haken (*Ill. J. Math.* **21**, 429 and 567; 1977) produced their celebrated proof that four colours are always enough. Their method involved testing some two thousand maps for a property called reducibility, which took about 1,000 hours on a fast computer. There are still a few die-hards who do not consider this to be a proof at all, because it uses a computer, and the odd rumour of errors still goes the rounds, but most people are convinced.

My concern here is not the nature of proof. That is a very interesting question, but it would take us too far afield. I also hasten to add that during the initial phase of mathematical creation, rigorous proof is usually left to one side until the basic ideas have crystallized out. My question is: why are mathematicians so hard to satisfy? In other sciences the evidence required to accept a theory is not a logical proof that nothing else could possibly be the case. It is experimental evidence that the predictions of the theory seem to be correct. The stronger the evidence, the happier people are with the theory; and they have no difficulty in operating under the slight possibility that one day the theory will turn out to be false after all. Not seeking absolute truth, they are content with not finding it.



I BAGGED THIS ONE ON A SAFARI FOR TOPOLOGISTS
ALEXANDER HORNED SPHERE
Cosgrove

Not so long ago, mathematics was felt to be exceptional. Its truths, it was said, really are absolute. After a good dose of Gödel, the general opinion changed. Mathematics is only as true as its foundations, and it is impossible to prove that the foundations are 100 per cent solid. Mathematicians have learned to live with that. The natural sciences went through something rather similar but a good deal earlier: eighteenth century fears that scientists knew so much about the Universe that they were doing themselves out of a job also turned out to be unfounded.

But mathematicians still insist on very high standards of logical rigour, and are unimpressed by experimental evidence, even when it appears to be virtually watertight. For example, perhaps the most important open problem in mathematics is the Riemann hypothesis, stated in 1859 by Bernhard Riemann. It is known that the zeta-function $\zeta(z) = 1^{-z}+2^{-z}+3^{-z}+\ldots$ is zero when the complex number z is a negative even number. The hypothesis is that any other zeros have real part equal to $\frac{1}{2}$, that is, they are of the form $z = \frac{1}{2} + iy$. J. van de Lune and Herman te Riele in Amsterdam have just shown, by computation, that the first 1.5×10^9 zeros satisfy this hypothesis. Nobody considers this strong enough to be a proof.

Why do mathematicians take scepticism to such a lunatic degree? There are several reasons. One is that there have been many occasions when intuition or strong experimental evidence has turned out to be misleading. An extension of the Jordan curve theorem states that when a curve divides the plane into two pieces, the inside piece is topologically equivalent to the inside of an ordinary round circle drawn in the plane, and the outside piece is topologically equivalent to the space outside that circle. The natural three-dimensional analogue of this is the hypothesis that when a surface topologically equivalent to a sphere is embedded in space, then the space is divided into two regions, topologically equivalent to the inside and outside of an ordinary round sphere. This is very plausible and natural. Unfortunately, it is not true. The Alexander horned sphere shows the outside space can get very messy indeed.

When a young research student called Stephen Smale first told his supervisor he had proved that you can turn a sphere inside out without introducing creases, he was told to go away and find the mistake. Smale is now one of the world's leading mathematicians, and his theorem is both true and famous.

In the theory of prime numbers the number of primes less than a given number x, denoted $\pi(x)$, is approximated by various analytic formula. One is the so-called logarithmic integral $\mathrm{Li}(x) = \int dx/\log x$. The ratio of $\pi(x)$ to $\mathrm{Li}(x)$ tends to 1 as x tends to infinity, so $\mathrm{Li}(x)$ is a good approximation to $\pi(x)$. What about the error? 'Experimental evidence' shows that $\pi(x)$ is less than $\mathrm{Li}(x)$ for x up to about 10^9 or so. This many successful experiments might be considered conclusive. Mathematicians do not see it that way, and neither did S. Skewes who proved in 1933 that $\pi(x)$ must be *greater* than $\mathrm{Li}(x)$ for some x no bigger than 10^10^10^34, where (for typographical convenience) ^ denotes exponentiation.

This points to a major problem with experimental evidence in mathematics. Evidence based on only a finite number of cases is really pretty thin, and that is usually all the evidence you can get. One billion is a tiny number compared with a googolplex (10^10^100), and most numbers are bigger still. Almost all numbers are immense. The proportion of numbers smaller than Skewes' apparently monstrous number, for example, is zero. Indeed in number theory many estimates on sizes of things grow like, say, log log log *x*. This is 34 (using logs to base 10 for convenience) for Skewes' number. Tiny.

So experience shows that plausible intuitions are not to be trusted, and that numerical evidence is not worth the computer paper it is printed on. The problem is compounded by the way mathematics is constructed. It is like a huge house of cards: theorem piled upon theorem, shored up by lemmas and corollaries, with axioms deep in the foundations acting like concrete pilings and hoped-for conjectures floating up in the clouds, unattached to the main building. If one tiny part is faulty, the whole edifice may collapse. I don't mean this too literally: if a mathematician makes a mistake, it seldom has implications that serious — maybe a balcony falls off. There are internal checks and balances. But to maintain the structural integrity of mathematics it is important not to admit shoddy components.

A standard method of proof, which is extremely powerful and therefore very popular, is 'proof by contradiction'. To prove a statement X the mathematician starts out by denying X, follows up the consequences, and eventually arrives at something that contradicts either itself or some known theorem This shows that the denial of X is false, hence X itself is true. It is rather like offering a gambit in chess in the hope of recouping greater gains later; but, in the words of Godfrey Hardy, the mathematician offers "the whole game". Imagine the dangers of using a result that has not been given a decent proof, however plausible it may be, in the course of such an argument. It does not bear contemplating, and mathematicians therefore try very hard not to contemplate it.

Another reason for wanting rigorous proofs is that their absence is a sign that something important is not understood. The Jordan curve theorem, for instance, led to algebraic topology. This is central to today's mathematics, and is currently producing useful payoff in various scientific areas, notably gauge field theory. On the whole, algebraic topology is not the sort of technique that gets invented in a direct attack on a practical problem. It is not like calculus, say, whose need becomes apparent the moment the real-world problem is formulated in mathematical guise. Obsession with proof is not just pedantry: it is a major source of new ideas and methods.

In science, the experimental method is paramount. It evolved primarily as a way of counteracting the natural human tendency to believe something because one wants it to be true. If scientists allow themselves the luxury of believing a theory because it is pretty, or conforms to their political prejudices, then they cease to do effective science. If an engineer wants to make sure that his bridge will not fall down he does not worry about the aesthetics of the design, or the colour: he checks that the design conforms to acceptable tolerances and he makes sure that the bridge is built to specification. In the same way, a mathematician dare not believe a plausible theorem just because he would like it to be true, and he cannot place great faith in even extensive numerical evidence because there are good reasons to assume that may be misleading. Proof, and proof alone, is the safeguard. ☐

Cancer chemotherapy

Progress in understanding multidrug resistance

George R. Stark

RESISTANCE to a wide range of drugs is often found in human tumours that have relapsed after initial regression in response to drug therapy[1]. An understanding of this phenomenon would be important in the search for more effective chemotherapy. On page 485 of this issue[2], Gerlach *et al.* report a striking similarity between the amino-acid sequence of P-glycoprotein, a membrane protein of relative molecular mass 170,000 (170K) whose overaccumulation can lead to multiple drug resistance, and the *hlyB* gene product, a 66K membrane protein that mediates active export of the protein haemolysin from *Escherichia coli.* This homology is sufficiently extensive to suggest functions for the P-glycoprotein. Two other groups have recently reported complete complementary DNAs predicting sequences of P-glycoproteins from mouse[3] and human[4] cells; the results are very similar to those obtained by Gerlach *et al.*[2].

Overaccumulation of P-glycoprotein results from amplification of a small family of closely related genes in multidrug-resistant cells[5,6] (for example, cells resistant to anthracyclines, vinca alkaloids, podophyllotoxins and dactinomycin but not to bleomycin nor most alkylating agents and anti-metabolites). Amplification of many genes occurs at a high frequency in cells of an advanced tumour stage and amplification of oncogenes undoubtedly contributes to malignant progression (see ref. 7 for review). It is likely that a small tumour containing around 10^9 cells already contains a few thousand cells in which the P-glycoprotein genes have been amplified, even before therapy[7]. Worse still, treatment with some anti-tumour drugs or radiation can increase the rate of gene amplification[8] and thus increase the fraction of multidrug-resistant cells.

Overexpression of the P-glycoprotein genes is almost always a result of amplification and is the predominant cause of multidrug resistance in current examples. It is clear that there is a small family of closely related P-glycoprotein genes[6,8] and by screening a complementary DNA library from normal mouse cells, Gros *et al.*[9] obtained a clone for one of the P-glycoproteins that includes the entire coding region. When this sequence was placed in an expression vector and transfected into drug-sensitive hamster cells, selection with adriamycin revealed multidrug-resistant colonies in which only the introduced mouse DNA was amplified. This result shows that overexpression of a single member of the P-glycoprotein gene family confers resistance.

P-glycoproteins are relatively scarce in the membranes of most cells but can be increased by 100-fold or more in multidrug-resistant cells. How can an overproduced membrane protein mediate resistance to a diverse collection of drugs, often unrelated in structure and function? Recent work shows that the drugs accumulate less in resistant cells, probably as a result of an increased rate of efflux rather than a decreased rate of influx, suggesting that the P-glycoproteins may pump many different small hydrophobic molecules out of cells[10,11]. Support for this idea comes from other studies using a derivative of vinblastine that can be photoactivated and appears to bind directly to the P-glycoprotein[12,13]. Note, however, that there are other cases of resistance to single drugs in which, for example, specific pathways for drug influx have been lost[14], and also well-known mechanisms of resistance that have nothing to do with transport[7].

Analysis of the similarity between P-glycoprotein and *E. coli* transport proteins supports and greatly extends the efflux model of multidrug resistance. Sequence analysis of the complementary DNAs reveals that the P-glycoproteins consist of a tandem duplication of a more basic structure[3,4]. Gerlach *et al.*[2] show that the homology with the haemolysin transport protein extends over about 230 amino acids at the carboxy terminus of P-glycoprotein. From work with monoclonal antibodies, it is known that the carboxy terminus is found on the cytoplasmic side of the plasma membrane[15]. By comparison with homologous regions of other transport proteins, it seems likely that part of this cytoplasmic domain functions as a nucleotide-binding site, probably using ATP to provide the energy for active efflux[2-4]. As the sequence of P-glycoprotein consists of a tandem repeat, each molecule would provide two such sites.

In anticipation of a direct study of the function of P-glycoproteins for their role in multidrug resistance, two major mechanisms have been considered[2-4]: (1) direct efflux of hydrophobic drugs through a P-glycoprotein pore, perhaps involving other components of the membrane; or (2) protein-mediated efflux in which the drugs are first bound to a carrier protein which is then expelled from the cell. The latter possibility is suggested by the close homology to the haemolysin transport system, which is known to function in this way. The homology also raises questions about the normal function of P-glycoproteins.

Knowledge of the structure and functions of the P-glycoproteins should lead to new attempts at tackling multidrug resistance in patients. It may be possible to take advantage of the exposure of part of the overproduced P-glycoprotein on the cell surface to target cytotoxic antibody conjugates to these cells after the bulk of the tumour has been destroyed by conventional chemotherapy. As the details of the transport mechanism become better defined, it will be possible to consider the design of specific drugs which can interfere with it; compounds have already been discovered that interfere with efflux of drugs from multidrug-resistant cells[16].

An understanding of the mechanism of multidrug resistance presents the possibility of much greater clinical benefit from the enormous effort that has in the past been put into developing and testing chemotherapeutic agents. □

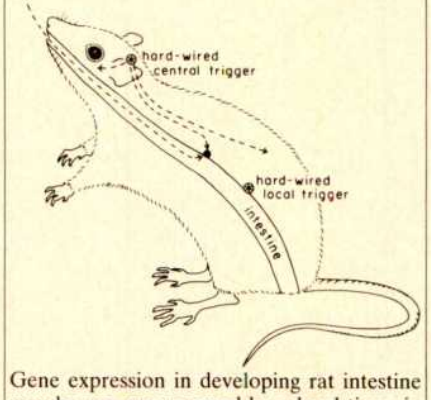
Developmental physiology

Hard-wired local triggering of intestinal enzyme expression

Jared M. Diamond

NORMAL development requires that each gene express itself at the right time and in the right cell. Is proper timing triggered by signals external to the animal, or is it 'hard-wired' within the animal (see figure)? If triggering is hard-wired, is the trigger local, within the tissue where expression will occur, or is it central, for example, in an endocrine gland whose hormones control many peripheral tissues? A recent report by K. Yeh and P. Holt (*Gastroenterology* **90**, 520; 1986) demonstrates the existence of a hard-wired local timer for sucrase expression in rat intestine, which will be a useful model for the identification of timers in other systems.

Infant rats are normally weaned from a diet of maternal milk to solid food around 25 days after birth. Starting around day 18, intestinal activity of lactase (which digests the milk sugar lactose) declines, whereas sucrase (which digests sucrose in solid food) first appears (Henning, S. *A. Rev. Physiol.* **47,** 231; 1985). These changes might be externally triggered by weaning and the resultant change of solutes entering the intestinal lumen: experimentally delaying the age of weaning, for example, is found to delay the decline of lactase.



Gene expression in developing rat intestine may be pre-programmed by a local timer in intestinal cells themselves; pre-programmed by a centrally released timer (for example, a thyroid or pituitary hormone); or not programmed at all but instead triggered by an external event.

The changes might also be under hard-wired central control by hormones that modulate many other developmental changes around the time of weaning. (Pituitary, thyroid and adrenal hormones affect development of intestinal lactase and sucrase, as well as that of many other functions.) Could a hard-wired local timer contribute as well?

Yeh and Holt transplanted isografts of mid-intestine from donor rat pups 0 or 5 days after birth to under the skins of newborn (day 0) host rat pups. Some of the grafts survived and exhibited normal migration rates of differentiating enterocytes along the crypt/villus axis. They found that the control of expression in the isografts differs between lactase and sucrase.

Isograft lactase does not begin to decline until after donor age 28 days (host age 28 or 23 days), although lactase in the host intestine begins to decline as usual around 18 days. Thus, the change in luminal solute input, which was experienced by the host intestine but not by the donor intestinal graft under the host's skin, is an important signal for turning off lactase expression. In agreement with this conclusion, the normal decline in lactase is delayed in bypassed intestinal loops (Tsuboi, K. *et al. Gastroenterology* **80,** 1550; 1981) and is accelerated in rat pups fed an artificial milk formula (Yeh, K. & Holt, P. *Pediatr. Res.* **19,** 963; 1985).

Sucrase activity begins to rise simultaneously around day 18 in donor and host tissue when day 0 donor tissue is transplanted into day 0 hosts. But when day 5 donor tissue is transplanted into a day 0 host, the isograft begins expressing sucrase when the host is only 13 days old and the donor tissue 18 days old. At this time the host tissue expresses no sucrase, which does not appear until 5 days later when the host reaches an age of 18 days.

Thus, donor sucrase expression is not triggered externally by luminal solute inputs (from which the donor intestinal graft was cut off), nor by a hard-wired central timer in the form of host hormones (which would have triggered host and donor expression simultaneously). Nor could the normal absence of sucrase expression at day 13 result from a systemic inhibitor present then, as the graft does express sucrase at a host age of 13 days. Instead, there must be a hard-wired local timer within the donor intestinal tissue that turns on sucrase expression at a tissue age of 18 days. In agreement with this conclusion, sucrase expression begins at the normal time in bypassed intestinal loops and in rat pups from which the pituitary, adrenal or thyroid gland is removed. □

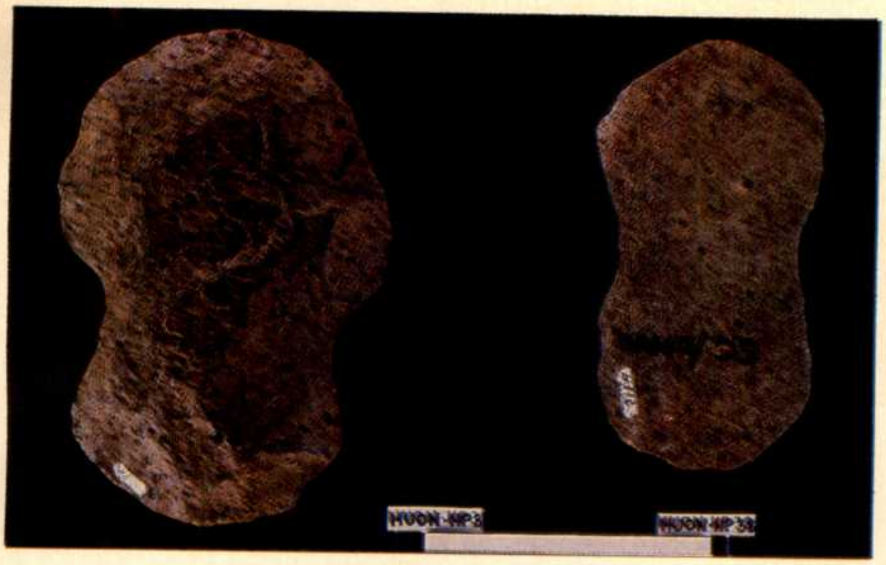
Discovery of waisted axes in New Guinea



THE recent discovery of waisted axes such as those pictured above indicates that human inhabitants were present in Papua New Guinea more than 40,000 years ago. On page 453 of this issue, Les Groube and his co-workers describe the excavation undertaken (at the south-east end of the Huon Peninsula in New Guinea) and the artefacts discovered there. The archaeological site consists of a series of coral terraces of varying ages, the waisted axes being localized to regions believed to be more than 40,000 years old. This dating was confirmed by thermoluminescence analysis of resident quartz particles. These new data suggest that New Guinea was inhabited at a relatively early stage in the Pleistocene settlement of Australia from the Indonesian–Indochina region, when it and Australia were connected by a land bridge. □

Albert Szent-Györgi (1893 – 1986)

ALBERT Szent-Györgyi, one of the most remarkable biochemists of our century, died in Woods Hole, Massachusetts, on 22 October. The son of a Hungarian well-to-do farmer, he grew up in a comfortable and cultivated household. He had started to study physiology when he was called up for military service in World War I. In the post-war upheavals he wandered from one laboratory to another, learning new techniques from Michaelis and others, until he settled in Holland, first in Leiden and then with H.J. Hamburger in Groningen. He became deeply interested in biological oxidations, especially the catalytic systems involving succinate, fumarate, malate and oxaloacetate. He recognized their wide general significance in metabolism, and his work represented an important preliminary step that helped toward the later demonstration of the total tricarboxylic acid cycle by Hans Krebs.

Szent-Györgyi also became interested in vegetable respiration, and detected a reducing agent, present in many plant juices, which he noted because it caused a slight delay in the progress of oxidations catalysed by peroxidases. That he took notice of this slight delay, which many investigators might have ignored, was characteristic. When Hamburger died, Szent-Györgyi had to find a job elsewhere; by great good fortune Sir Frederick Hopkins, who had followed his work with interest, invited him to Cambridge and obtained a fellowship for him. Here he succeeded in crystallizing the reducing agent from the juice of oranges, lemons and cabbages, and from adrenal glands.

About this time (1932) an enlightened Hungarian minister of education recognized Szent-Gyögyi's ability and invited him back as professor of medical chemistry at the University of Szeged. A young Hungarian, J. Swisbely, who was familiar with the assay for vitamin C, came to work with him. It was soon apparent that the crystalline reducing agent was indeed vitamin C (ascorbic acid). Szent-Györgyi found that Hungarian paprika was extraordinarily rich in this substance, and was able to prepare crystals in kilogram quantities, which he distributed to other researchers throughout the world. It was for his work on ascorbic acid that he received the Nobel Prize in 1937; the citation also noted the importance of his work on the role of dicarboxylic acid anions in biological oxidation systems.

Next he became involved in the study of muscle contraction and the proteins of muscle. On extracting myosin with salt solutions by the standard procedures, he noted that, if the extraction was prolonged, the extract became considerably more viscous, although the total amount of protein extracted was not much greater. This led to the recognition that another protein, later called actin, was associated with myosin. Szent-Györgyi's young co-worker, F.B. Straub, purified actin, while he himself investigated the ATP-induced contractility of actomyosin threads.

Szent-Györgyi carried out this work, which opened great new vistas in muscle biochemistry, during World War II under constant danger from the Nazis, who had become aware of his contacts with the British Secret Service. He was placed under house arrest, and escaped seizure by the Gestapo only by taking refuge in the Swedish Legation in Budapest. When the Nazis broke into the Legation, he fled just in time, and he and his wife went into hiding until the war ended.

When the Soviet armies arrived, Szent-Györgyi and his family were protected and well cared-for on personal orders from Molotov, and later he was brought to Moscow for two months. But he became disillusioned and outraged by the character of the Soviet regime and the atrocities committed by the Soviet armies in Hungary. Although personally well treated by the authorities, he found it impossible to continue the work of his laboratory and so departed for the United States, where he settled at the Marine Biological Laboratory in Woods Hole.

Always ready to strike out into new fields, he became fired with interest in the concepts of quantum mechanics, although he never claimed to have mastered (or even to have actually grasped) the mathematical complexities of the subject. Along these lines, he wrote a small monograph on what he termed 'submolecular biology'.

His major preoccupation during the last decades of his life, however, was with cancer. His views on the origins of cancer differed widely from those of almost all other workers in the field, and government grants for his support, although available in limited amounts, were quite inadequate to support research on the scale that he considered necessary. He continued research with a small group, but his last years must have been embittered with a sense of frustration.

He was always, especially in his earlier years, a man of infinite jest; he loved to announce his ideas and discoveries in a manner that could lead the unwary to believe that he was talking nonsense; but they soon discovered that there was a very solid basis for it all. Like many jesters, he had a deeply tragic vision of the world; he was appalled by the follies of its rulers, teetering constantly on the brink of destruction. Somehow he still managed to cherish hope. Scientist and humanist, he was a unique and unforgettable man.

Evolutionary ecology

Toxins and grazing resistance

Peter D. Moore

ONE of the most useful things about plants, where human beings are concerned, is their capacity to resist the attentions of grazing organisms by the production of deterrent chemicals. These secondary compounds are among the most important controls on grazing insects[1] and by happy chance provide a rich source of drugs, for example, caffeine[2]. Considerable effort is now being directed towards the study of plant/grazer interactions as a potential source of pesticides and drugs, and simply as an area in which co-evolution is most graphically illustrated. Some recent investigations seek to demonstrate the importance of secondary compounds in a range of lower plants, including cycads[3], lichens[4] and algae[5], as well as in higher aquatic plants[6].

Unpalatable meals? Larvae of Eumaeus atala florida *(photograph courtesy of D.C. Lees, London Butterfly House).*

Cycads are well known as plants toxic to vertebrates[7], but the North American cycad *Zamia floridana* is fed upon by the brightly coloured caterpillar of a Lycaenid butterfly, *Eumaeus atala*. It has been supposed that the red and yellow coloration of the larva indicates that it sequesters glycosides for its own defence, as is the case in the monarch butterfly[8], but the study of this particular plant/animal inter-relationship has been hampered by the extreme rarity of the insect. A captive breeding programme has now provided sufficient larvae to permit analysis and Rothschild, Nash and Bell[3] report that both the caterpillars and the adult insects do indeed contain the glycoside cycasin and are therefore toxic to predators. They also emit a pyrazine-like odour which presumably deters enemies. Their conspicuous coloration, also a deterrent, is unusual almong the Lycaenids, suggesting that the association between cycad and butterfly has been a long one. It would be interesting to know whether the cycad receives any benefit from the relationship, perhaps in the form of pollination.

100 years ago

I WISH to suggest a possibility, which if true will considerably alter our views of the facts of chemistry. Let us take the electrolysis of hydrochloric acid.

At present we state the facts thus: Every molecule of hydrochloric acid consists of one atom of chlorine and one atom of hydrogen, the chlorine atom weighing 35.5, the hydrogen atom weighing 1. On passing a current, each molecule is split into these two atoms, each atom carrying a unit charge of electricity.

It is not just possible that we may some day state: A molecule of hydrochloric acid consists of one molecule of hydrogen weighing 1 combined with 35.5 molecules of chlorine each weighing 1. On electrolysis, the chlorine atoms are split from the hydrogen atom, the chlorine atoms each carrying unit charge of electricity, and the hydrogen atom carrying 35.5 charges of electricity. If this is the truth, then all the atoms of the elements are of the same weight, and probably are made of the same "stuff", and we have only two things which condition the properties of the atom — its electrical charge and its electric potential, and Mendelejeff's table becomes a statement of the periodic relationship between these.

From *Nature* **35**, 132: 9 December 1886.

Down the scale of evolutionary complexity, secondary compounds in the lichens are also implicated in herbivore deterrence. Lawrey[4] examined the behaviour of slugs when presented with a selection of lichens and found that they exhibit a distinct preference for certain species — perhaps it would be more accurate to say that they definitely avoid the unpalatable species. Even acetone extracts of the thalli of avoided species are effective in deterring the predators. The fact that it is avoidance of the distasteful rather than preference for the attractive which operates is shown by the higher levels of nitrogen, phosphorus, potassium and calcium in the avoided species. Those lichen species, which should have been most alluring to the slugs, are in fact the most distasteful because of their heavy load of secondary compounds.

In marine algae, there are secondary compounds which could also be involved in grazing resistance. For example, many species of the red alga genus *Laurencia* have sesquiterpenes, compounds which are often involved as insect deterrents in higher plants[9]. There are even parallels to the terrestrial grazers which have an immunity to toxins or even store them for their own protection against predators. The sea hare *Aplysia californica*, a marine mollusc, is though to do this with the sesquiterpenes of *Laurencia pacifica*[5]. But it is evident that not all the grazing effects of herbivores on algae are necessarily harmful to the plant. Zooplankton may stimulate phytoplankton growth rates by local enrichment of water with ammonia[10]; Connor and Quinn[11] propose that growth of some microalgae is stimulated by the mucus of grazing limpets.

But Crews and Selover[5] now suggest that *Erythrocystis saccata*, a red algae semi-parasitic on *L. pacifica*, may take up sesquiterpenes from its host and retain them in the same concentration in its own thallus. They have not demonstrated actual transport, but any other source of this particular suite of compounds seems unlikely. Perhaps the parasite gains some degree of predator immunity from the sequestered defence materials.

It is not only the algae among aquatic plants that are well equipped to deal with the attentions of grazers. Ostrofsky and Zettler[6] show that the same is true of many aquatic higher plants, such as some species of the pondweed genus *Potamogeton*. Possession of deterrent secondary compounds may account for the low level of herbivore attack on such species. *P. crispus* is particularly well supplied with alkaloids and the authors consider that the concentrations present (0.2–0.5 mg per g dry weight) are adequate to account for the general lack of grazing on such aquatic macrophytes. But some terrestrial mammals are known to graze on aquatic plants, for example the moose, which derives most of its sodium requirement from summer grazing in shallow lakes[12]. Perhaps this animal, like the sheep[13], has some degree of resistance to the alkaloids contained in the aquatic macrophytes and thus takes advantage of a relatively underexploited resource. ☐

Galactic evolution

Do globular clusters belong?

Virginia Trimble

Do the globular star clusters really belong to the galaxies they now inhabit, in the sense of having formed in and with them? Yes, according to some of the results presented at a recent symposium*, and no, according to others. The issue arises because these clusters are a bit like dinosaur teeth — small hard things that could have survived a long time under harsh conditions. Thus, they might, alternatively, have formed separately before their host galaxies or as part of other systems that amalgamated to make those galaxies. The issue is important because the globular clusters, unlike dinosaur teeth, are not just very old, but are actually the oldest subjects in the Universe available for study at close range. They ought, therefore, to tell us something of when and how galaxies and stars began.

Globular clusters have so far been seen in about 40 galaxies (spirals, ellipticals and irregulars) and studied closely in half a dozen. The 125-or-so clusters known in our own Milky Way contain, for instance, about 1 per cent of the stars of the spherical halo. Evidently, indicators are needed to show whether the clusters resemble the stars around them more than they resemble each other, and whether their properties (individually or as populations) are correlated with those of their host galaxies. Resemblance and correlation would suggest formation *in situ*, and the opposite would suggest a more complex process.

The evidence, unfortunately, is contradictory and rather evenly balanced. Starting with our own Galaxy, the globular clusters (according to R. Zinn, Yale University) do generally resemble the other halo stars in their distribution of numbers as a function of radius, in their average heavy-element abundance and its gradient with galactocentric distance, and in their dynamical properties (net rotation, velocity dispersions in three dimensions and average orbital eccentricity). Differences exist, however, in the periods of variable stars as a function of their composition (G. Wallerstein, University of Washington) and in the metallicity distribution, in the sense that the field stars have a larger representation at very high and very low values than do the clusters (J.B. Laird, University of North Carolina).

Other indicators that the clusters 'belong' to their hosts are: the likelihood that galaxies more massive than the Milky Way, including M31, NGC5128 and M87, have redder, more metal-rich clusters (F. Fusi Pecci, University of Bologna; H.C. Harris, US Naval Observatory; J. Huchra, Center for Astrophysics, Cambridge, Massachusetts), though the high value for M87 was disputed by J. Nemec (University of British Columbia); the two-standard-deviation result that central (massive, cD) galaxies in clusters have more than their fair share of globulars (W.E. Harris, McMaster University); and the undisputed fact that gas-rich galaxies, including M33 and the Magellanic Clouds, unlike the Milky Way and similar spirals, are still producing massive clusters (though not quite such massive ones as the true, old globulars; E. Olszewski, Steward Observatory; C. Christian, Canada–France–Hawaii Telescope).

In contrast, several other observations suggest that the clusters did not originate with the galaxies they now inhabit. First, the number of clusters at a given luminosity, the function $N(L)$, seems to be much the same, a gaussian with the same width and a peak at $M_v = -7.4$, in nearly all galaxies examined; at any rate, the assumption that this is so leads to a consistent distance scale out at least as far as the Coma cluster (D.A. Hanes and D.G. Whittaker Queen's University, Ontario; L.A. Thompson and F. Valdes, Institute for Astronomy, Hawaii). Second, the clusters in M31 (Fusi Pecci) and M87 (Huchra) do not show the kind of gradient of abundance from centre to periphery seen in the Milky Way. Both items suggest that the clusters did not know where they were going to end up when they formed.

Finally, and most striking, the clusters in some galaxies differ from the non-cluster stars at the same radial position in a number of related ways. The cluster populations are less centrally condensed than the underlying star light, scaling as $r^{-2.5}$ rather than as r^{-3} in M87, M49 and other large elliptical galaxies[1], where r is the distance from the centre of the galaxy concerned. They are more spherically distributed around the galactic centre than the background stars in disk galaxies including NGC3115, 4594 (the Sombrero) and 7814 (Harris). They are bluer than the star light at the same positions both in M87 (J. Cohen, Caltech, confirming earlier work[2]) and in several dwarf ellipticals[3]. And they display a larger velocity dispersion than the other stars at the same radius in NGC5128[4] and M87[5]. The net impression is that the clusters constitute an older, more primitive population, the bluer colours resulting from lower metal abundancies; and the greater extension, sphericity and velocity dispersion representing a lesser degree of collapse and dissipation.

This could mean that the clusters are pregalactic and primordial[6,7], or that they formed as part of larger units that merged to make modern galaxies (R.B. Larson, Yale University). But it could also mean that the globulars formed *in situ* as galactic halos collapsed, their population statistics having been gradually modified as the most vulnerable clusters were torn apart tidally during close approaches to the galactic centres (J.P. Ostriker, Princeton University; M.J. Rees, Institute of Astronomy, Cambridge; D. Chernoff, Cornell University). Tidal disruption would systematically remove central clusters (hence the shallower density profile) and ones on eccentric orbits. The remaining circular orbits then give the impression of increased velocity dispersion at any given off-centre point. To account for the colour difference, the metal-rich clusters must also have been systematically removed, which is also plausible, at least in galaxies with radial abundance gradients. Apparently, then, all the scenarios can still accomodate all the data and no-one suggested unambiguous clues that might be sought in the near future. □

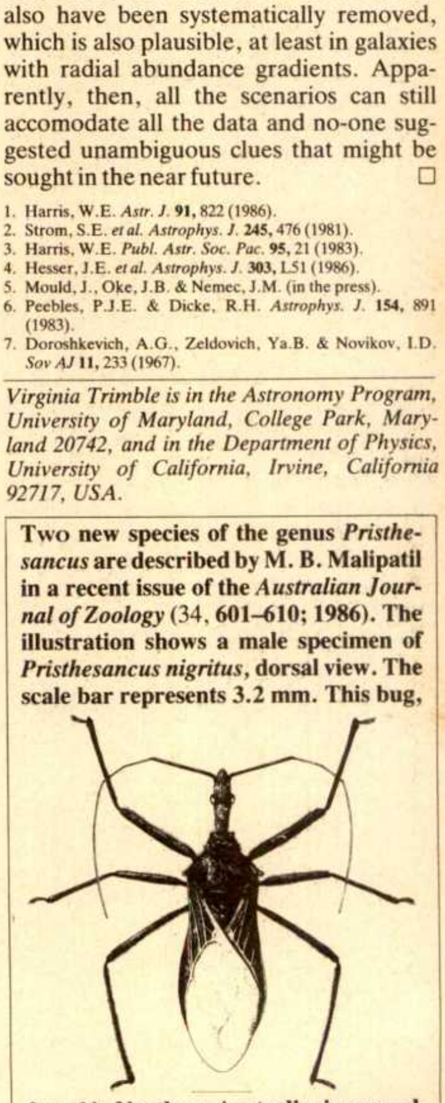
Two new species of the genus *Pristhesancus* are described by M. B. Malipatil in a recent issue of the *Australian Journal of Zoology* (34, 601–610; 1986). The illustration shows a male specimen of *Pristhesancus nigritus*, dorsal view. The scale bar represents 3.2 mm. This bug,



found in Northern Australia, is generally black with two pale distal antennal segments. Like other members of the order Heteroptera, this specimen has two pairs of wings and mouthparts modified for piercing and sucking. Many heteropterous insects are vectors of plant and animal diseases. □

Clinical pharmacology

New hopes for the treatment of coronary heart disease

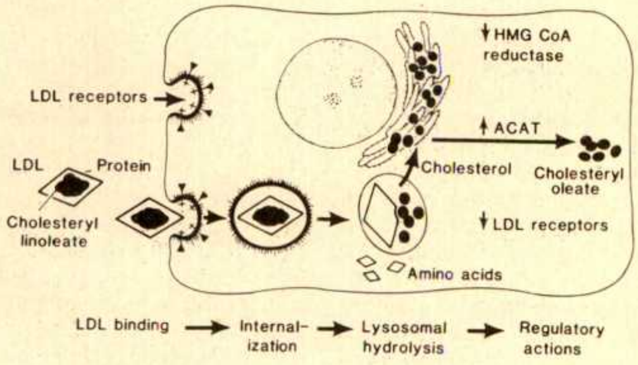
Gilbert Thompson

A RECENT 6-year survey[1] of more than 350,000 middle-aged men in the United States confirms that both total mortality and death from coronary heart disease are strongly correlated with the concentration of cholesterol in the blood. Death rates rise steeply once serum cholesterol exceeds 6.5 millimoles per litre, and values above that level are found in 15 per cent of the population. In the United Kingdom, new epidemiological data[2] indicate that there are twice as many men with this degree of hypercholesterolaemia. In most instances this problem can be managed by dietary means, but a significant minority of individuals will require drug therapy. A new agent that reduces the concentration of cholesterol in the blood is described by A.H. Underwood and colleagues on page 425 of this issue[3].

The suggestion that hypercholesterolaemia causes coronary heart disease is confirmed by the atherogenetic effect of increased levels of low-density lipoprotein (LDL) cholesterol and the protective effect of high levels of high-density lipoprotein (HDL) cholesterol. Drugs that lower LDL and increase HDL are used to treat familial hypercholesterolaemia. People with this condition (0.2 per cent of the population of the United Kingdom) have a propensity to accelerated atherosclerosis and premature death from coronary heart disease. M. Brown and J. Goldstein discovered that this disorder represents a genetically determined defect of specific cell-surface receptors for LDL and have elucidated the structure and function of the receptors.

As illustrated in the figure, the LDL receptor provides a path of entry for exogenous cholesterol into the cell and reduces endogenous cholesterol synthesis through down-regulation of the rate-limiting enzyme β-hydroxy-β-methylglutaryl coenzyme A (HMG CoA) reductase[4]. The number of LDL receptors expressed and the activity of this enzyme in the cell have complementary roles in maintaining cholesterol homeostasis. This process is disturbed in familial hypercholesterolaemia where defective function of the receptors results in diminished uptake from plasma and decreased degradation of LDL, processes which normally take place mainly in the liver. The LDL receptor is a glycoprotein of relative molecular mass 160,000 (160K), the gene for which is on chromosome 19, whereas HMG CoA reductase is a 97K glycoprotein, the gene for which is on chromosome 5 (ref. 5). Several mutations of the gene encoding the receptor have been described[6], any of which can give rise to familial hypercholesterolaemia, but no mutations of the gene encoding HMG CoA reductase have been identified.

Hitherto the ability to stimulate hepatic LDL receptors has depended on the use of insoluble anion-exchange resins such as cholestyramine. These resins bind bile acids within the intestine and thus impair their re-absorption into the blood. To make good this loss, the rate of conversion of cholesterol to bile acids in the liver increases, the consequent need for additional cholesterol being met partly by increased expression of LDL receptors and partly by a compensatory rise in cholesterol synthesis.



A cultured fibroblast showing binding to receptor, endocytosis and lysosomal degradation of LDL, resulting in hydrolysis of protein to amino acids and of cholesteryl ester (linoleate) to free cholesterol. This leads to down-regulation of HMG CoA reductase and LDL receptors. Excess free cholesterol undergoes esterification to cholesteryl oleate by the enzyme acylcholesterylacyltransferase (ACAT). (Reproduced from ref. 11 with permission from M.S. Brown and J.L. Goldstein).

The LDL-lowering effects of cholestyramine can be markedly enhanced by concomitant administration of a new class of drugs that block cholesterol synthesis by competitively inhibiting HMG CoA reductase. Like cholestyramine, these compounds promote receptor-mediated LDL catabolism but are much easier to take. They include mevinolin (lovastatin) and synvinolin, and look set to revolutionize the treatment of heterozygous familial hypercholesterolaemia[7,8]. Unfortunately homozygotes, with fewer functional LDL receptors, respond less well.

The new work of Underwood *et al.*[3] in this issue is based on the well-known fact that thyroid hormones lower serum cholesterol. In attempts to use this effect therapeutically, avoiding undesirable side-effects by administering D-thyroxine instead of L-thyroxine, even D-thyroxine proved dangerous, causing cardiac arrythmias when given to patients with coronary heart disease, and its use has been largely discontinued. Underwood *et al.*[3] have discovered a thyromimetic agent, SK&F L-94901, which has significant cholesterol-lowering properties in animals. Their data suggest that this compound is equipotent to triiodothyranine in its effect on the liver but one thousand-fold less active in its effect on the heart. Although its development is still at an early stage, the outlook seems promising. The mechanism of the cholesterol-lowering effect presumably involves enhancement of receptor-mediated LDL catabolism, which also occurs during treatment of hypothyroidism with L-thyroxine[9]. The possibility that it stimulates selectively hepatic LDL receptors is intriguing but if, like thyroid hormones, SK&F L-94901 also increases HMG CoA reductase activity[10], it might be necessary to administer it with an HMG CoA reductase inhibitor. Such a combination could be just what is needed if diet-resistant hypercholesterolaemia is to be treated as routinely and effectively as hypertension, as the evidence[1] suggests it should. ☐

Astrophysics

Big, repulsive boson stars

Robert Walgate

THERE is normally little need to remark that all familiar stars — even quark stars and neutron stars — are made of fermions, particles of half-integral spin whose quantum statistics forbid them to enter the same quantum state. The result of this well-known fact is the 'degeneracy pressure' which keeps the fermions in different states like the electrons in an atom, and prevents even quite massive, relativistic stars from collapsing under gravity. But is it possible to conceive of a stable gravitating star made of bosons, the integral-spin particles which can form a single quantum state of, in principle, unlimited intensity? The theoretical Universe is, after all, beginning to be filled with exotic particles of many kinds from the bosonic 'superpartners' of the quarks and leptons to Higgs bosons and 'ghost' matter; it is conceivable that if boson stars exist then some of the supposed missing matter of the Universe could be in the form of such objects. In fact, as M. Colpi, S.L. Shapiro and I. Wasserman report (*Phys. Rev. Lett.* **57,** 2485; 1986), the answer seems to be yes.

Initial calculations supported by refined work with general relativity led R. Ruffini and S. Bonazzola (*Phys. Rev.* **187,** 1767; 1969) to suggest that boson stars would be possible. But by astronomical standards these early calculations gave the stars a tiny mass, of the order of the square of the Planck mass divided by the boson mass (around 300 million tons, or 10^{-19} solar masses for 1 GeV bosons), and a radius of the order of the Compton wavelength of its constituent bosons (1 fm or so for 1 GeV). It was difficult then to argue for a real astronomical role for such objects. The new work of M. Colpi *et al.* shows that the earlier conclusions — which assumed non-interacting bosons — can be drastically modified if the bosons have the slightest repulsive force among them.

The new work thus demonstrates that boson stars of in principle any mass might be assembled, depending on the interaction strength and mass of the constituent bosons. For example, it follows that a unit interaction strength (of the same order as the strong interaction) and a 1 GeV boson mass would lead to a boson star not of 1 fm, but of 100 m radius, and to the corresponding relativistic maximum mass of 0.1 solar masses. If the bosons were the putative axions of 10^{-5} eV mass, the star would be a crazy 10^{28} times bigger; whereas smaller interaction strengths could produce an object of, for example, the mass of Jupiter. This range indicates at least that boson stars must now be considered candidates to join the observers' menu of theoretical exotic stars.

Why is the interaction important? Essentially because any repulsive force of the order of magnitude of, or greater than, the gravitational force can keep the star buoyed up against gravity. If the force is short-range, at some critical mass gravity will overcome the repulsion and collapse will ensue; but the critical mass will be sensitive to the parameters of the repulsion. As the gravitational force is so weak (10^{-39} times the electromagnetic interaction between protons, for example), the assumption of even an extremely tiny force can have a dramatic effect. This is what Colpi *et al.* observe and develop in a full general-relativistic calculation.

Whatever the details of this calculation, the quantities and orders of magnitude involved are themselves illuminating. To set a baseline, the authors first assume non-interacting bosons. The radius, R, of a relativistic star (one near gravitational collapse, so that gravitationally bound particles have velocities near the speed of light) of such bosons will be of the order of the Compton wavelength of a single relativistic boson. Thus $R \sim 1/m$ in natural units, where m is the mass of the boson. (In natural units Planck's constant and the speed of light are taken to be unity. In such units, with masses in GeV, roughly the proton mass, lengths are approximately in femtometres.) But as the orbits are relativistic, R must be near the Schwarzchild radius GM, where G is Newton's gravitational constant and M is the mass of the 'star'. Combining these equations we find $M \sim 1/Gm$. Now we can replace G by its expression in terms of the Planck mass — the mass M_p such that the gravitational self-coupling GM_p^2 is roughly unity, and we find that the mass of the 'star' is $M \sim M_p^2/m$. This reproduces the bones of Ruffini and Bonazzola's result. The mass density of such a star would be M/R^3, or $M_p^2 m^2$, a gargantuan 10^{38} times nuclear density for 1-GeV bosons.

The first appropriate expression of Colpi *et al.* for the energy density of the interacting bosons, if ϕ is the boson field (or wavefunction, to use a more familiar name), is $m^2\phi^2 + \lambda\ \phi^4$. Here the first term approximates the mass and kinetic energy of a relativistic particle and the second is the assumed contact interaction term, which would arise, for example, if the bosons repelled one another by the exchange of a heavy intermediate particle. The question now is, what do we mean by 'small' interactions being important? By small we must mean that $\lambda\phi^4 << m^2\phi^2$, in other words that the interaction energy is much less than the kinetic or mass term. To extract λ from this inequality it is necessary to know the value of ϕ, the boson amplitude in the star. But the mass density of the star is $M_p^2 m^2$, as shown above, which must equal the boson-energy density. If λ is 'small' we can set the latter equal to $m^2\phi^2$. As a result, we see $\phi \sim M_p$, so that finally we get the limit on λ that $\lambda << (m^2/M_p^2) = Gm^2$. This means the self-interaction must be much weaker than gravity if its effect is to be negligible.

The next problem is to develop the theory with large λ, but the problem (S. L. Shapiro, personal communication) is that there are two dimensionless quantities to deal with in the calculations: λ and m/M_p. Hand-waving arguments thus fail to give any guidance, and it is necessary to solve the full relativistic equations. The resulting maximum boson star masses work out, for 'large' λ, to be around $M \sim 0.1 M_\odot \lambda^{1/2}/m^2$, with $M_\odot$ the mass of the Sun, rising as expected with the repulsion but falling as the square of the boson mass.

This is not the end of the story, however: refinements are still needed. Colpi *et al.* would like to deal with Higgs bosons, key elements of current unified field theories which in the empty (pre-inflationary) vacuum have an energy density much like that assumed above but with an attractive term (λ is negative). This leads to a condensation of Higgs field in the vacuum at the minimum of the energy density function (rather like the transition to superconduction in a superconductor). The condensate shortens the range of the weak interaction, giving the intermediate vector bosons the corresponding mass. Oscillations of the Higgs density are also allowed, and the corresponding waves are, in principle, observable, through wave–particle duality, as Higgs 'particles'. These are bosons, and could form boson stars — Higgs stars. Inside such stars, the Higgs field (which creates all particle masses) will vary, and the most intriguing physical possibilities arise. Unfortunately, Colpi *et al.* have so far been unable to solve the appropriate equations, which involve cubic as well as quartic terms, but work is in hand.

The group must also include the possibility of gauge forces such as colour and electromagnetism amongst the bosons. So far, Colpi *et al.* have assumed the particles to be neutral to a level equivalent to that of Ruffini and Bonizzola's neglect of possible λ terms. If the bosons were gauge charged, but on average neutral, the result would be an attractive force and the bose stars would undoubtedly collapse. So it will be necessary to consider non-neutral stars, those with a net gauge charge. Work on such stars, including the full Higgs terms, is now under way (S. L. Shapiro, personal communication). □

Plant molecular biology

Tailoring crop improvement

Chris Lamb and Leona Fitzmaurice

GENE manipulation techniques are likely to result in great improvements in crop production. Successful first steps towards introduction of disease resistance and herbicide resistance in plants were reported at a recent meeting*.

Cross-protection, inoculation of plants with mild strains of viruses, is often used to reduce losses due to more virulent strains, such as tobacco mosaic virus. To elucidate the molecular mechanism of resistance to tobacco mosaic virus infection, a chimaeric gene containing a cloned complementary DNA of the virus coat protein under the control of the cauliflower mosaic virus 35S transcript promoter has been introduced into tobacco cells on a tumour-inducing plasmid of *Agrobacterium tumifaciens*. The transfected plants produce high levels of the virus coat protein (R. Beachy, Washington University, St Louis; ref. 1). Protection from the virus, manifested as a marked delay in the appearance of symptoms, is dosage-dependent and can be partially overcome by inoculation with naked viral RNA. The number of primary sites of infection may be reduced when the virus is encapsulated by the coat protein, and the limited amount of protection to naked viral RNA suggests that there is a second mechanism affecting viral replication or spread. It will be of interest to see whether this strategy for engineering protection will be useful in other plants.

There has been progress in improving resistance of some plants to the broad-spectrum herbicide glyphosate, which inhibits the enzyme 5-enolpyruvyl shikimate 3-phosphate synthase (ESPS). A mutant bacterial enzyme which is insensitive to glyphosate inhibition confers some resistance to the herbicide when expressed in the cytoplasm of transgenic plantlets[2,3]. The plant enzyme is chloroplastic, and by expression of a chimaeric gene comprising transit peptide sequences of the small subunit (*ssu*) gene of ribulose bisphosphate carboxylase fused to the glyphosate-insensitive bacterial gene, the resistant ESPS can be made to accumulate rapidly in chloroplasts of transgenic plantlets (G. della Cioppa, Monsanto, St Louis; ref. 4). These plantlets are 1,000-fold less sensitive to the herbicide than those in which the transgene product accumulates in the cytoplasm.

Transgene regulation and protein targeting will be crucial for effective engineering, and new data indicate that 5′ flanking regions are not the only place where *cis*-acting gene regulatory sequences act. In petunia, the ribulose bisphosphate carboxylase small subunit is encoded by a family of eight genes that exhibit markedly different levels of expression. Analysis of the expression of transgenes comprising 5′ flanking, coding and 3′ flanking regions of different *ssu* genes indicates that sequences within the gene and 3′ flanking region have a major impact on expression (C. Dean and J. Bedbrook, Advanced Genetic Sciences, Inc.). Similarly, in chimaeric gene constructs containing the chloramphenicol acetyl transferase (*cat*) reporter gene and various promoters, the first intron from the maize alcohol dehydrogenase-1 (*Adh-1*) gene has a great impact on expression in electroporated maize protoplasts (V. Walbot, Stanford University). Expression of *cat* increased nearly 200-fold with the weakest promoter tested, 60-fold with the *Adh-1* promoter, and only 7-fold with the cauliflower mosaic virus 35S promoter, the most efficient promoter tested.

Future prospects depend on the development of an increased repertoire of gene transfer methods and systems, as well as the identification of plant genes that are agriculturally significant targets for manipulation. It is striking that only one plant receptor has so far been cloned — the photoreceptor phytochrome, involved in morphogenetic and tropic responses[5,6]. Two isoforms of phytochrome have been identified in etiolated plants. This polymorphism, as well as differences identified between phytochromes in etiolated and in green plants[7], could have considerable functional significance. The different polypeptides seem to arise from differential expression of members of a small gene family, although alternate translation of a single transcript, as well as post-translational modification of the proteins, may also be involved (P. Quail, University of Wisconsin, Madison). The au^{w} mutant of tomato exhibits many features of etiolated plants, and protein blot analysis indicates that the level of a phytochrome polypeptide is very low in the mutant. This system offers the potential for studying the relationships between structure and function of this receptor by examination of the effects of specific mutations engineered *in vitro* on phytochrome levels in transgenic plants following re-insertion of the modified genes, and may provide opportunities for precise engineering of changes in day-length requirements and response to shading of target crop plants.

Arabidopsis thaliana, the common wall cress, possesses several attractive features (ref. 8 and discussed in *News and Views*[9]). Its generation time of 4–5 weeks, the ease with which it may be propagated in large numbers, its lack of repetitive sequences and small genome size (about 70,000 kilobase pairs)[10] are advantageous for the rapid identification and cloning of mutated plant gene sequences. C. Somerville (Michigan State University) produced three *Arabidopsis* plants resistant to sulphonylurea by screening 300,000 mutagenized seedlings[11]. In collaboration with J. Smith and B. Mazur (DuPont), a yeast acetolactase synthetase gene was used to identify the gene encoding the *Arabidopsis* enzyme in a genomic library generated from one of these sulphonylurea-resistant plants. Somerville also identified *Arabidopsis* mutants that are defective in lipid biosynthesis[12]. Mutants for many of the biosynthetic steps, including most of the desaturase steps, can be identified by gas chromatographic analyses of leaf tissue derived from mutagenized plants. When these data are combined with two-dimensional gel analyses of proteins, it will be possible to identify proteins that are differentially expressed in the mutants and to clone the genes of this pathway.

P. Ahlquist (University of Wisconsin, Madison) described the designed modification of brome mosaic virus for use as a vector[13]. Extremely high levels of expression can be achieved with this gene transfer system. Milligramme quantities of virion coat protein are produced in infections with the wild-type virus. With engineered constructs, *cat* activity already has been obtained which is five- to fifteen-fold greater than that achieved with tumour-inducing plasmid-based vectors, and may be further increased by control of messenger RNA and/or protein degradation. Future potential advantages of this viral vector are the broad range of monocot and dicot hosts as well as effective gene transfer to vegetative cells of perennial crop plants. □

IN
THE NICK
OF
TIME.

With the Pharmacia NICK™-Column you don't need to compromise.

CHOOSE HIGH RECOVERY AND PURE SAMPLE. Your DNA recovery is at least 90% with less than 1% contamination of the nucleotides originally present in the sample.

CHOOSE SPEED AND CONVENIENCE. Your purified sample of nick-translated DNA is eluted in two minutes after column equilibration.

GET HIGH REPRODUCIBILITY. Pharmacia Sephadex® DNA Grade and our thorough quality assurance means that you get consistent results from batch to batch.

GET READY FOR IMMEDIATE USE. NICK-Columns are ready to use, prepacked with Sephadex G-50 DNA Grade, and a complete step-by-step protocol which comes with every pack.

Put Du Pont's Knowledge in Molecular Biology to Work for You

Because we ourselves are biotechnology researchers, all Du Pont products are designed with an in-depth understanding of your needs. Each product is manufactured to meet high quality standards. This assurance of reliable performance can help save you precious research time and money... again and again.

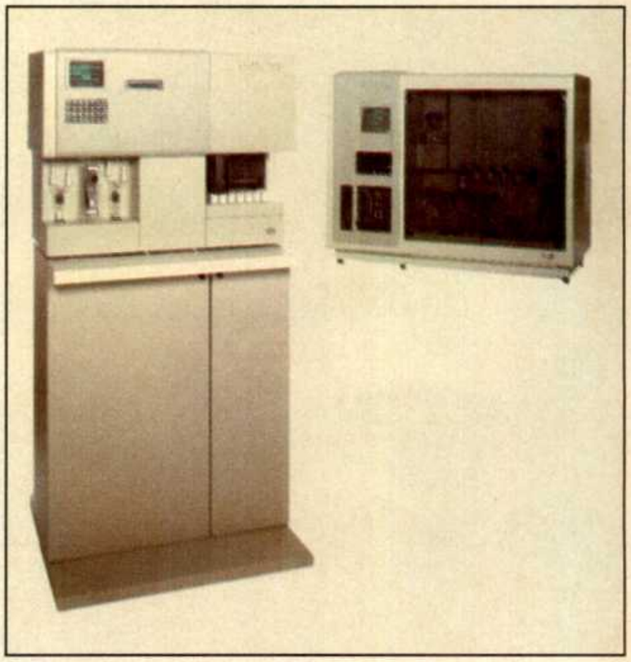
And, all are backed by a comprehensive support network of skilled technical experts and service representatives who are on call for you.

But you already know how well our knowledge works. We're the company providing over 1,000 molecular biology research tools, including widely used and highly accepted NEN® labeled chemicals such as ^{32}P nucleotides and ^{35}S amino acids; molecular biology research systems, such as the Nick Translation and *in vitro* Translation Kits; and NENSORB™ 20 nucleic acid purification cartridges. In addition, we provide SORVALL® Ultracentrifuges and ZORBAX® Bio Series HPLC Columns for molecular biology research.

Now, we bring you a new family of molecular genetic instruments to support you and your work in molecular biology.

Save research time in molecular synthesis with programmed strategy selection

COUPLER® 2100 Peptide Synthesizer—The new COUPLER® 2100 introduces Integrated Synthesis Logic (ISL). It considers both the amino acid being coupled and the existing peptide sequence, then selects and executes the most efficient coupling strategy... just as you would. The COUPLER® 2100 automates the formation of amino acid symmetrical anhydrides and active esters. And you can synthesize either 0.5 mmol or 2.0 mmol of peptide.



Du Pont's COUPLER® 2100 Peptide Synthesizer (left) and CODER® 300 DNA Synthesizer.

CODER® 300 DNA Synthesizer—The new CODER® 300 uses cyanoethyl phosphoramidite chemistry for state-of-the-art yields and purity, and has a flexible operating scale of 0.25, 1.0 or 5.0 μmol. Its unique solvent control system with proprietary low-volume/high-cycle reliable valves ensures superior mixing and highly efficient reagent use.

An unbeatable pair from Olympus

Olympus' new CK2 and IMT-2 inverted photomicroscopes redefine tissue culture microscopy.

Exceptional versatility and ease of operation are superbly blended into the Olympus CK2 and IMT-2 inverted tissue culture photomicroscopes.

The CK2 provides superior routine research functions in phase contrast microscopy and in photomicrography. And it's in a class by itself. Because it has a unique single-condenser system that is capable of handling a full range of magnifications from 4X to 40X—without changing condensers. Newly designed LB objectives capture crisper, sharper, aberration-free images for observation and photomicrography.

The sophisticated IMT-2 advanced research photomicroscope sets new standards of excellence. Its versatility is virtually unlimited, handling a full range of methodologies with minimal adjustments.

Superior high resolution optics, multiple viewing and multi-format photomicrography, a sextuple revolving nosepiece, and a wide variety of components make the IMT-2 ideally suited to tissue culture research and photomicrography.

Olympus — creating new standards in biomedical technology.

CELL BIOLOGY TITLES FROM ELSEVIER

CELL STRUCTURE AND FUNCTION

Published by the Japan Society for Cell Biology (JSCB)
Distributed outside Japan by Elsevier Science Publishers

Editor-in-Chief:
Y. TASHIRO, *Department of Physiology, Kansai Medical University, Moriguchi-shi, Osaka 570, Japan*

Assistant Editor:
K. OMORI, *Kansai Medical University*

Aims and Scope
Cell Structure and Function publishes reviews and original research reports on the biology of cells from the molecular level to the level of cell differentiation and cell interaction. Preference is given to papers with an interdisciplinary approach using recent techniques of investigation in biochemistry, biophysics, molecular biology and structural organization. Papers with applied or clinical aspects will also be considered. A worldwide authorship is encouraged.

Subscription Information
1987 – Vol. 12 (1 vol. in 4 issues)
Price: US $ 106.00/Dfl. 265.00 including postage and handling.
US $ price is definitive.
Please apply to Amsterdam or New York address below.
ISSN 0386-7196

BIOLOGY OF THE CELL

Published under the auspices of the European Cell Biology Organization

Editor-in-Chief:
D. SANDOZ, *Centre de Biologie Cellulaire du CNRS, 67 rue Maurice Gunsbourg, 94200 Ivry sur Seine*

Editors:
R. CHARRET, *Paris/Orsay,* **M. DUBOS,** *Paris/Clamart* and **D. SZAFARZ,** *Paris/Orsay*

Aims and Scope
Biology of the Cell is an international journal publishing original reports, review articles and rapid communications concerning the structure and function of cells in the context of developmental biology, genetics, immunology and physiology. Papers about prokaryotes and viruses are also welcomed as well as those on new methodologies for cell study. Especially favoured are results obtained by complementary methodologies using recent techniques of investigation in cellular and molecular biology, which permit the comprehension of structural/functional relations in normal and pathologic cells. Papers devoted to *in vitro* and *in vivo* cell differentiation and cell interaction as well as those reporting original results on the organization of genetic material, cytoskeleton and membrane traffic are also of particular interest.
Special attention is given by the editor to the high quality reproduction of the illustrations.

Subscription Information
1987 – Vols. 59-61 (3 vols. in 9 issues)
Price: France: 1395 FF including postage, handling and V.A.T.
Rest of the world: US $ 219.00 including postage and handling

CELL DIFFERENTIATION

The official journal of the International Society of Developmental Biologists (I.S.D.B.)

Editor-in-Chief:
L. SAXÉN, *Department of Pathology, University of Helsinki, Haartmaninkatu 3, SF-00290 Helsinki 29, Finland*

Associate Editor-in-Chief:
T. S. OKADA, *National Institute for Basic Biology, Myodaiji-cho 38, Okazaki, Aichi-ken 444, Japan*

Cell Differentiation is an international journal which serves its contributors by the rapid publication of novel research on **all** aspects of cellular differentiation in eukaryotes. Papers deal with molecular and structural aspects of cytodifferentiation and morphogenesis; gametogenesis and fertilisation; molecular and structural aspects of early development; cell and tissue interactions; pattern formation; genetic control of differentiation; growth factors and differentiation factors; and regeneration.

TITLES IN CELL BIOLOGY FROM

· ACADEMIC PRESS ·

Gene Activity in Early Development

Third Edition

Eric H. Davidson

September 1986, 490pp., $49.50/£41.50 (UK only), ISBN: 0.12.205161.0

This new third edition reflects the ten years of technological progress since the last edition. Providing a unique blend of classical and molecular knowledge, it discusses all major embryonic systems from both a comparative and mechanistic point of view. In deriving overall interpretations of developmental phenomena, it brings into play all the disparate forms of evidence, including genetic, molecular, and cytological.

Transport and Diffusion Across Cell Membranes

Wilfred D. Stein

1986, 685pp., $49.95/£42.50 (UK only), ISBN: 0.12.664661.9 Pbk.
$79.50/£67.00 (UK only), ISBN: 0.12.664660.0 Hbk.

Enhanced by numerous references and citations of important experimental findings in the field of biological transport, this volume thoroughly covers the molecular and kinetic aspects of the movement of molecules and ions across cell membranes. Step-by-step treatment of methods, kinetics, and design principles makes this volume very accessible to researchers who need an up-to-date, reliable resource on membrane transport.

Cell Culture and Somatic Cell Genetics of Plants

Volume 3 Plant Regeneration and Genetic Variability

Edited by **Indra K. Vasil**

1986, 688pp., $89.50/£74.50 (UK only), ISBN: 0.12.715003.X

This volume addresses the problems and questions surrounding the culture and modification of the many major crop plants, their regeneration, and the use of genetic variability to breed new, improved varieties.

Cell Separation

Volume 4 Methods and Selected Applications

Edited by Thomas C. Pretlow II and Theresa P. Pretlow

December 1986, 368pp., $59.50/£49.50 (UK only), ISBN: 0.12.564504.X

Methods for separation of specific types of cells such as cancer, basophil, and lymphoid are included in this volume of the treatise, which is designed for use by those not expert in cell separation who are searching for appropriate methods.

Current Topics in Cellular Regulation

Volume 28

Edited by **Bernard L. Horecker and Earl R. Stadtman**

December 1986, 337pp., $75.00/£62.50 (UK only), ISBN: 0.12.152828.6

prices subject to change without notice

Angiogenesis

O. Hudliká and K. R. Tyler

November 1986, c.230pp., $40.00/£25.00 (UK only), ISBN: 0.12.360130.4

This volume is a unique synthesis of information on the many aspects of blood vessel growth (angiogenesis) reflecting the increase in interest that has occurred in this field following the discovery of many growth factors and the development of appropriate tissue culture techniques. This material will be of relevance to a wide audience, including both basic researchers and clinicians, summarizing current knowledge and presenting hypotheses for future investigation.

Contents: Introduction. Techniques for Investigation of Capillary Growth. Growth of Vessels *In vitro* and *In vivo* — General Aspects. Growth of Vessels During Pre- and Postnatal Development. Comparative Aspects of Differentiation and Growth of Microcirculation in Different Species. Growth of Vessels in Normal Adult Tissues. Growth of Vessels Under Pathological Conditions. Factors Involved in the Growth of Vessels. Factors in the Inhibition of Vessel Growth. Conclusions.

Dimensions in Aging

The 1986 Sandoz Lectures in Gerontology

Edited by **M. Bergener, M. Ermini and H.B. Stahelin**

December 1986, c.350pp., $45.00/£25.00 (UK only), ISBN: 0.12.090162.5

This volume forms the proceedings of the 1986 Sandoz Lectures in Gerontology at which papers were presented by eminent scientists from various domains of aging research. As such it provides a valuable record of current research in this field and will interest all those involved in biological, medical and sociological aspects of gerontological research.

Under New Editorship

Genetic Engineering *Volume 5*

Edited by **Peter W.J. Rigby**

1986, 112pp., $19.00/£11.50 (UK only), ISBN: 0.12.270305.7 Pbk.

"The fifth volume in the series Genetic Engineering is now available. The emphasis under the editorship of Peter Rigby has moved away from reviews on the techniques of genetic engineering towards articles reviewing key areas of biology which, as a result of these techniques have been reborn."

Ann Dell, New Scientist, September 1986

Contents: Oncogenes, *A. Hall.* The Regulation of Gene Expression in *Eschericha coli* and its Bacteriophage, *C.F. Higgins.* Genes of the Immune System, *M. Steinmetz.*

Genetic Engineering Volumes 6—8

Articles in preparation include: The Genomes and Genetic Engineering of Plant Cytoplasms, *D.M. Lonsdale.* Vectors for Plant Engineering, *C.P. Lichtenstein.* The Structure and Function of Plant Genes, *J. Messing.* Molecular Biology of Parasites Causing Human Disease, *J.G. Scaife.* Molecular Biology of Trypanosomes, *C.E. Clayton.* Genes Controlling Development in *Drosophila, M.E. Akam.* Production or Proteins in Animal Cells, *M. Bendig.* Site Directed Mutagenesis, *G. Winter.*

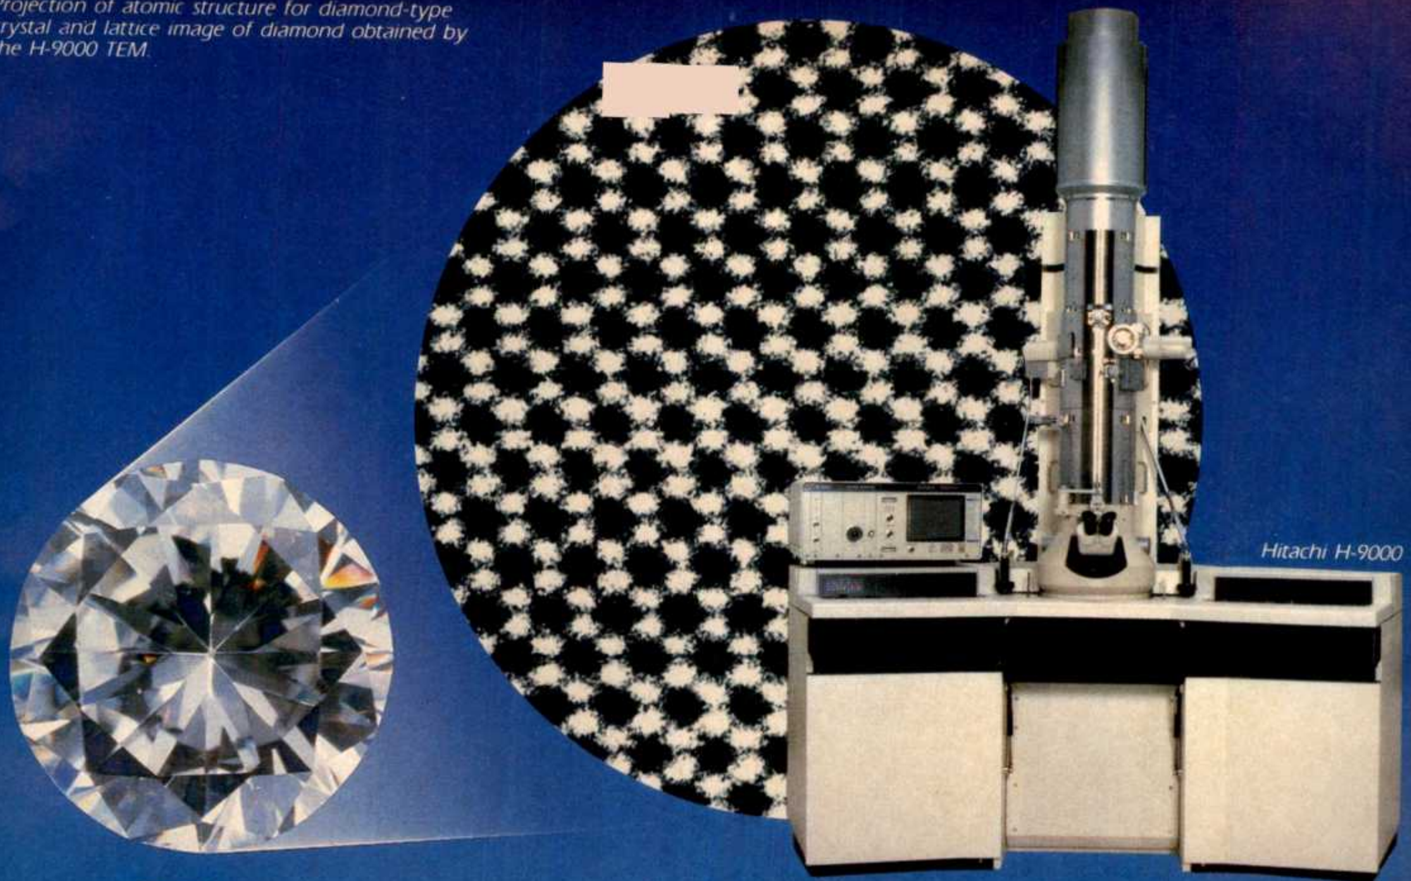
Interferon *Volume 7*

Edited by **I. Gresser**

November 1986, 224pp., $29.50/£16.00 (UK only), ISBN: 0.12.302256.8

24-28 OVAL ROAD, LONDON NW1 7DX, ENGLAND • ORLANDO, FLORIDA 32887, U.S.A.

Reader Service No.45



Projection of atomic structure for diamond-type crystal and lattice image of diamond obtained by the H-9000 TEM.

Hitachi H-9000

Clear as a Diamond

The Hitachi H-9000 300-kV TEM produces images with the stunning brilliance of a diamond.

The incredible penetration power and superb ultrahigh resolution of the Hitachi H-9000 300-kV transmission electron microscope has produced the world's first micrographs of the atomic structure of the diamond.

Dramatic Improvement Over Conventional 100-kV and 200-kV TEMs

Combining improved imaging resolution, a specimen penetration proportional to the electron velocity, an improved electron diffraction mode accuracy, and an improved spatial resolution for X-ray analysis, in which spread of beam penetration within a specimen is inversely proportional to the accelerating voltage, the Hitachi H-9000 TEM has produced stunningly clear micrographs of the diamond at the atomic level in remarkable detail.

This important achievement dramatically demonstrates the H-9000's ability to observe and analyze thicker specimens — a capability critical to the advancement of materials science, semiconductor technology, biomedical research, and other high-tech fields.

Compact Power

Based on Hitachi's extensive experience in million-volt microscopes, the H-9000 features a 10-stage acceleration system that provides ultrastable accelerating voltages of up to 300kV in an instrument of modest proportions. Enabling simple installation, use, and maintenance, the H-9000 easily fits in a normal-sized laboratory room, and operates just like a conventional 100-kV or 200-kV TEM.

Sophisticated Analytical Features

In addition to the conventional Be-window detector, a UTW detector may be mounted simultaneously, forming a dual EDX detection system. A special EELS using secondary aberration corrected three-dimensional focus spectrometry provides optimum analytical capability at 300kV. A TV monitor image intensifier system, SEM/STEM analytical applications, and a CBED fine probe add to the capabilities of the H-9000, one of the most powerful analytical microscopic systems available today.

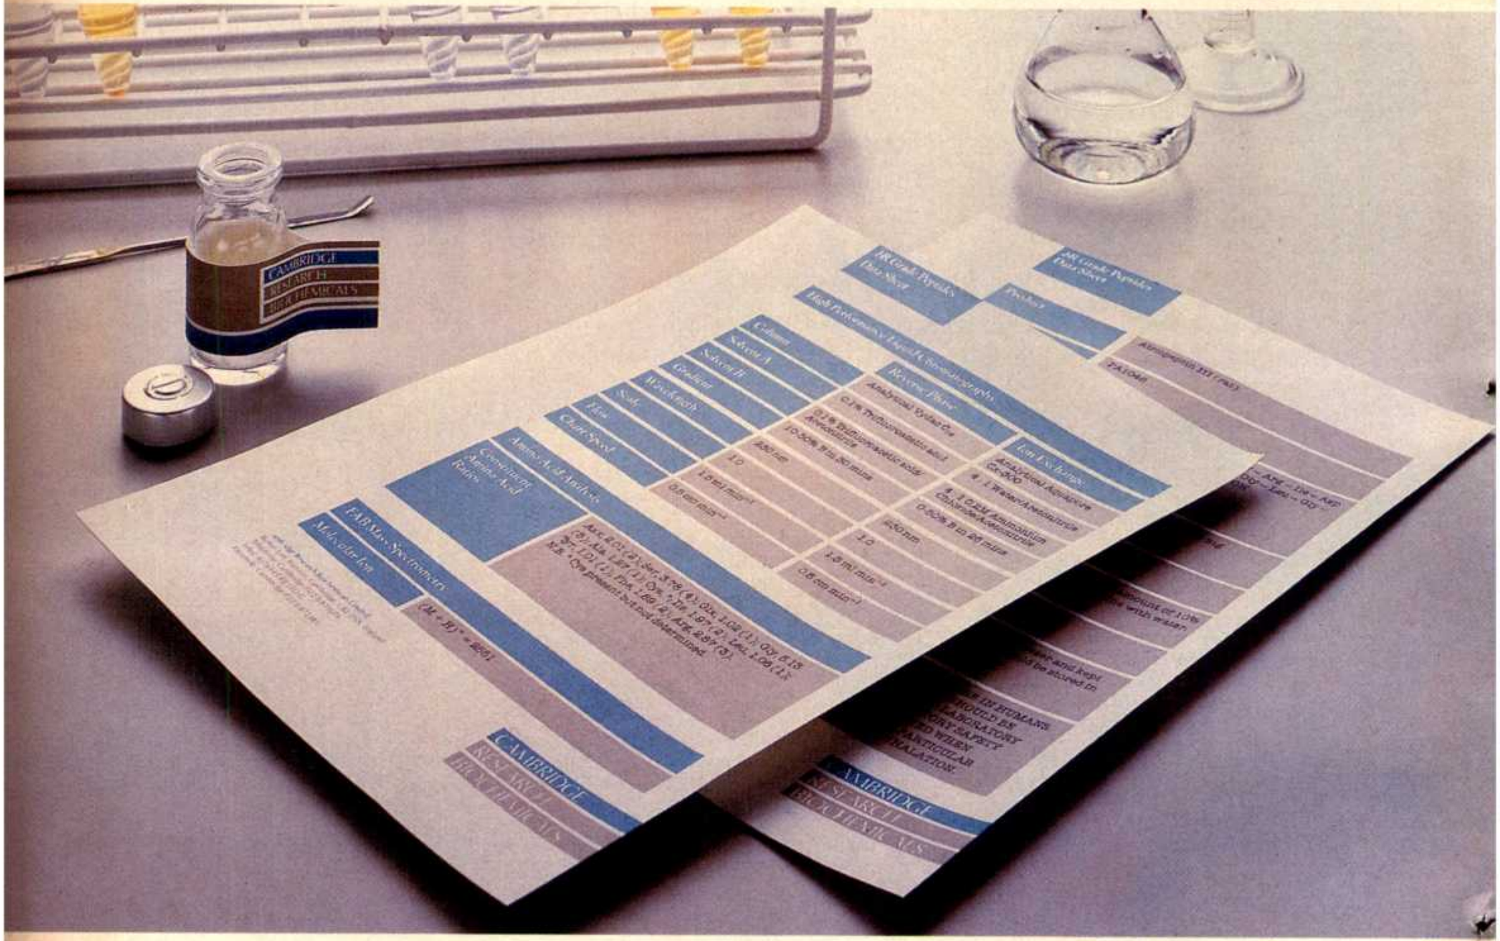
Free with every full analysis from Cambridge...



...a bR grade peptide.

The new range of 'biological reagent', (bR grade) peptides from Cambridge Research Biochemicals guarantees you a truly defined product for consistent, accurate results.

Setting the standard in peptide specification, each bR grade reagent is supplied by net peptide weight as determined by amino-acid analysis and enables standard solutions to be made directly from each vial.

Each product comes complete with a full analysis including amino-acid composition, high resolution HPLC and FAB mass spectrometry data confirming molecular weight, together with detailed storage and handling information.

Send now for your free copy of the new 'Cambridge bR Grade Peptides and Antibodies' catalogue which gives full details on over 100 products and custom synthesis services, and discover how bR grade peptides pass with honours at Cambridge.

BSF-2 is not just a differentiation factor

SIR—An interesting point has escaped Hirano *et al.*[1] in their report of the sequence of BSF-2, a B-cell differentiation factor. The point is that the sequence of BSF-2 is identical to that recently described by Haegeman *et al.*[2] of the State University of Ghent for a molecule called 26K. This molecule was originally described as a byproduct of interferon-β_1 (IFN-β_1) produced in human fibroblasts[3,4], and called IFN-β_2 after investigators at the Weizmann Institute detected antiviral activity associated with the molecule[4].

In both laboratories the primary structure of the 26K/IFN-β_2 molecule has been determined by molecular cloning of the complementary DNA[2,4,5]. But the question of whether the natural 26K/IFN-β_2 product possesses antiviral activity has remained a matter of controversy[3]. Hence, its true biological function has remained in question.

A first hint at an answer to this question came from the observation both in the laboratory of J. Content at the Pasteur Institute in Brussels and in our own laboratory that the mRNA for the 26K/IFN-β_2 molecule is induced in fibroblasts by interleukin-1 (IL-1)[6]. This suggested that the molecule might be one of the mediators of the multiple biological effects of IL-1. In an extensive search for biologically active substances released from fibroblasts by treatment with IL-1, Van Damme from our laboratory, together with J. Van Snick of the Ludwig Institute in Brussels discovered that fibroblasts exposed to treatments that induce appearance of the mRNA for 26K/IFN-β_2, release a potent growth factor for B-cell hybridomas and plasmacytomas[7,8]. In an effort to demonstrate whether this hybridoma/plasmacytoma growth factor (HPGF) is identical to the 26K/IFN-β_2 molecule, these investigators found that the mRNA for HPGF hybridizes to a cDNA probe of 26K/IFN-β_2[8]. Subsequently, HPGF was purified to homogeneity and, in collaboration with R. Simpson of the Ludwig Institute in Melbourne, its amino terminus was sequenced. This sequence matches exactly that predicted from the 26K cDNA clones and allows us to identify exactly the cleavage point between the signal peptide and the mature protein.

Recently there has been renewed interest in the possibility that the molecule may have direct antiviral activity[9]. Two cytokines, IL-1 and tumour necrosis factor (TNF-α), which are both able to induce the mRNA for the factor[6,9], also possess antiviral activity that can be neutralized by antisera against interferon-β. The question is whether these antiviral effects are mediated by IFN-β_1 or IFN-β_2. By using the B-cell promoting effect as an assay system, we have succeeded in preparing an antiserum that reacts with 26K/IFN-β_2 but not with IFN-β_1. This antiserum fails to neutralize the antiviral effect of IL-1 and TNF (J. Van Damme *et al.*, unpublished data). In contrast, sera that are specific for IFN-β_1 and do not neutralize the HPGF activity of 26K/IFN-β_2, do neutralize the antiviral effects of IL-1 and TNF[10]. This clearly demonstrates that IFN-β_2 does not play a role in the antiviral effect of IL-1 or TNF.

In conclusion, the substances known as BSF-2, IFN-β_2 26K and HPGF are one and the same. The substance certainly qualifies as a B-cell differentiation and growth factor but has little, if any, antiviral activity.

Plant tumour induction

SIR—In Conrad Lichtenstein's otherwise excellent short comment on tumour induction by *Agrobacterium tumefaciens*[1], he omitted to mention the biological context of the bacterium. Wounding is a prerequisite for tumour formation, the basis for which is that wounded cells release inducers, such as acetosyringone, that activate the *vir*-region of the Ti plasmid of the bacterium, and thus facilitate its T-DNA transfer. *A. tumefaciens* occurs in the rhizosphere, and has been demonstrated to bind to plant cells. This implies that the bacterium is attracted to plants, but the biochemical basis for this has been left unexplained.

Intrigued, we set out to investigate chemotaxis in *Agrobacterium*. Using the methods of Adler[2,3], we have demonstrated that *A. tumefaciens* is capable of chemotaxis towards a range of phenolic plant wound exudates[4] including vanillyl alcohol. Crucially, we have discovered that chemotaxis towards the acetosyringone is determined by the Ti-plasmid. Interestingly, the chemotactic optimum occurs at 100 nM acetosyringone, some 100-fold lower than the concentration giving maximal *vir*-induction.

This suggests a biological system in which acetosyringone, at low concentrations, acts as a chemoattractant for *A. tumefaciens*. The bacterium thus moves up the concentration gradient towards the wounded plant cells. Then at higher concentrations, acetosyringone causes *vir*-induction, and ultimately T-DNA transfer.

An alternative view of the origin of life

SIR—In his *News and Views* item on the discovery of enzymatic activities in RNA molecules, Gilbert goes on to "contemplate an RNA world, containing only RNA molecules that serve to catalyse the synthesis of themselves"[1]. But what would be the source of energy in this RNA-run world? Another, and more basic question is, all these RNAs to what end? Are we interested in finding mere self-replicating machinery as an answer to the origin of life, or are we looking for a prototype of the self-propagating form as it exists in an organism?

At the simplest level, life is a massive molecular network that is able to gather a few substances to make usable energy and more molecules of different types that permit the replication of genetic material, which contains the information to run the network. The genetic material, the encoded proteins and the intermediary RNAs have received ready recognition from those engaged in the study of origin of life and its evolution; the tiny metabolites whose numerous linear, branched and cyclical conversions constitute the network, have received next to no attention. This is like embarking on the study of a kingdom and concentrating only on the king's family.

Enzymes can conceivably arise as the result of the formation of appropriate sequences of nucleic acids by random associations of nucleotides; but what function (and hence what selection value) can any of them have if there is no substrate to act upon? And, where does the substrate come from and what happens to the product? Meaningfulness demands a full pathway; but a pathway by itself is as meaningless as an enzyme in isolation. Pathways have to be able to interact with each other. The hypothesis of the formation of life by random associations of nucleotides and selection suffers from the need for prior and continual (for who knows when the gene encoding the proper enzyme might arise?) existence of the substrate molecules.

The 'central dogma' asserting the one-way transfer of information from DNA-to-RNA-to-protein has been challenged, apart from reverse transcriptase, by the proposition of reverse translation[2,3], and impressive evidence exists that anticodons and their corresponding amino acids show good sterochemical fits (see ref. 4). These findings deserve to be kept in view in any formulation on the origin of genes. It is conceivable that amino acids arranged around a prebiotically-formed stable molecule (all contained in the 'soup' trapped in the self-assembled lipid bilayer) became linked to form a miniprotein. If the miniprotein had catalytic activity for the stable molecule, this 'substrate' would be converted to a new molecule, setting in motion the formation of a pathway. Branching of pathways can be visualized as two distinct types of arrangement of amino acids around a molecule, generating two enzymes for the same substrate. In time the minienzymes could be reverse-translated and reversed-transcribed to minigenes. Their integration would form the genome, providing an explanation for the clustering of functionally related genes in bacteria.

The origin and evolution of life is the most basic problem of biology. Its elucidation demands the widest permissible latitude in thinking. Is it not time that we did away with the dictates of dogmas and labels like 'heresy'?

The kingdoms of organisms

SIR—Having been concerned with the proper definition of eukaryote kingdoms[1-5], I wish to comment on the controversy over prokaryote kingdoms between Lake[6,7], Woese[8] and colleagues[9,10]. Three distinct questions are at issue: phylogeny, the chopping up of phylogenetic trees to make taxa, and the ranking of taxa. As Woese rightly insists, only phylogeny is a matter of objective science; the others, however, are not merely semantic[8] but questions of taxonomic judgement — that is, a mixture of art and science[11].

None of Lake's three trees[7] is inconsistent with the validity of Archaebacteria as a taxon. He confuses phylogenetics and classification in dismissing as irrelevant those characters he calls "three-and-one"; as if characters unique to all vertebrates are irrelevant to the validity of the taxon Vertebrata because they are irrelevant to overall animal phylogeny. Such characters are the most important of all in defining taxa. The distinctiveness of the wall and membrane chemistries of archaebacteria and eubacteria and their congruence with rRNA and tRNA sequences justifies the subdivision of prokaryotes into two major taxa of equal rank, the Archaebacteria and Eubacteria. This classification does not "fit all trees"[7]: it would be invalid if either taxon were shown to be polyphyletic, which Lake has not done.

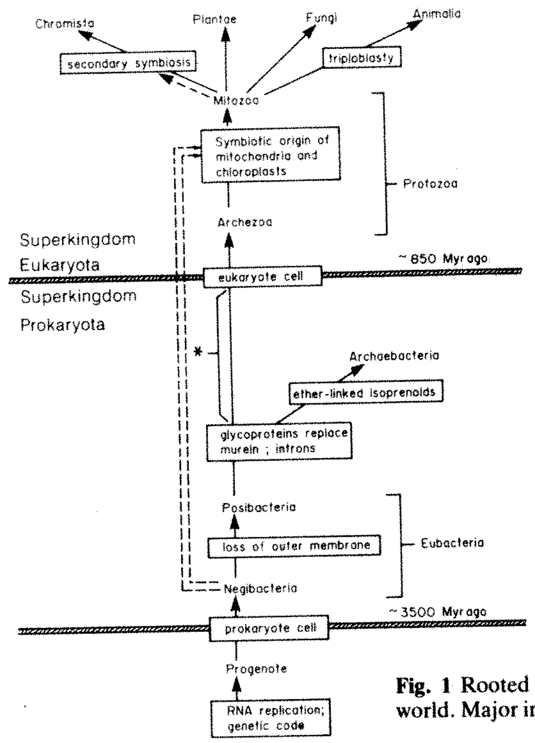

Fig. 1 Rooted phylogenetic tree of the living world. Major innovations shown in boxes.

The characters favoured by Lake are relevant to the subdivision of Archaebacteria into lower taxa and to which archaebacterial phenotype is closest to their nearest eubacterial relative. But his discussion of the distribution of the arginine deiminase pathway is flawed by ignoring evolutionary loss: repeated independent loss of characters in different lineages is common in evolution and is the most parsimonious explanation for the patchy distribution of arginine deiminase in bacteria. Because loss of enzymes is easy, one must not give too much taxonomic weight to the mere absence of a pathway of metabolite; many differences between Halobacteria and Methanobacteria can be attributed to the loss of ancestral proteins by the latter. The differences demand separation at least at the level of class but not at the level of kingdom or subkingdom. Similarities in RNA polymerases, antibiotic sensitivities and rRNAs make it sensible to rank Methanobacteria and Halobacteria as subphyla within a single phylum (=division), for which I propose the name Halomebacteria. I suggest that the sulphur-dependent archaebacteria ('eocytes') be ranked as a separate phylum (=division), the Sulfobacteria. This is compatible with all four 'prokaryote' trees.

The ranking of the taxa Eubacteria, Archaebacteria and Eukaryota has also been insufficiently carefully considered. Woese and Fox[13] referred to them as "urkingdoms"; this term, with no status or rank in the Linnean hierarchy, was chosen to avoid begging the question as to their taxonomic rank. Unfortunately numerous authors have carelessly substituted the Linnean term kingdom. But eukaryotes are universally subdivided into several kingdoms, commonly four[14], and more recently five[3-5]: Animalia, Fungi, Plantae, Protozoa and Chromista. Therefore Eukaryota must be ranked as a superkingdom[1,3], not a kingdom. The subdivision of the living world into two major structural cell types (eukaryote and prokaryote)[15] is in no way invalidated by recognition of the Archaebacteria and Eubacteria. This fundamental divergence, and their even more fundamental similarity in prokaryotic cell structure, can be most usefully represented by ranking Eubacteria and Archaebacteria as kingdoms within the superkingdom Prokaryota[12], rather than as subkingdoms[1,3].

The differences between halobacteria and photosynthetic eubacteria (all negibacteria) are so great that to place them in a 'photocyte' group[16] that excludes other archaebacteria is taxonomically meaningless. The affinities of the archaebacteria lie instead with Gram-positive eubacteria on the one hand and eukaryotes on the other[12]. The phylogeny shown in the accompanying figure is consistent with cell structure[12], with the 16S rRNA tree (if rooted where eubacterial phyla diverge)[8], and with the fossil evidence that eubacteria evolved 2,500 Myr before eukaryotes[17]. Lake's opinion[6,7] that eubacteria have a "fast clock" is counter to the fossil record which suggests they are the most conservative of the three groups, several times more so than eukaryotes.

Postulating a 'fast clock' or a 'slow clock' for a whole group does not explain the close bunching within, compared with the wide separation between, the three major lineages on the rRNA tree[8]. This pattern can be produced only by a temporary phase of accelerated rRNA sequence change during the divergence of the three lineages (on my tree at the time indicated by the asterisk, not seperately in three lineages diverging from the progenote as postulated by Woese).

Because it confuses phylogeny and classification, and is objectionable to eukaryote biologists, the misleading phrase 'three primary kingdoms' should be eschewed and replaced by the accurate 'three major lineages' when referring to the eubacterial, archaebacterial and eukaryotic branches of the tree of life. As there are two kingdoms of prokaryotes, and with the separation of the Chromista and Protozoa, five monophyletic eukaryotic kingdoms, we should speak of 7 not 3 kingdoms.

How many reactor accidents?

SIR—It does not take advanced statistical calculations to conclude that there is a disturbingly high probability of another serious nuclear reactor accident in the next ten years, given that there have been two so far amongst 374 reactors with a total of 4,000 reactor-years experience. In their letter, Islam and Lindgren[1] are undoubtedly right to conclude from these data that the true probability is irreconcilable with the probability apparently claimed by reactor designers on the basis of 'technical risk assessment'. Their statistical arguments, however, are characterized by a failure to distinguish between probability and likelihood, which has led them to make unwarranted statements.

Assuming a Poisson process with parameter r (reactor-years^{-1}) they correctly find the probability of two accidents in T = 4,000 reactor-years to be $\tfrac{1}{2}(rT)^2e^{-rT}$. But they then treat this as an unnormalized probability distribution with parameter r, writing "If we want this to be a probability density, we have to normalize it". But one cannot turn any mathematical function into a probability distribution just by making it integrate to unity, and the function in question is a likelihood function for r, not a probability distribution, and cannot be integrated[2].

By treating the likelihood function as though it were a probability distribution, the authors have unwittingly adopted a Bayesian approach with implicit prior probability distribution dr for r. But even if one wished to admit the Bayesian approach here, no Bayesian would use this prior for a non-negative parameter since its integral obviously diverges and it distorts any analysis in favour of the larger values of r. The commonest Bayesian recommendation[3] is to adopt the arbitrary prior distribution $(1/r)$dr, which would have the effect of shifting the graph of the authors' Fig. 1 to the left, placing its maximum at r = 0.00025 rather than 0.0005.

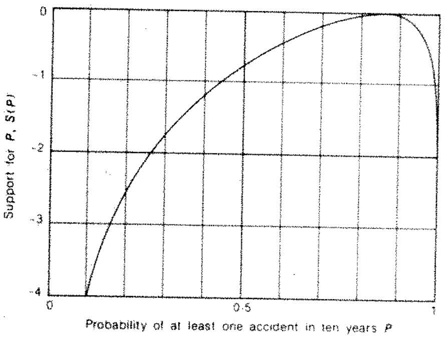

Fig. 1 The support for various values of the probability of at least one reactor accident in ten years, given two accidents in 4,000 reactor-years so far and the continued use of 374 reactors worldwide.

Islam and Lindgren then conclude from an integration of their probability distribution between two values of r that "This [the value 0.21] indicates that the probability that one significant accident will occur between 1,667 and 2,500 reactor years is 21%", a strange statement which presumably rests on an erroneous interpretation of their probability distribution for r (the caption to their Fig. 1 suggests this explanation).

The authors next compute the probability of at least one accident in t reactor-years, integrating out the unknown r in accordance with the Bayesian posterior probability distribution they have derived for it on the basis of the prior distribution dr and the two observations. They conclude "The probability that a reactor accident could happen during the next decade is 86%" (another strange statement since the probability that an accident could happen is manifestly 1; they mean will).

Aside, however, from these detailed criticisms, there remains the major issue of treating a likelihood function as though it were a probability distribution. Avoiding this issue, the analysis might proceed as follows.

As stated above, $\tfrac{1}{2}(rT)^2e^{-rT}$ is the likelihood function for the unknown parameter r in the light of two accidents in T = 4,000 reactor-years, and, as the authors say, the probability of at least one accident in t reactor-years is $P = 1-e^{-rt}$, and r is unknown. But rather than adopt a probability distribution for r we should use the above likelihood function for it and derive the corresponding likelihood for the unknown P by simple substitution: $r = -(1/t)\ln(1-P)$. So the likelihood for P is;

$$L(P) = \tfrac{1}{2}[-(T/t)\ln(1-P)(^2exp)(T/t)\ln(1-P)]$$

It is customary to work with the standardized log-likelihood, or *support*[2], which is;

$$S(P)l = 2\ln[-(T/t)\ln(1-P)] + (T/t)\ln(1-P) + 2 - 2\ln 2$$

(support is standardized by adding a constant so that the support function is zero at its maximum).

Figure 1 shows the support function for P with T = 4,000 and t = 10 × 374 reactor-years. The maximum-likelihood value for the probability of at least one explosion in ten years is seen to be 0.85 but, as is entirely to be expected with only two observations, there is great uncertainty about this value, the 2-unit support limits being 0.26 and 1.00. Islam and Lindgren's Bayesian analysis, by confounding likelihoods and probabilities, completely obscures this uncertainty, and consequently confers spurious scientific accuracy on what can only be an educated guess. All we can really say is that the probability of an accident in the next ten years is unlikely to be less than a quarter — a sufficiently alarming prospect not to detract from the main point they were making.

It may be tiresome to have to maintain these distinctions between likelihood and probability, but they are of especial importance when dealing with sparse data and infrequent events. Physicists usually use statistical theory in connection with large samples, where the finer points of statistical inference are relatively unimportant, but biologists often have to argue from quite small samples. It is no accident that the greatest impetus for the refinement of the logic of statistical inference has come from the biological sciences, and especially from human genetics, where the paucity of the data is matched only by the importance of the inferences. Nuclear accidents fall into the same category.

Stunning whales

Sir—M.A. Taylor's comments on prey echolocation and sonic squid-stunning by whales (*Nature* **323**, 298, 1986) contain an incorrect discussion of the relation between the maximum detection distance by the whale (D) and the maximum distance at which potential prey can detect the whale's echolocating emissions (d). If for simplicity we neglect absorption, refraction, scattering by extraneous bodies, inhomogeneities, anisotropies, near-field and frequency-dependent effects, then the outward power-flux at distance r is $W/4\pi r^2$, and the returning power-flux experienced by the whale is $W\sigma/16\pi^2r^4$, where W is the emitted power and σ is the backscattering cross-section of the prey. If the minimum flux detectable by the whale is S and by the prey is s, we may find D and d from the equations $S = W\sigma/16.235^2D^4$ and $s = W/4\pi d^2$. The ratio d/D is $(WS/\sigma s^2)^{1/4}$. This expression can be made more illuminating by normalizing to prey-length, L, letting $\sigma = \alpha\pi L^2$ and $D = \beta L$, yielding $d/D = 2\beta(S/\alpha s)^{1/2}$. For any useful sonar system, the maximum prey detection range will be several prey-lengths ($\beta > 1$), and typically $\alpha < 1$.

Thus, for roughly equal hearing sensitivity, d/D will be greater than unity, and the prey will be able to take evasive action before detection by the whale. The ratio d/D is not 2, as indicated by Taylor's Fig. 1. This does not affect his fascinating discussion, but the relation given here permits additional variations of strategy in Taylor's "evolutionary arms race".

Body temperature and the specific heat of water

Sir—John Paul attempts to explain why the normal body temperature of homoiotherms is approximately 36 °C by its proximity to the temperature of minimum specific heat of water[1]. He states: "An organism functioning at this temperature will find it necessary to generate or dissipate the minimum amount of heat energy in order to maintain its temperature constant". But the rate of heat loss (and therefore rate of heat generation with which it is balanced) is equal to the temperature differential between body and environment times the heat transfer coefficient ("conductance"). This is independent of heat capacity, or heat content (specific heat times mass times temperature change). In fact, temperature would be maintained more easily if the specific heat and heat content were greater — that is, for a given amount of heat loss, the temperature decrease would be less.

Perhaps a better reason for maintaining body temperature considerably higher than the average ambient temperature is that this ensures that excess heat produced by the high metabolism of terrestrial mammals and birds can be dissipated by conductive, connective and radiative means which require no evaporative water loss[2].

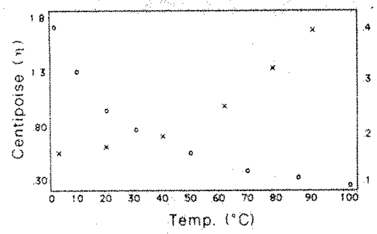
William A. Calder III

Department of Ecology
and Evolutionary Biology,
University of Arizona,
Tucson, Arizona 85721, USA

1. Paul, J. *Nature* **323**, 300 (1986).
2. Calder, W.A. & King, J.R. in *Avian Biology* Vol. 4 (eds Farner, D.S. & King, J.R.) 259–413 (Academic, New York, 1974).

Sir—We were intrigued by the proposal[1] that the nearly constant body temperature (around 36 °C) of many homoiothermic animals can be explained by the fact that the specific heat of water passes through a minimum around this temperature. The explanation offered was that "an organism functioning at this temperature will find it necessary to generate or dissipate the minimum amount of heat energy in order to maintain its temperature constant. From the point of view of the organism's energy economy this temperature is clearly the most efficient at which to function".

This explanation is appealing but it cannot be correct. The amount of heat required to maintain a given temperature is, of course, exactly equal to the amount of heat lost to the environment; this depends on many factors, such as the temperature difference, surface area and thermal conductivity of a body, but it is independent of its specific heat. Moreover, the smaller the specific heat, the larger will be the fluctuations in the temperature of the body, so that the problem of maintaining a constant body temperature becomes all the more difficult. Finally, the specific heat minimum at about 36 °C applies to pure water. Aqueous solutions generally shown no minimum in the specific heat, which usually decreases monotonically as the temperatue drops and is appreciably lower than that of pure water in the relevant temperature region. The specific heat of normal blood plasma is about 6 per cent lower, that of haematopoietic cells about 11 per cent lower[2].



Crosses, solubility; circles, viscosity.

What then is the explanation? We do not know, but most likely, a temperature of around 36 °C, if it is the product of natural selection at all, is selected because it corresponds to an optimal mix of properties. We consider here only two, viscosity and 'hydrophobic' effects.

The rates of many biological processes are limited by diffusion. As temperature rises, long-range structures in water are disrupted, the viscosity decreases, and the rates of diffusion-limited processes become faster. This factor by itself would appear to favour higher body temperatures. But disruption of the long-range structures in water will also lead to changes in hydrophobic effects, which are important in many vital processes, such as substrate binding, protein folding and bilayer membrane formation.

The accompanying figure shows the viscosity of water and, as a measure of hydrophobic forces, the solubility of benzene in water[3], both as a function of temperature. By inspection, a temperature of around 36 °C seems to be a reasonable compromise; high enough to give a low viscosity, low enough that hydrophobic molecules do not dissolve too easily.

What is supersymmetry?

Michael Atiyah

Supersymmetry and its Applications: Superstrings, Anomalies and Supergravity.
Edited by G.W. Gibbons, S.W. Hawking and P.K. Townsend.
Cambridge University Press: 1986. Pp.481. £27.50, $49.50.

PHYSICISTS are an ambitious lot. Their aim is to understand the Universe and what makes it tick. What is matter? What are the forces that act on it? How did it start and where will it end? These, no less, are the monumental questions that theoretical physicists attempt to answer. So far, in historical terms, their track record in answering these questions is quite impressive. The two great triumphs of earlier centuries, Newton's theory of gravitation and Maxwell's theory of electromagnetism, remain outstanding examples of what a physical theory should be. Universal in application, and capable of simple and rigorous formulation in mathematical terms, they provide a firm basis from which to attack complex and realistic problems.

At the core of both theories are the notions of "particles" and "fields", that is of matter and force. Particles produce fields and fields act on particles in a perpetual duet. As physicists have delved further into the nature of this interaction, the theories that have emerged have become more and more complex, both conceptually and mathematically. Einstein altered our view of the separateness of space and time, and his theory of general relativity is much more sophisticated than Newton's, although equally rigorous in its mathematical formulation. Quantum mechanics involved an even greater revolution and its foundations are much less clear. "Elementary particles" have been emerging from the laboratories in ever-increasing numbers, and theories to explain them have been just as numerous.

In all this excitement and turmoil two main problems have always stood out. What are the ultimate "elementary particles"? And how does one reconcile general relativity with quantum mechanics? The first of these is closely tied to experimental discoveries and alters with each new generation of accelerators, while the second is a purely intellectual or mathematical problem because gravitation and quantum mechanics operate at quite different scales.

Quantum field theory aims to provide a theory of elementary particles consistent with quantum mechanics and based on a sophisticated unification of the notions of particle and field. The details of the theory may vary depending on how many kinds of particle one postulates. In fact, it is extremely difficult to construct any mathematically consistent quantum field theory. Many theories are plagued with "ultraviolet divergences" or "anomalies" and the mathematical study of these problems has become quite an industry.

Given all the difficulties, it is not hard to understand why, in the past couple of years, there has been such widespread enthusiasm amongst theoretical physicists for what are called "superstring" theories. These theories appear to offer the first realistic chance of a consistent account of nature which combines quantum field theory and general relativity. As the term suggests, these new theories are a combination of two different ideas, namely strings and supersymmetry, both of which have been investigated separately for some time.

In one form or another, symmetry has always played a prominent part in physics. Essentially, the requirement that a physical law be independent of the particular location or orientation in space or time means that the relevant theory has to admit the appropriate symmetries of space–time. Beyond this physicists have found that elementary particles tend to come in families, and the best explanation has again been couched in terms of symmetries, not of space–time but of some "internal" space.

Particles in quantum mechanics come in two different species, depending on their "spin". There are fermions, which have half-integral spin and obey the Pauli exclusion principle, and bosons which have integral spin and have symmetric wavefunctions. Physically they are fundamentally different but supersymmetry ignores this difference and puts them on an equal footing. Roughly speaking, a supersymmetric theory should allow the interchange of fermions and bosons. Despite its physical implausibility supersymmetry has many theoretical attractions, and the mere requirement that a theory be supersymmetric is so strong that it greatly limits the number of possible candidates. For these reasons it has been extensively studied.

String theory starts from the idea that the idealized picture of a point-particle should be replaced by that of a string. This also has been studied, off and on, for many years with varying degrees of enthusiasm and optimism. The subject really hit the headlines however when, in its supersymmetric form, it was discovered by John Schwarz of Caltech and Michael Green of Queen Mary College that a consistent anomaly-free theory could be constructed. This would in principle give a unified theory of elementary particles, incorporating gravity and quantum mechanics. Since then, there has been intense activity developing the several variants of the superstring theory and examining their consequences.

In 1985 a workshop in Cambridge, UK, was essentially devoted to these latest developments, and this volume records the various contributions. Many of the leading experts were present, and their talks give an authoritative view of the situation. While the material is highly technical, a few talks were addressed to the uninitiated, notably the introduction to strings by Edward Witten of Princeton.

Although superstring theories hold great promise and have generated renewed optimism about unified field theories, they are still very mysterious. The foundations are not at all clear, and surprises are probably in store for us. At the mathematical level, strings are difficult to understand, but it is already clear that they will involve many new techniques and ideas. It should be emphasized that the unification of forces involved in superstring theory takes place way beyond the realms of direct experimental verification. Thus the main tests of the theory are those of internal mathematical consistency. However, these are extremely severe. In fact physicists would like to believe that there is only one possible consistent solution. All they have to do is find it!

Perhaps the final word should be given to Witten, one of the high-priests of the subject, who, having explained the peculiar mathematics of superstrings, goes on to say:

> But the fact that these things work, that these seemingly bizarre rules give ways of computing things in quantum gravity, giving sensible results and finite answers and leading in many different directions to all kinds of beautiful areas in mathematics, is a very deep mystery — probably one of the deepest which has ever been encountered in physics. It is unlikely that a proper understanding of this mystery will be found either soon or simply. But it will be worth the wait. ☐

Sir Michael Atiyah is Royal Society Research Professor in the Mathematical Institute, University of Oxford, 24–29 St Giles, Oxford OX1 3LB, UK.

- Accounts of supersymmetry and associated topics are now reaching textbooks for advanced undergraduates and postgraduates. Four such books have appeared over the past few months and will be reviewed in a future issue of *Nature: Introduction to Supersymmetry* by P.G.O. Freund; *Introduction to Supersymmetry and Supergravity* by P. West; *Supersymmetry, Superfields and Supergravity: An Introduction* by P.P. Srivastava; and *Supersymmetry: A Decade of Development* edited by P. West.

Webs of intrigue

J.L. Cloudsley-Thompson

Spiders: Webs, Behavior, and Evolution. Edited by William A. Shear. *Stanford University Press: 1986. Pp.492. $55.*

WHEN, in his arbitrary way, Callimachus the Alexandrian announced that a big book is a big nuisance, he cannot have had in mind books like this one. It is, indeed, fairly large — nearly 500 pages in length — but far from being a nuisance and a bore it is an intellectual delight. Twenty-five years ago, worthwhile publications on the webs of spiders, their construction and functions, numbered a few dozen at the most. The bibliography of the present volume occupies over 38 pages, and the books and papers listed in it have mostly appeared in recent years.

The 13 chapters have been written by internationally recognized arachnologists, and it is no coincidence that they are either American or have done a lot of work in the United States — no longer is the study of spider behaviour confined to European naturalists and amateur zoologists. Four of the authors are ecologists who look at problems of web-building from the viewpoint of the interactions of spiders with the environment and with one another; eight are interested in behavioural biology (although half of them began as taxonomists); three others adopt a highly technical approach, focusing a laser beam on a single, vibrating silk thread; and one has found computers useful in monitoring the activities of a social species of spider. There are contributions on the selection of web sites, webs as sensory transducers, and the effects of the geometry of webs on their efficiency in catching prey: surprisingly, many orb-web spiders have reduced or even lost their web, so that they use up less rather than more silk.

By the secretion of chemical mimics of the sex-pheromones of Lepidoptera, certain spiders are able to attract male moths to a bolas of silk whirled by one of the legs. Other species construct narrow ladder-webs which attract large numbers of moths; as the prey slides down the elongated web, it sheds its scales until it has lost so many that its body is held firmly in place by the viscid threads. One nocturnal spider has acquired the anomalous behaviour of preying, not on flying insects, but on pedestrian arthropods. Its asterisk-shaped web has no sticky elements, and serves only to signal the presence of prey which is then wrapped with a swathe of silk so that the spider can administer a poisonous bite. Yet other species actively net prey in diminutive webs held between their legs.

Some spiders are kleptoparasites, living in the webs of larger species and stealing prey from them. More than a few attack their hosts as well. There is even a small parasitic spider that crawls over the bodies of larger species, feeding on the fluids that ooze from the prey of their hosts. Other of the more interesting topics developed in the various chapters are the monophyletic origin of the orb-web, and the evolution of web-building behaviour. It may surprise some readers to learn that jumping spiders (Salticidae), the quintessential visual predators of all land invertebrates, and equipped as they are with large and highly specialized eyes, have nevertheless evolved from web-building ancestors.

This is a book of puzzles, problems and paradoxes in spider behaviour, a synthesis of much recent work carried out, often in extremely uncomfortable tropical conditions, by a number of young and enthusiastic research workers. It is not difficult to understand the reasons for their motivation. □

J.L. Cloudsley-Thompson, Department of Zoology, University College London, Gower Street, London WC1E 6BT, UK, is Emeritus Professor of Zoology in the University of London.

Debatable physics

Michael Redhead

The Ghost in the Atom: A Discussion of the Mysteries of Quantum Physics. Edited by P.C.W. Davies and J.R. Brown. *Cambridge University Press: 1986. Pp.157. Hbk £17.50, $29.95; pbk £6.50, $9.95.*

HISTORICALLY, arguments about the interpretation of quantum mechanics divide into three periods. First, from 1927 to 1935, there was the famous debate between Bohr and Einstein over Bohr's complementarity interpretation. Bohr considered that quantum mechanics had led him to a profound metaphysical discovery about the physical world and our epistemological relationship to it; roughly, he argued that a complete understanding of microphysical reality requires us to recognize the existence of incompatible (complementary) descriptions, couched in the language of classical physics, but relativized to the specification of the whole experimental context in which that particular aspect of reality is being displayed. This is the so-called Copenhagen interpretation. Einstein argued that such relativization signalled a limitation in the completeness of the quantum-mechanical description, a fact which he sought finally to demonstrate in the famous paper he wrote with Podolsky and Rosen in 1935.

Bohr refused to accept the reasoning in that paper, and such was his charismatic authority that the scientific community in effect declared him the winner and for the next 30 years Copenhagen orthodoxy reigned supreme. However there were some dissenters, notably David Bohm, who in the early 1950s produced a "completed" interpretation of quantum mechanics along the lines envisaged by Einstein. However, Bohm's interpretation involved violently nonlocal features, whereas Einstein's 1935 paper had been predicated on the assumption of no-action-at-a-distance.

The third period of lively debate stems from the mid-1960s, when John Bell showed that *any* "completed" version of quantum mechanics must exhibit nonlocality as a result of violating the now famous Bell inequality. Two matters have been the centre of recent interest. First, are there any hidden assumptions in Bell's argument in addition to locality which could be impugned if the inequality is violated? And second, is the inequality actually violated experimentally? A succession of positive answers to the second question (after some initial indecisiveness) has culminated in the recent work of Aspect and his collaborators in Paris. With regard to the first question it is now largely accepted that "completed" versions of quantum mechanics do involve some feature of nonlocality, but of a rather subtle kind that does not for example allow the construction of "Bell" telephones for superluminal transmission of information!

The present book originated in a programme for BBC Radio 3 in which Paul Davies interviewed eight physicists with widely differing views on the interpretation of quantum mechanics. The most diehard defender of the orthodox position is Sir Rudolf Peierls. He announces: "there is only one way in which you can understand quantum mechanics". Such dogmatism (which is also factually incorrect) is what a number of other contributors are reacting against. In particular, Bohm and Hiley each explain how the traditional view of an external reality, possessing all its attributes independently of observation, can be accommodated in their quantum potential approach. They fully recognize the holistic or nonlocal features arising in their interpretation, but argue that this does not contradict the special theory of relativity, understood as applying to statistical effects.

Aspect lucidly describes the special features of his own experiments, while John Bell explains how he arrived at his inequality by "thinking intensely all around these questions". Bell usefully emphasizes that Aspect's experiment is not directly concerned with settling questions about indeterminism, of God's playing dice with the Universe, but bears directly on the distinct issue of non-locality. It is true, however, that one's understanding of this nonlocality and its apparent conflict with relativity may look very different from a deterministic and an indeterministic point of view.

David Deutsch explains and defends his own version of the Everett many-universes interpretation, that reality "splits" every time we take a measurement. His claim that the existence of the resulting "parallel" universes could be demonstrated experimentally is interesting but undoubtedly controversial. John Wheeler in his interview explains why he has now abandoned support for the Everett approach — "too much metaphysical baggage", as he puts it. He now leans to the view that the existence of conscious observers is crucial to quantum observation, a view definitely not to be ascribed to Bohr. Indeed it is fair to say that the whole language of observers and observables that clutters up books on quantum mechanics is an unfortunate legacy of a long-outmoded positivist attitude to the nature of science, but which tends regrettably to invite the casual reader to incorporate an ineliminable subjectivity into the understanding of quantum mechanics.

John Taylor attempts to defend what he calls the statistical interpretation, that quantum mechanics is a theory about ensembles of identically prepared systems, and has nothing to say about the single system. It is quite true that the nonlocality difficulties do not arise in terms of statistics. But Taylor's discussion of the Einstein–Podolsky–Rosen experiment is very confused, leading one to believe that mirror-image correlations do not exist in the *statistics* of measurement results on the same spin-component of the two particles. For example, Taylor says that "We can't say in any particular case what that spin of the far away particle is from the measurement nearby". This is potentially misleading, because it might be taken to imply that we cannot predict what the result of a subsequent far-away measurement would reveal, and that is just wrong. Presumably Taylor means that we cannot say what the spin of the far-away particle was *before* the measurement on the nearby particle. This is much closer to Bohr's position than what most people would regard as the statistical interpretation.

In all, this book is a useful introduction to a variety of ideas and approaches about understanding quantum mechanics. It shows that there is no longer a regimented uniformity of view even among "respectable" physicists. That is a healthy sign: dogmatic metaphysical strait-jackets are best consigned to the scientific lumber-room. □

Michael Redhead, currently Professor in the Department of History and Philosophy of Science, King's College London (KQC), Chelsea Campus, Manresa Road, London SW3 6LX, UK, is Professor-elect of History and Philosophy of Science at the University of Cambridge.

Captured in clay — 15,000-year-old models of bison from Le Tuc d' Audoubert cave in the French Pyrenees; the animal in the foreground is 60 cm long. The picture is reproduced from Dark Caves, Bright Visions: Life in Ice Age Europe, *by Randall White, an account in words and pictures of the accomplishments of the inhabitants of Europe during the Upper Palaeolithic (35,000–12,000 years* BP*). The book is based on an exhibition at the American Museum of Natural History, New York, and is published by W. W. Norton. Price is $35.*

Change in the field

Subir K. Banerjee

Environmental Magnetism. By Roy Thompson and Frank Oldfield. *Allen & Unwin:1986. Pp.227. £35, $50.*

THE TITLE of Thompson and Oldfield's book may lead one to think that it deals with the magnetic field and its fluctuations in the human environment. This, however, is not the case. The authors' respective backgrounds are in geophysics and geography, and over the past decade or so they have worked together on the magnetism of terrestrial materials — such as soil, and sediments deposited in lakes, peat bogs and oceans — with the purpose of reconstructing environmental and climatic changes. In spite of the complexities of natural magnetic minerals, the myriad ratios in which two or more such minerals can be present and the simplicity of the magnetic apparatus used, many of the stories told and the examples given constitute brilliant successes in scientific detective work.

Because of the many examples listed, the book will probably be of most use to non-magnetists interested in palaeoenvironmental change. It is well-structured, in that the first six chapters cover the basics of magnetism, magnetic minerals and the behaviour of the geomagnetic field, while the remainder deal with the applications to nature. The diagrams are many and of excellent quality, although a large number of them suffer from lack of acknowledgement of the source so that the reader will mistakenly think that they are either the results of the authors' own work or "given truths" in rock magnetism. For example, in Fig. 4.9 the authors purport to show the grain-size dependence of the ratio of susceptibility to saturation remanence for magnetite, but it is not made clear that these are the results of a thought experiment only. Similarly, on p.56 a non-magnetist not familiar with the literature may interpret the authors' hypothetical model of frequency dependence of susceptibility of very small magnetite grains to be proven, while a thorough test of such a model has yet to be made.

It is important to emphasize that nature's cooperation in sometimes providing a simple mixture of one strongly magnetic and one weakly magnetic mineral (for example, magnetite and haematite) has been most helpful to the authors in solving their magnetoforensic problems. In discussing one particular topic, the magnetism of lake sediments, Thompson and Oldfield themselves point out that "further progress, as distinct from the pragmatic application of the approaches illustrated above to new sites will depend on ... closer and more quantitative specification..." (p.123). I believe that the statement applies to most of the applications of magnetism to the environment, as described in this book. □

FOCUS ON: CELLS

CELL AND MOLECULAR BIOLOGY OF THE CYTOSKELETON
edited by **Jerry W. Shay**
A thorough exploration of the cytoskeleton's molecular, biochemical, and structural properties with an emphasis on how they function in the living cell. Among the outstanding contributions in this volume are chapters on the structural aspects of intermediate filaments, molecular mechanisms controlling tubulin synthesis, probing the cytoskeleton by microinjection, and actin—a regulator of cell growth and differentiation.
0-306-42175-5/356 pp./ill./1986 $49.50 ($59.40 outside US & Canada)

VIDEO MICROSCOPY
by **Shinya Inoué**
A practical handbook for those getting started in video microscopy. The basics of both video and microscopy are reviewed and sufficient theory is provided to aid in the selection and use of video microscopy equipment. A list of hard-to-find pamphlets—along with the addresses of their sources—and a glossary—with relevant section numbers included for each entry—are among the many features that make this a valuable reference as well as a practical handbook.
0-306-42120-8/612 pp./ill./1986/$65.00 ($78.00 outside US & Canada)
Text adoption price on orders of six or more copies: $37.50

INTERACTION OF CELLS WITH NATURAL AND FOREIGN SURFACES
edited by **N. Crawford** and **D. E. M. Taylor**
One of the few interdisciplinary works to focus on the morphological and physiochemical aspects of cell-cell surface interactions and cell-foreign or natural surface interactions. Topics include electrokinetic properties of membranes, biotolerance, vascular grafts, sutures, and biocompatiability.
0-306-42373-1/proceedings/368 pp. + index ill./1986/$59.50 ($71.40 outside US & Canada)

Other sides of the astronomer

Robert S. Westman

Nicholas Copernicus: Complete Works. Vol. III Minor Works. Edited by Paul Czartoryski. Translation from the Polish edition and commentary by Edward Rosen with the assistance of Erna Hilfstein. *Macmillan, London: 1986. Pp.380. £60.*

Few scientists and general readers are aware that Copernicus's first published work (1509) was a translation from Greek into Latin of a book entitled *Ethical, Rustic, and Love Letters* by an obscure ninth-century Byzantine writer named Theophylactus Simocatta. "Your natural beauty has faded and your good looks are approaching [the stage of] wrinkles", so opens letter No. 3. "But you try to give the impression of truth when you deceive your lovers with artificial cosmetics. Hearken to time, you hag, for in the autumn meadows are not the place for flowers." Etc. It is good fun and a fine way for a young humanist to sharpen his Greek. And, because Copernicus's Greek dictionary has survived, it is possible to see just how good his Greek was given the lexicographical tools at his disposal. Because every letter in his dictionary began with a capital letter, he could never be certain that he was considering a proper or a common noun. In letter 31, the peacock is described by Simocatta as "the Persian bird" who acquires "the arrogance of the Persians", but Copernicus produced instead "an active bird" that took on the "splendor of the energetic birds" (p. 8).

In 1517, Copernicus, a canon or administrative official of the Warmia chapter of the Church, composed a Latin treatise on the urgent matter of the debasement of coinage; two years later, at the behest of the West Prussian Estates, he prepared a German version that differs in certain respects from the first. "It is not the least advisable to introduce a new, good coinage", wrote Canon Copernicus, "while an old, debased coinage remains in circulation. How much worse was this mistake, while an old, better coinage remained in circulation, to introduce a new debased coinage, which not only spoiled the old coinage but, so to say, swept it away!" (p. 187).

The passages cited above are but two examples of the rich feast to be found among the "minor works" of Nicholas Copernicus, a figure otherwise known in the history of science for daring to propose that the Earth and the other "elements" beneath the Moon revolve annually around a motionless Sun. To be sure, astronomical writings are not missing from this volume: the *Commentariolus*, Copernicus's first formulation of the heliocentric hypothesis, probably written sometime between 1508 and 1514, and not published in Copernicus's lifetime; the *Letter Against Werner* (1524), which attacks Johann Werner's treatise on the motion of the sphere of the fixed stars but deferring to another occasion the author's own views on whether that sphere moves or not. In addition, one finds translations of all 17 extant letters written by Copernicus as well as a group of administrative documents. Copernicus had studied medicine at Padua; in one of his books, one finds a prescription for pills that promises to do the following:

> harmlessly eliminate whatever is excessive... postpone gray hair, which comes from corrupt humors...repress catarrh, stop a cough, relieve the congestion...alleviate gas in the stomach... sharpen the wits, strengthen and invigorate the nerves, preserve the teeth from decay...induce sleep...and purge gently [p.301].

Vast talents and international energies went into the preparation of this volume. Professor Paul Czartoryski, general editor of the *Complete Works,* deserves the highest praise for the difficult task of coordinating the Polish and American research teams. His job was not an easy one. Although the late Edward Rosen, assisted by Erna Hilfstein, produced the English translation, their work built significantly but with thin acknowledgement upon the Polish contributions. Few of the scholars mentioned in Czartoryski's detailed introduction, such as Jerzy Dobrzycki and Jerzy Drewnowski, are referred to in Rosen's notes; indeed, scholars will need to consult the Polish edition for material arbitrarily excluded by Rosen and Hilfstein.

On the other hand, a veritable firestorm of polemic fills Rosen's footnotes to the *Commentariolus* (pp. 91–126) where Noel Swerdlow (baptized as "Sw" in order to eliminate him from the Citation Index!) is roasted to a crisp for having had the temerity to translate anew in 1973 Rosen's supposedly canonical 1939 version of that same work. Rosen has now adopted some of Sw's language in this new translation — without acknowledgement. The principle of ignoring what you take from others while castigating them for their minor peccadilloes, real or imagined, seems here to have been raised to the status of a major editorial axiom. Copernican specialists will easily spot these off-the-text dog fights; general readers will probably miss them (without loss). Everyone will benefit from what is left over: a much richer picture of Copernicus as a Renaissance humanist, church astronomer and man of practical action. ☐

CALL FOR PAPERS

We invite you to contribute to **Oncogene Research.** Papers can be submitted to the editor of your choice Decisions on submitted papers will be made as rapidly as possible, usually within four weeks from the date of receipt Publication of accepted manuscripts will be within three months Some of the various topics that will be considered for publication are

- Molecular structure of cellular and viral oncogenes and oncogene products
- Function of oncogene proteins
- Cellular transformation
- Expression of oncogenes during development
- Growth factors and their receptors
- Oncogenes, gene rearrangements and other mutations
- Recessive oncogenes and tumor suppressor genes
- Tumor viruses as mutagens
- Viruses associated with human tumors and cancers
- Oncogenesis in transgenic mice
- Evolution of oncogenes
- Regulation of cell cycle proliferation

First issue due March 1987

Plant Physiology and Biochemistry publishes original theoretical, experimental and technical contributions in the various fields of Plant Physiology at diverse levels of integration (molecular, subcellular, cellular, organ, whole plant, environmental).

Plant Physiology and Biochemistry primarily publishes original experimental results It also publishes Short communications, Reviews, Letters to the Editor, Hypotheses, Technical articles and papers devoted to computer methods
Papers are published in English (72 % in 1986) and French.

Plant Physiology and Biochemistry is a journal of the Federation of European Societies of Plant Physiology (FESPP) As such, it cooperates with the two other journals of the FESPP, ***Physiologia Plantarum*** and ***Journal of Experimental Botany,*** through regular meetings of the Editors, exchange of expertise in reviewing the papers, common standards of presentation, etc

Plant Physiology and Biochemistry is published by the French Society for Plant Physiology.
The Society is open to all interested persons Application for membership and inquiries about Society activities should be addressed to the General Secretary

EUROPEAN JOURNAL OF medicinal chemistry

ELSEVIER IS PROUD TO ANNOUNCE THAT FROM 1987 ONWARDS, IT WILL PUBLISH THE **EUROPEAN JOURNAL OF MEDICINAL CHEMISTRY** ON BEHALF OF THE **FRENCH SOCIETY OF THERAPEUTIC CHEMISTRY** AND OF THE **EUROPEAN FEDERATION OF MEDICINAL CHEMISTRY**

Created in 1965 as "Chimica therapeutica", this journal turned to its present title in 1974, when it had reached an European audience Now E J M C enjoys not only an European but an international reputation

AIMS AND SCOPE

The European Journal of Medicinal Chemistry publishes studies on all aspects of Medicinal Chemistry It provides a medium for publication of

- Original Papers
- Laboratory Notes
- Short Communications
- New Product News

The journal is intended for the use of medicinal chemists, pharmacologists, pharmacists, biochemists and physicians

- No page charges
- Instructions to authors are available at the editorial secretariat
- Manuscripts should be sent in triplicate to the Editor-in-Chief

CELL MOTILITY AND THE CYTOSKELETON

In the past six years, **Cell Motility and the Cytoskeleton** has become a major forum for reporting all aspects of cell motility and its relationship to the cytoskeleton This publication provides its readers with an easily accessible source for the latest developments in the field In addition, the journal's 8¼″ × 11″ format accommodates the increased flow of papers and allows for high quality reproduction of micrographs

Highest priority is given to papers combining more than one of the following approaches dynamic morphology, ultrastructure, biochemistry, biophysics, and genetic and molecular biological analysis Theoretical and mathematical papers are encouraged if based upon, and consistent with, realistic data in the literature Those wishing to make contributions may contact the Editor Dr B R Brinkley • Department of Cell Biology and Anatomy • University of Alabama at Birmingham • Birmingham, Alabama 35294 Authors in Europe may choose to send their manuscripts to the European office Dr Jeremy S Hyams • Department of Botany and Microbiology • University College London • Gower Street • London WC1E-6BT, England

Topics of interest include

- molecular architecture, supramolecular structure, cell shape
- interactions of motile systems (e g , tubulin- and actin-based systems)
- interactions of cytoskeletal proteins, intranuclear movements
- non-motile roles of motile or cytoskeletal proteins
- biochemical, biophysical, and molecular aspects of cytoskeletal proteins and related control- or binding-proteins
- the pathology of motile behavior and the cytoskeleton
- nuclear-cytoplasmic transport and interchange
- action of drugs on motility and the cytoskeleton
- prokaryotic flagellar and gliding motility
- changes in organelle shape (e g , axostyles, costae), the nuclear matrix
- microtubule gliding and particle transport
- axonal transport, amoeboid motility, morphogenetic movements
- reticulopodial movement in foraminifera, radiolaria
- targeted intracellular particle transport, actin-based particle transport
- bulk cytoplasmic streaming (in protists, plant, animal, and fungal cells)
- movement of tissue cells in vitro or in vivo
- endo- and exocytosis, spreading of platelets, tissue cells
- the role of motile and cytoskeletal proteins in development
- mitotic movements (e g , kinetochore, centrosomes and particle)
- cytokinesis, muscular contraction, cytoplasmic contractility
- spasmoneme and myoneme contraction
- eukaryotic flagellar and ciliary movement
- the centriole, centrosome, and flagellar rootlet derivatives
- interaction of the cytoskeleton with the extracellular matrix

Volumes 7 & 8 1987, Eight Issues, $250 00, A personal rate of $80 00 is available to individuals Subscriptions at the personal rate must be paid by personal check, credit card, bank draft, or money order For all subscriptions outside the United States add $26 00 postage

Thomas H Jukes

An alliance of scientists and educational and religious leaders has converged to defend evolution from determined attack by the creationist lobby

THE appeal in the case Edwards *et al* appellants [Edwin W Edwards is Governor of Louisiana] versus Aguillard *et al*, appellees, will be heard by the US Supreme Court next week (10 December) The case pits creationism against evolution The action originated in a 1985 opinion of the US Court of Appeals, affirming the unconstitutionality of an act passed in Louisiana "Balanced Treatment for Creation-Science and Evolution-Science in Public School Instruction, Requiring the Teaching of Creation Science in Louisiana Public Schools Whenever Evolution is Taught"

The act requires that textbooks, library materials, and educational programmes include balanced coverage of both 'creation science' and evolution, that both evolution and 'creation science' be taught as theories rather than as proven scientific facts, that each local school board develop and provide to each public school teacher a curriculum guide on the presentation of 'creation science', and that the governor designate a panel of seven 'creation scientists' to assist local school boards in the development of these curricula The act argues that "creation science consists of scientific evidence and not religious concepts" and therefore should be taught in science classes The act states that its purpose was "For protecting academic freedom " However, the US Court of Appeals ruled that "the principle of academic freedom abjures state interference with curriculum or theory as antithetical to the search for truth The balanced treatment act is contrary to the very concept it avows "

Religiosity

The strategy used by creationists in writing the Louisiana act was developed as a response to their 1982 court defeat in Arkansas, where "the inescapable religiosity" of creationsism had been exposed by Judge Overton In the Louisiana act they kept mum about the religious nature of creationism and pretended that a viable 'creation science' existed

The Governor, in his officical capacity, together with the Attorney General and State Superintendent of Education of Louisiana, are appealing against the decision of the US Court of Appeals of the State The legislature passed the act by a large majority, and it appears to have a strong popular appeal in Louisiana The appellants are heartened because the Appeals Court ruled on a majority of only one seven judges dissented

The US Supreme Court procedure is that the appeal will be argued by lawyers for the appellant and appellees Permission has been granted for other interested parties to file *amicus curiae* briefs These will be added to the record to be read by the Court, but the lawyers who filed the briefs will not be allowed to present oral arguments on 10 December

FASEB's brief

The Supreme Court has received 16 *amicus curiae* briefs, most of them in support of the appellees As far as I know, the scientific and educational communities have never previously joined together on a legal issue to a comparable extent One brief for the appellees is joined by the Federation of American Societies for Experimental Biology with 28,000 elected members, nearly all with doctoral degrees Another brief was filed by 72 Nobel laureates and 17 state academies of science Probably this arousal of activism has come about because creationism threatens other natural sciences, such as astronomy, astrophysics and geology, in addition to biology A third brief for the appellees was filed by four clergymen

A typical statement by creationists is that they are "fully committed to the inerrancy of Scripture", as well as to "the strict creationist young Earth position taught in Scipture " This places the date of creation as about 10,000 years ago, which accounts for opposition by creationists towards any of the natural sciences that state that the Earth and the Universe are thousands of years old Creationists reject radiometric dating, by claiming that isotopic changes do not occur at uniform rates Similarly contrived arguments are used by creationists against any and all scientific findings that are in contradiction with a literal intepretation of the King James version of the Holy Bible

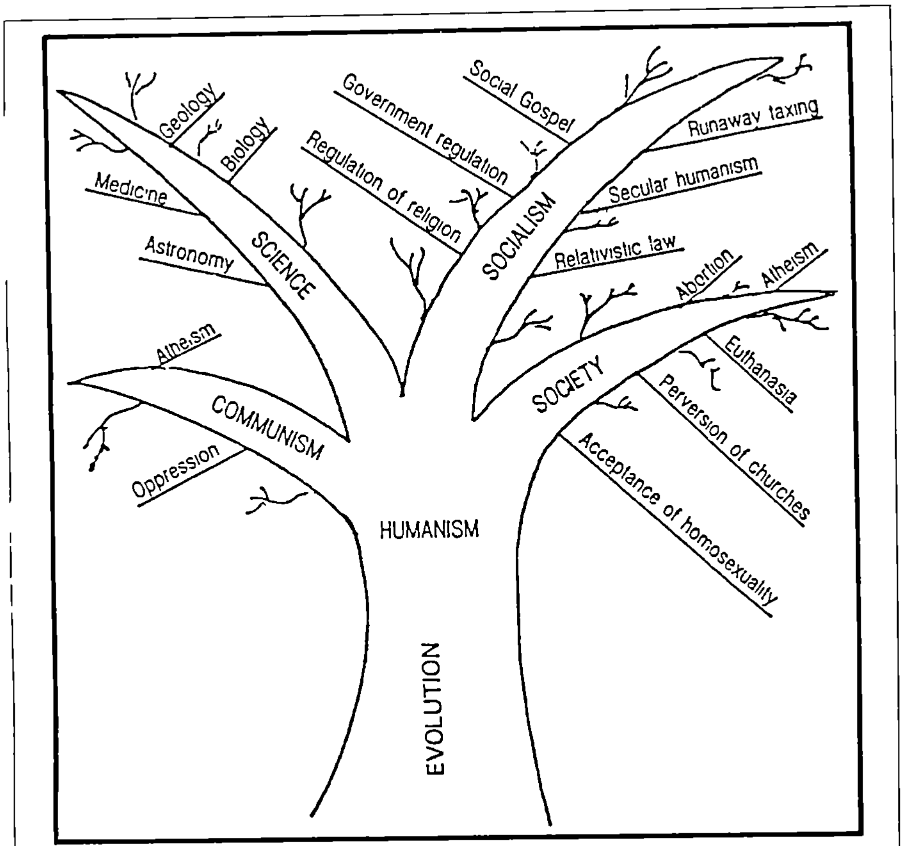
An irony is that the present case depends on legalities surrounding the establishment clause of the United States Constitution rather than on the validity of evolution Only one brief, that of the US National Academy of Sciences, says anything descriptive about evolution, in a discussion of divergence of cytochromes *c* in terms of the molecular evolutionary clock News of the current studies of proteins and DNA that reveal relationships of all living organisms with each other have not yet reached most people, and, of course, the knowledge has been deliberately excluded from most public school science textbooks by the successful efforts of creationists This exclusion is a victory for obscurantism It is therefore strange to read in *Nature* articles and letters affirming that creationism is a rather interesting sociological phenomenon, and one that should be treated sympathetically[1 2]

Four of the briefs are on behalf of the appellants, that is, for creationism, by the Christian Legal Society, the Rabbinical Alliance of America (joined by Congressman William E Dannemeyer, who is well known for his opposition to the pasteurization of milk), the Catholic League for Religious and Civil Rights (anti-abortion) and, as mentioned below, Concerned Women for America

The other 12 briefs are for the appellees, and usually emphasize the constitutional separation of church and state which the Louisiana Act would violate, also the attack on academic freedom presented by the act, and the threat to the teaching of other secular subjects, in addition to evolution, that is posed

"Anti-Christian"

In view of thepending Supreme Court case, a ruling by US District Court Judge Thomas G Hull in Greenville, Tennessee on 25 October, 1986, takes on added significance He ordered public schools in Hawkins County, Tennessee, to excuse fundamentalist children from attending classes where they would be exposed to books that their parents say promote themes which they regard as "anti-Christian " The parents objected to stories in the Holt-Rinehart-Winston books



“Evolution is the taproot which is feeding the oppressive, murderous and infidel directions we see gaining acceptance around us ” says Paul Bartz of Bible Science Newsletter

about “Cinderella” and “Macbeth,” because of their mention of magic, to *The Wizard of Oz,* because it portrayed a witch as good, and *The Diary of Anne Frank* because it suggested all religions are equal Ominously, another objection was to stories about dinosaurs if the creatures were said to be older than the Biblical account of the beginning of the world, presumably 10,000 years ago Judge Hull's decision included a statement that “the plaintiffs believe that after reading the entire Holt series, a child might adopt the views of a feminist, a humanist, a pacifist, an anti-Christian, a vegetarian, or an advocate of “one world government” He found that the plaintiff's objections were sincerely held religious convictions, thus apparently conceding that objections to almost anything should be upheld if under the guise of religious convictions The leading complainant also objected to reading about catholicism, which she said “could produce changes in my children's way of thinking—they could become confused”

It is of added significance that Michael Farris, the plaintiffs' chief attorney, is the author of the *amicus curiae* brief of the Concerned Women for America in the Supreme Court case In it, he argues that “the Louisiana law has the clear secular purpose of promoting academic freedom and of insuring that students learn the scientific evidence of both evolution and creation” This fallacious argument is based on the erroneous presumption that there is scientific evidence for creation, which evidence actually rests on literal acceptance of the Book of Genesis It is noteworthy that the Concerned Women for America, in one court action, object to *their* children reading about Cinderella, and in a second court action would foist creationist travesties of science on *all* children

Judge Hull also stated “This opinion shall not be interpreted to require the school system to make this option available to any other person or to these plaintiffs for any other subject ” Does this statement represent a disturbing challenge to the doctrine of *Stare decisis e non modere quieta*, which could thus be used against previous decisions that permit the teaching of evolution?

Another component that must be weighed in a Supreme Court case is the presence of William Rehnquist in his newly appointed role as Chief Justice Given the impact of the recent US Court decision in Greenville, what can we expect from him? It should be noted that the US District Court first threw out the case in December 1983, following which the parents appealed to the United States Court of Appeals in Cincinnati This court sent the case back to the lower court, holding that the parents' complaints deserved the hearing of a trial, with the result that the parents won Will the Supreme Court react to this precedent?

Taxation

The fantastic accusations against evolution by the creationists are seemingly endless The figure shown above accompanied an article written in 1983 by Paul A Bartz, the executive editor of *Bible Science Newsletter* The article included the sentence “Evolution is the taproot which is feeding the oppressive, murderous and infidel directions we see gaining acceptance around us ” Mr Bartz builds a powerful case for his opposition to evolution by alleging that it leads to “runaway taxing ” In a sense, this is quite true, in that runaway taxing did not exist before the appearance of vertebrates

It is more likely, however, that by “evolution” Bartz refers to the teaching of evolution rather than to its existence A sample of creationist “teaching material” for young children[4] contains a cartoon for each letter of the alphabet The letter *A* shows Adam and Eve surrounded by dinosaurs, *B* for Bible and brachiosaurus has Adam at his first job — naming the brachiosaurus *F* says that fossils were formed by the sudden inundation of the Biblical Flood, but “normally, when an animal dies, no fossil is formed” We are assured that “God put dinosaurs on the Ark” A chilling cartoon on *U* (for “unchanged”) implies that, just as the mockers of Noah were drowned, those who today jeer at church-goers will be destroyed by the vengeful Deity

Evolution started in Darwin, and grew with genetics The mechanism of inheritance had to provide for changes occurring during long periods of time Information in the genes is used every time a living organism develops from a fertilized egg cell, this event, because it happens so quickly, is far more remarkable than evolution The pervasive influence of biochemistry grew steadily, biochemists showed the universal nature of many metabolic pathways and showed that all living organisms had coenzymes containing the same remarkable molecules Specific procedures have firmly established evolution at the centre of the biological sciences, aided by population genetics, plate tectonics and computer sciences “Gaps in the fossil record” are irrelevant in the face of molecular evidence All lines of scientific inquiry show that the great apes are our closest relatives We are sorry that the creationists do not approve of their cousins, but, regardless of the Establishment Clause, this is the way it happened ☐

A thyromimetic that decreases plasma cholesterol levels without increasing cardiac activity

A. H. Underwood, J. C. Emmett, D. Ellis, S. B. Flynn, P. D. Leeson, G. M. Benson, R. Novelli, N. J. Pearce & V. P. Shah

Smith Kline and French Research Limited, The Frythe, Welwyn, Hertfordshire AL6 9AR, UK

A number of agents that mimic the ability of the thryoid hormone, T_3, to decrease plasma cholesterol levels are described, one is as effective as T_3 at reducing cholesterol levels and stimulating liver function, but has very little effect on cardiac function and is thus less likely to be toxic The agent may be useful in the treatment of atherosclerosis

CHOLESTEROL concentrations are increased in plasma in hypothyroidism and diminished in hyperthyroidism, treatment of thyroid disease normalizes plasma cholesterol[1] In man[2], and animal models[3 4] with normal thyroid function, relatively low doses of thyroid hormones reduce circulating cholesterol But 3,3′,5-triiodo-L-thyronine (T_3) and L-thyroxine (T_4) cannot be used therapeutically to treat hypercholesterolaemia because of the adverse consequences of some of their other actions, notably on the heart The cardiac effects could either be a direct consequence of the interaction of the hormones with their cardiac receptors, or a result of the characteristic increase in metabolic rate leading, indirectly, to increased cardiac output Several groups of workers have attempted to design analogues that retain hypocholesterolaemic activity but lack cardiac and metabolic effects However, despite claimed selectivity in animals for certain compounds[3,5], all agents that mimic the thyroid hormones (thyromimetics)[6 7], including D-T_4 (ref 7), have shown unacceptable cardiac side effects when tested in man

Thyroid hormones act on the liver in several ways that could increase cholesterol elimination These include induction of low-density lipoprotein (LDL) receptors[8], lecithin-cholesterol acyl transferase[2,9], hepatic lipase[2,10] and lysosomal acid cholesterol esterase[11] Thus an agent that mimics the thyroid hormones in their hepatic but not their cardiac activity could be a valuable agent for treating hypercholesterolaemia Here we describe a new class of selective thyromimetics The most potent of these, SK&F L-94901, after chronic administration, is as active as T_3 on the liver but has about 0 1% of the activity of T_3 on the heart We also show that this compound is a very potent hypocholesterolaemic agent with only a small effect on metabolic rate

Experimental approach

The primary assay used was the induction of the enzyme GPDH (mitochondrial cytochrome *c* 3-phosphoglycerate oxidoreductase) in the heart and liver of a hypothyroid rat Both natural and synthetic thyromimetics caused large (3–6-fold), easily quantified increases in cardiac and hepatic GPDH 48 hours after the administration of a single dose to hypothyroid rats (A H U and D E, unpublished data) The assay gave similar results to ones based on changes in whole body or tissue oxygen consumption, and is thought of as an excellent measure of the effects of thyromimetics on specific organs[12] Secondary screening involved chronic administration, usually oral, of selected compounds to either hypothyroid rats or rats with normal thyroid function, to determine hypocholesterolaemic activity and effects on whole body oxygen consumption (WBOC) and thyroid function

We have used measurements of the affinities of novel compounds for the thyroid hormone receptor of isolated cardiac

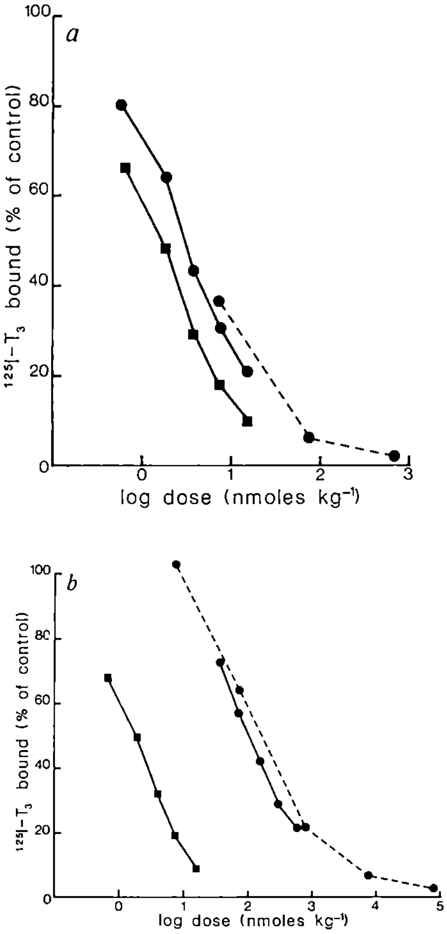

Fig 1 Competition of T_3 and SK&F L-94901 with ^{125}I-T_3 for occupation of nuclear receptors *in vivo* *a*, hepatic nuclei, *b*, cardiac nuclei, ■, unlabelled T_3, ●, SK&F L-94901

Methods Rats were rendered hypothyroid by providing them with drinking water containing 0 3 g l^{-1} of the antithyroid agent 2-mercapto-1-methylimidazole (MTI) for at least 4 weeks They were then given intravenous injections of ^{125}I-T_3 and various doses of unlabelled T_3 or SK&F L-94901 One hour later hepatic and cardiac nuclei were isolated[22] and the ^{125}I and DNA[23] content determined Nuclear ^{125}I was expressed as d p m mg^{-1} DNA and corrected for small variations in the injected dose by dividing by plasma ^{125}I-T_3 determined as that fraction of the plasma ^{125}I content precipitable by trichloracetic acid[22] The experiment with T_3 and the two experiments with SK&F L-94901 (dotted and solid lines) were done on separate occasions The symbols represent the means of three hearts or two livers

Table 1 A comparison of the potencies and receptor binding properties (*in vitro* and *in vivo*) of various substituted thyronines

			Heart			Liver		
				Relative receptor binding		Relative	Relative receptor binding	
SK&F No	R′	R″	Relative potency	*in vitro*	*in vivo*	potency	*in vitro*	*in vivo*
T_3	I	I	100	100	100	100	100	100
L-92904		I	0.5	13	0.3	2.2	15	5.1
L-93236		I	0.1	56	0.7	2.2	17	19
L-93993		I	Inactive	2.7	0.2	1.7	2.3	10
L-94690		I	0.1	4.0	0.4	2.4	2.0	38
L-94901		Br	0.1	2.0	1.3	18	0.9	50

Male, Wistar rats were rendered hypothyroid by administering 0.3 g l^{-1} of the antithyroid agent 2-mercapto-1-methylimidazole (MTI) in drinking water for at least 4 weeks before use. Single doses of thyronines were given intramuscularly in a vehicle of 0.15 M NaCl/0.01 M NaOH (1 ml kg^{-1}) 48 h before the GPGH activities of hearts and livers were determined. A standard '2+2' method was used to determine the potency of SK&F L-92904 and L-93236. Two doses of either T_3, SK&F L-92904 or L-93236 were administered, dose ratios were determined for hearts and livers, and relative potencies calculated. For SK&F L-93993, L-94690 and L-94901, as well as T_3, six doses were administered. For hepatic GPDH the resulting dose response curves were fitted to a hyperbolic curve by a non-linear curve fitting procedure and the mean effective dose (ED_{50}) calculated as described[19]. Potency is defined as the reciprocal of the ED_{50}, relative potency is the ratio of the potency of the novel compound to that of T_3, expressed as a percentage. The ED_{50} for T_3 on cardiac GPDH activity was 0.7×10^{-7} moles kg^{-1}, on hepatic GPDH it was 1.6×10^{-7} moles kg^{-1}. All 6 compounds caused the same maximal increase in hepatic GPDH and are thus full agonists. Only SK&F L-92904 caused the same maximal increase in cardiac GPDH as did T_3. The highest dose used of the remaining compounds was 50 mg kg^{-1} (77–90 μmol kg^{-1}). For SK&K L-93236, L-94690 and L-94901 only this dose significantly increased cardiac GPDH to about 50% of the level achieved with a maximally active dose of T_3. The potencies for these three compounds are, therefore, an approximation based on this figure and the assumption that the compounds would be full agonists if a high enough dose could have been administered. Even at a dose of 50 mg kg^{-1} SK&F L-93993 had no effect on cardiac GPDH. Receptor binding *in vitro* was determined using isolated nuclei. Briefly, nuclei, prepared by sedimentation of homogenates through high-density sucrose solutions, were incubated with ^{125}I-T_3 and increasing concentrations of non-radioactive T_3 or novel compound using published conditions for liver[20] and heart[21]. Bound and free ^{125}I-T_3 were separated by centrifugation and the concentration of non-radioactive ligand reducing the binding of ^{125}I-T_3 by 50% (IC_{50}) was determined. The affinity of T_3 for these receptors (determined from Scatchard plots) was about 10^9 M^{-1} for both heart and liver. *In vivo* receptor binding studies were conducted as described (Fig. 1, legend). Relative receptor binding is defined as the ratio of either the IC_{50} or the ED_{50} for T_3 to that for novel compound expressed as percentage.

and hepatic nuclei[13] to examine the relationship between structure and affinity, and to optimise receptor binding. Indirect evaluations of the capacity of compounds to occupy receptors *in vivo* have also been made using their ability to compete with ^{125}I-T_3 for uptake by nuclei when both ^{125}I-T_3 and the compound are administered simultaneously to rats[14].

Selective thyromimetics

We used the natural hormone, T_3, as the starting point and have confirmed that (1) a diphenylether core structure carrying a 4′-OH and 3,5-halogens is essential for high receptor affinity and (2) 3′-alkyl substituent is an effective replacement for a 3′-iodine atom in T_3 (ref. 15). We then tried to define the optimum 3′-substituent properties for high receptor affinity and hormonal activity. The 3′-benzyl analogue (SK&F L-92904) was made to test the effect of increasing substituent lipophilicity and/or size. This compound had 2.2% of the activity of T_3 in the liver but only 0.5% of the activity of T_3 in the heart. Its receptor affinity is greater, however, being 13% of that of T_3 for isolated cardiac nuclei and 15% for isolated hepatic nuclei (Table 1). This could be a consequence of limited solubility, so the potentially more soluble 4-hydroxybenzyl analogue, SK&F L-93236, was made. This compound showed clear selectivity, being similar in activity to SK&F L-92904 as a hepatic thyromimetic (2.5% of T_3), but much weaker (0.1% of T_3) in the heart (Table 1).

The selectivity of these two compounds is not due to their receptor affinities. The affinities of SK&F L-92904 for the heart and the liver nuclear binding sites are essentially the same, and SK&F L-93236 actually has a higher affinity for cardiac receptors than for those from the liver. Both compounds were less active than would be predicted from their affinities for the receptors *in vitro*. To investigate these anomalies we conducted *in vivo* binding studies with SK&F L-92904 and SK&F L-93236. The results (Table 1) showed that both compounds were much less effective in preventing ^{125}I-T_3 binding to heart nuclei than to liver nuclei. If we asume that the ability of these T_3 analogues to depress nuclear binding of ^{125}I-T_3 *in vivo* is a measure of their capacity to bind to and activate the nuclear thyroid hormone receptor, then the reduced *in vivo* nuclear binding in the heart compared with the liver is broadly consistent with the observed selective thyromimetic activity. We have termed this differential effect on *in vivo* nuclear binding 'selective access'.

A larger group of related compounds was made, the pyridone derivative (SK&F L-93993) was found to be a full agonist in

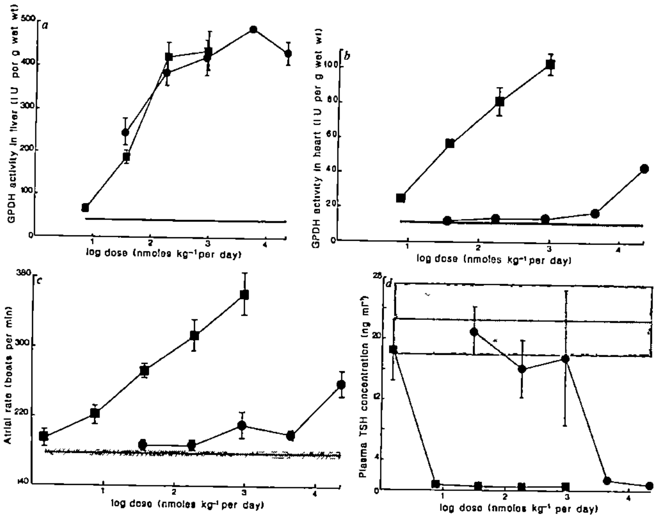

Fig 2 Chronic treatment of hypothryoid rats with T_3 or SK&F L-94901 Effect on *a*, hepatic GPDH activity, *b*, cardiac GPDH activity, *c*, spontaneous rate of beating of isolated right atria, *d*, plasma TSH concentration, ■, T_3, ●, SK&F L-94901

Methods Newly weaned, male, Wistar rats were rendered hypothyroid using MTI as in Fig 1 They were then given seven daily consecutive intramuscular injections of either vehicle (0 15 M NaCl/0 01 M NaOH), or T_3 or SK&F L-94901 solutions in vehicle The rats were anaesthetised with halothane 24 h after the final injection and blood samples withdrawn from the dorsal vena cava Plasma was prepared and stored frozen at −20 °C until TSH could be measured by radio immunoassay (reagents were supplied by the NIH, Bethesda) The right atria were dissected out and mounted in Krebs-Henseleit saline buffered with CO_2/bicarbonate Atrial rates were recorded after a 40-min stabilisation period at 33 °C The remainder of the hearts and samples of liver were frozen on dry ice until their GPDH content could be determined as described[19] Each point represents the mean of between 2 and 7 observations the vertical bars are 2 s e m Horizontal line, mean of values from rats treated with vehicle, cross-hatching, 2 s e m

the liver but inactive in the heart (Table 1) Data from *in vivo* nuclear binding experiments also showed that all selective agonists exhibit selective access Regression analyses suggest a dependence on 3′-substituent polarity and this prompted the synthesis of the more polar pyridazinone (SK&F L-94690), a selective thyromimetic showing a greater degree of selective access But although selective access and selective activity is dependent on 3′-substituent hydrophilicity, the receptor affinity (and hence hormonal activity) was found to be correlated with high 3′-substituent lipophilicity We therefore explored alternative structural modifications to increase activity The 3,5-dibromo analogue (SK&F L-94901) was made because it was likely to be metabolically more stable than T_3 and was found to be highly selective and more potent than the diiodo analogue (Table 1) Like all other selective thyromimetics, SK&F L-94901 shows marked selective access (Table 1, Fig 1)

Note that D-T_4 is not selective as assayed by induction of GPDH, having 7% and 11% of the activity of T_3 in heart and liver respectively

The phenomenon of selective access implies that there is a different relationship between relative receptor binding *in vitro* and *in vivo* for the heart than for the liver The significance of this is discussed below But it is apparent from the data in Table 1 that there is no constant relationship between relative receptor binding *in vivo* and *in vitro*, nor between *in vivo* binding and overall potency for this group of compounds The reasons for these differences have not been examined in detail, but many factors, as well as affinity for isolated receptors, control occupation and hence activation of receptors *in vivo* These factors include binding to plasma proteins, metabolic transformations and the distribution of the thyronines between blood, organs and cellular compartments Finally the possibility that the compounds have differing efficacies cannot be ruled out

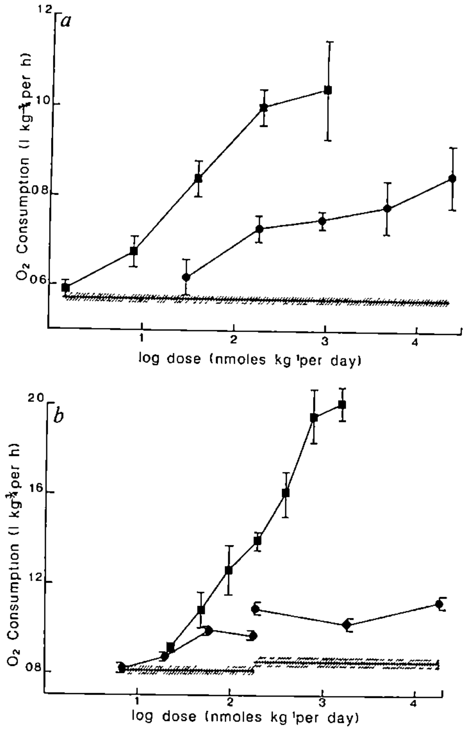

Fig 3 The effects of T_3 and SK&F L-94901 on oxygen consumption *a*, hypothyroid rats, *b*, normal rats, ■, T_3, ●, SK&F L-94901

Methods. Rats were familiarised with the procedure for determining oxygen consumption to ensure that minimum values were obtained, then given seven daily consecutive doses of vehicle (0 15 M NaCl/0 01 M NaOH), T_3 or SK&F L-94901 Oxygen consumption was measured 24 h after the final dose and expressed as litres of O_2 (at Standard temperature and pressure (STP)) consumed $kg^{-3/4}$ per h since this is independent of body weight[24] Symbols represent the means of between 3 and 7 rats, vertical bars, 2 s e m , horizontal lines, mean oxygen consumption in vehicle-treated controls ($n = 12$ in *a* and 5 in *b*) *a*, hypothyroid rats, as in Fig 2, given intramuscular injections at 1 ml kg^{-1} Oxygen consumption, at 30 °C, was determined by a modification of the 'flow-through' technique[26] and was significantly greater than in controls for all groups except those given the lowest doses of either compound *b*, normal rats dosed orally Oxygen consumption was measured, at 29 °C, as described[19] Three separate experiments over different dose ranges are shown on this graph The mean oxygen consumption in the controls ($n = 5$) for the two experiments with SK&F L-94901 ate shown as horizontal lines below the relevant curves hatching 2 s e m The mean oxygen consumption of vehicle-treated controls for the T_3 dose-response curve was intermediate at 0 84 ± 0 02 (4) l O_2 at STP $kg^{-3/4}$ per h Oxygen consumption was significantly greater than control in all treated groups except for those given the two lowest doses SK&F L-94901 and three lowest of T_3

The most active selective compound

After a single dose SK&F L-94901 has about 20% of the potency of T_3 in the liver and 0 1% in the heart (Table 1) Chronic treatment enhances the hepatic potency of SK&F L-94901 After seven daily intramuscular doses SK&F L-94901 is as potent as T_3 as a thyromimetic in the liver of hypothyroid rats, but still only had 0 1% of the activity of T_3 on cardiac GPDH activity and on the spontaneous rate of beating of isolated atria (Fig 2*a*, *b* and *c*) In rats with normal thyroid function, given SK&F L-94901 or T_3 orally for seven days, a very similar result was obtained The two compounds were equipotent in the liver but only T_3 had an effect on cardiac GPDH SK&F L-94901 was inactive at a dose 200 times greater than the cardiac ED_{50} for T_3 In this experiment the effects of SK&F L-94901 and T_3 on

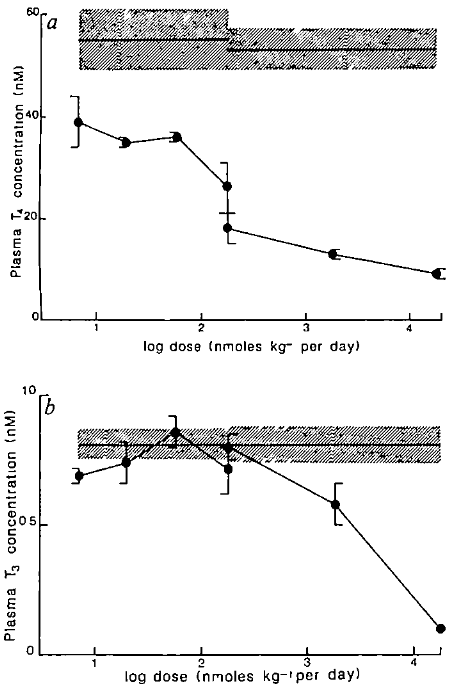

Fig 4 Effect of SK&F L-94901 on *a*, plasma T_3 and *b*, T_4 concentrations Male euthyroid rats were given seven daily sonsecutive oral doses of KS&F L-94901 and samples of blood from the dorsal aorta collected 24 h after the final dose under halothane anaesthesia Plasma T_3 and T_4 concentrations were determined by radioimmunoassay (RIA) using commerically available kits (Amerlex T_3 and T_4 RIA kits, Amersham) which are validated for use with rat plasma Values shown are the means of 4 or 5 rats, vertical bars, 2 s e m , horizontal lines, vehicle treated controls, cross-hatching, 2×s e m of controls Two separate experiments are shown, the control values for each experiment are shown above *a*, T_3 concentrations Only the highest dose of SK&F L-94901 had a statistically significant effect and this was to reduce T_3 concentrations to below the limit of detectability (0 15 nM) *b*, T_4 concentrations Mean values in all treated groups, except those given the lowest dose of SK&F L-94901, were significantly smaller than in vehicle-treated controls

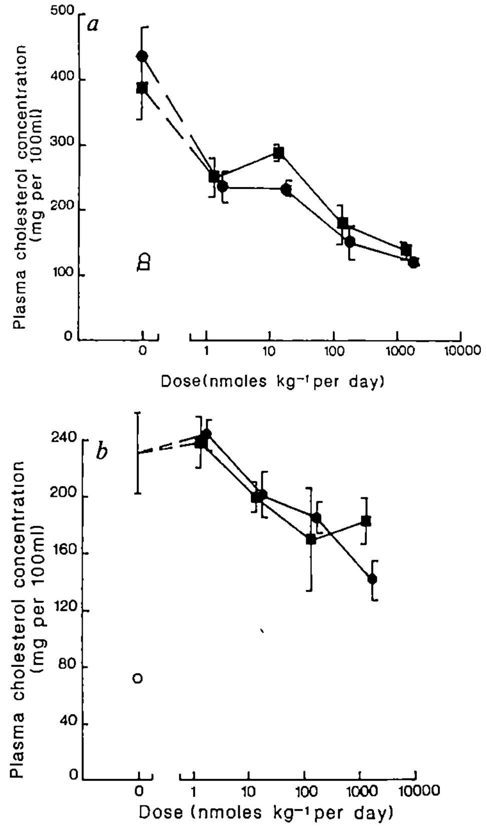

Fig 5 Effects of T_3 and SK&F L-94901 on plasma cholesterol concentrations *a*, Hypothyroid rats, fed with cholesterol *b*, normal rats fed with cholesterol, ■, T_3, ●, SK&F L-94901, open symbols indicate groups fed with a normal diet Male rats were rendered hypercholesterolaemic by feeding a diet containing 1 5% cholesterol and 0 5% cholic acid for 3 weeks Seven daily consecutive oral doses (5 ml kg^{-1}) of vehicle (0 15 M NaCl/0 01 M NaOH), T_3 or SK&F L-94901 were given Groups of male rats receiving a normal diet were also dosed with vehicle for seven days Blood was taken under anaesthesia 24 h after the final dose and total plasma cholesterol measured with commercially available kit (Diagnostica Merck, E Merck) using cholesterol oxidase The symbols represent the mean values from groups of 4–5 rats, the vertical bars are the s e m

renal GPDH were also measured, both compounds were fully active and roughly equipotent

Chronic administration of either SKF L-94901 or T_3 increases the minimal WBOC of rats, although the character and magnitude of the responses are very different In hypothyroid rats the highest dose of T_3 used roughly double the WBOC SK&F L-94901 increases the WBOC by 50% at its highest dose, with a shallower dose-response curve (Fig 3*a*) This phenomenon was even more apparent in rats with normal thyroids, where the maximum response to SK&F L-94901 was about one quarter of that to T_3, and the dose-response curve to SK&F L-94901 was esentially flat over a considerable dose-range (Fig 3*b*) This would be expected if a smaller number of organs gave a thermogenic response to SK&F L-94901 than to T_3 administration

Both SK&F L-94901 and T_3 diminish plasma thyroid stimulating hormone (TSH) concentrations in hypothyroid rats after chronic treatment, but have dramatically different potencies The lowest dose of SK&F L-94901 that reduced plasma TSH significantly was more than 1,000 times greater than the lowest effective dose of T_3 (Fig 2*d*) When administered chronically to rats with normal thyroids only the highest dose of SK&F L-94901 reduces plasma T_3 concentrations significantly (Fig 4*a*) This is similar to the lowest dose that significantly reduced plasma TSH in hypothyroid rats, implying that the effect of SK&F L-94901 on plasma T_3 could have been mediated by an action on pituitary thyrotrophs By contrast, SK&F L-94901 reduces circulating T_4 significantly in a dose-related manner, although no dose eliminated T_4 altogether (Fig 4*b*) This maintenance of plasma T_3 while T_4 concentrations decrease is unusual and could be due to increased conversion of T_4 to T_3 or diminished elimination of T_3

Unlike man, normal rats have very low circulating plasma cholesterol concentrations (about 50 mg per 100 ml), and almost all of this is in the high-density lipoprotein fraction (HDL) Thyroid hormones do not reduce total plasma cholesterol in this model Hypocholesterolaemic activity was therefore determined in rats with artificially elevated plasma cholesterol produced by feeding a cholesterol-rich diet Ultracentrifugation of plasma from cholesterol-fed rats revealed a discrete peak of cholesterol in the HDL fraction and a more diffuse fraction of lower density (reported to contain βVLDL and LDL[16]) When hypercholesterolaemic hypothyroid rats were given SK&F L-94901 orally for 7 days the concentration of cholesterol in their plasma was reduced in a dose-related fashion This was mainly due to a reduction in the lower density fraction leading to an increase in the proportion of cholesterol carried on HDL A daily dose as low as 1 μg per kg per day caused a significant reduction compared to a vehicle-treated control group Higher doses reduced plasma cholesterol concentrations to those found in animals given a normal diet T_3 was also active under these conditions and the two compounds were of similar potency (Fig 5*a*) Rats with normal thyroids are less sensitive to both

T_3 and SK&F L-94901, but even under these circumstances, the two compounds have similar hypocholesterolaemic potency (Fig 5*b*)

Discussion

Unlike many hormone agonists and antagonists, the organ selectivity of SK&F L-94901 does not appear to result from differences in the receptors in the relevant tissues, as cardiac and hepatic nuclear receptor affinities are very similar for several hundred compounds (unpublished data), strongly suggesting that the two receptors are identical The evidence that interaction with the nuclear T_3-binding protein is an obligatory step in the action of these hormones is now very strong, but factors controlling the access of the hormone to the nuclear proteins may exert a strong influence on activity Indeed Oppenheimer and Schwartz[17] have recently shown that both the plasma membrane and the nuclear membrane do have such a role In particular, their experiments suggested that the free concentration of T_3 inside the nucleus is much greater than that in the cytoplasm, and they propose that some sort of concentrating mechanism or 'nuclear pump' must be in operation This nuclear pump could be the source of selective access if the liver was more active *in vivo* in pumping SK&F L-94901 into the nucleus than was the heart A corollary of this would be that the nuclear pump does not operate in our *in vitro* binding assay Alternatively, hepatic cytosol may contain higher concentrations of SK&F L-94901 than does cardiac cytosol—either because it is actively accumulated by hepatocytes, or excluded by cardiac myocytes

The similar potencies of SK&F L-94901 as an hepatic thyromimetic and as an hypocholesterolaemic agent support the idea that the actions of thyroid hormones on the liver are, at least in part, responsible for their ability to reduce plasma cholesterol concentrations This is corroborated by the finding that in cats with normal thyroid function and a genetically hypercholesterolaemic strain of rabbit[18] heterozygous for an LDL-receptor deficiency, SK&F L-94901 can also reduce circulating plasma cholesterol levels by about 30% Again, LDL-cholesterol was preferentially reduced, resulting in an increased HDL LDL cholesterol ratio Humans with normally functioning thyroid are relatively sensitive to the hypocholesterolaemic effects of T_3, doses of a few microgrammes per kilogramme of body weight having a significant effect[2] These doses are similar to those reducing plasma cholesterol in the hypercholesterolaemic hypothyroid rat and suggest that SK&F L-94901 could reduce plasma cholesterol in man (and perhaps prevent atherogenesis) at doses far below those having a direct cardiac effect, and which would have minimal or no activity on basal metabolic rate and the thyroid-pituitary axis The necessary toxicological evaluations are under way to allow the administration of SK&F L-94901 to man

We thank Professor Sir James Black, Professor C R Ganellin and Dr R Pitt-Rivers, for support, advice and helpful discussions, G R Showell and H D Prain for contributions to the design and synthesis of compounds, Dr P C Sivelle for measurements of hormones, and I Busolini, M Knowles and P Nixon for experimental support

The *Tetrahymena* ribozyme acts like an RNA restriction endonuclease

Arthur J. Zaug, Michael D. Been & Thomas R. Cech

Department of Chemistry and Biochemistry, University of Colorado, Boulder, Colorado 80309-0215, USA

A shortened form of the Tetrahymena *self-splicing ribosomal RNA intervening sequence acts as an endoribonuclease, catalysing the cleavage of large RNA molecules by a mechanism involving guanosine transfer The sequence specificity approaches that of the DNA restriction endonucleases Site-specific mutagenesis of the enzyme active site alters the substrate sequence specificity in a predictable manner, so that endoribonucleases can be synthesized to cut at a variety of tetranucleotide sequences*

THE *Tetrahymena* ribosomal RNA intervening sequence (IVS) is a catalytic RNA molecule or ribozyme It mediates RNA self-splicing, excising itself from the large ribosomal RNA precursor, and then converts itself to a circular form[1,2] In these reactions, the splice sites and circularization sites can be viewed as intramolecular substrates for an enzymatic activity of the IVS RNA[3]

This view is supported by studies of the L-19 IVS RNA, a linear form of the IVS that lacks the first 19 nucleotides Because it has no circularization sites, the L-19 IVS RNA cannot undergo intramolecular reactions[3], but it retains activity and can catalyse cleavage-ligation reactions on other RNA molecules[4] When provided with oligo(cytidylic acid) as a substrate, the L-19 IVS RNA acts as an enzyme with nucleotidyltransferase (poly(C) polymerase) and phosphodiesterase (ribonuclease) activities[4] With 3′-phosphorylated oligo(C) substrates, the same ribozyme

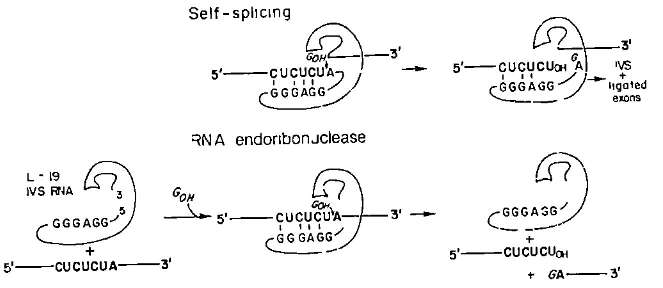

Fig 1 A model for the endonuclease action of L-19 IVS RNA The mechanism is an intermolecular version of the first step of pre-rRNA self-splicing Thin letters and lines, IVS sequences, bold letters and thick lines, exon sequences (top) or substrate RNA sequences (bottom), the G in italics is a free guanosine nucleotide or nucleoside

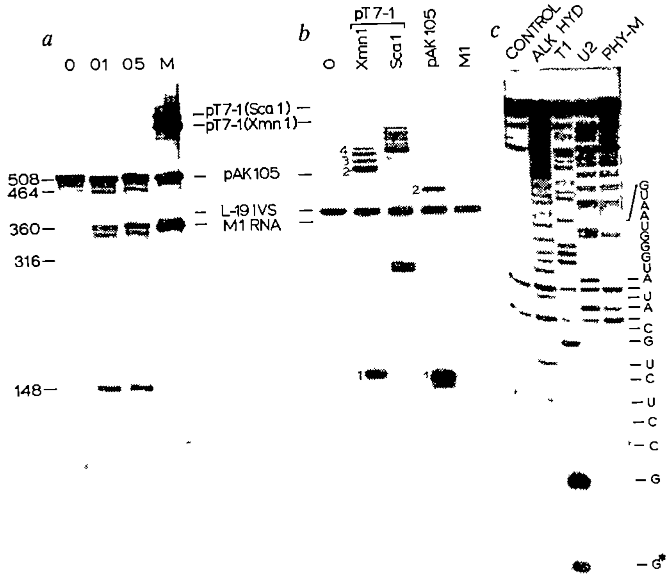

Fig 2 The L-19 IVS$_\beta$ RNA cleaves large RNA substrates with transfer of guanosine *a*, Uniformly labelled 0 6 µM pAK105 RNA (508 nt) incubated with 0 2 µM L-19 IVS$_\beta$ RNA and 0, 0 1 or 0 5 mM GTP (unlabelled) for 1 h under conditions described below M, Mixture of 4 substrate RNAs as molecular weight markers *b*, Various ^{3}H-RNA substrates (1 µg each) incubated with 0 2 µM L-19 IVS$_\beta$ RNA for 1 h, under the same reaction conditions as *a*, but with 120 µM [α-^{32}P]GTP The autoradiogram reveals [^{32}P]GTP-labelled products only The L-19 IVS$_\beta$ RNA also becomes ^{32}P-labelled during incubation *c*, Nucleotide sequence of the cleavage product pAK105(1) determined by the enzymatic method[33] Some nucleotides could not be assigned due to the presence of a band in the untreated (control) RNA sample G*, labelled GTP joined to the RNA during the reaction

Methods L-19 IVS RNA was made by methods similar to those described[4], except that a different RNA polymerase-template system was used Plasmid pT7-TT1A3 (which contains a T7 RNA polymerase promoter, a 42-bp 5' exon, the entire 413-bp IVS, and an 82-bp 3' exon) was cleaved with *Eco*RI and transcribed with bacteriophage T7 RNA polymerase[34] The transcripts were incubated further under self-splicing, circularization, and site-specific hydrolysis conditions to produce L-19 IVS RNA[3,4] The 3'-terminal guanosine was then removed by periodate oxidation and β-elimination[12] to yield L-19 IVS$_\beta$ RNA Substrate RNAs were produced by T7 RNA polymerase transcription of *Bam*HI-cleaved pAK105 (ref 13), *Xmn*I- or *Sca*I-cleaved pT7-1 (purchased from U S Biochemical Corp), and *Sna*BI-cleaved pDW27, which encodes M1 RNA (obtained from D Wahl and N Pace) Substrate RNAs were incubated with L-19 IVS$_\beta$ RNA in 5 mM MgCl$_2$, 10 mM NaCl, 50 mM Tris-HCl, *p*H 7 5 at 50 °C, GTP was present at the concentration indicated Reactions were stopped by adding EDTA to a final concentration of 25 mM Products were analysed by electrophoresis in 4% polyacrylamide, 8 M urea gels and subjected to fluorography (*a*) or autoradiography (*b*)

acts as a phosphotransferase and an acid phosphatase[5] A key feature of all four of these reactions is the formation of a covalent enzyme-substrate intermediate in which a nucleotide or phosphate is esterified through the 3'-O of G414, the 3' terminal guanosine of the IVS RNA

Here we describe a fifth enzymatic activity of the *Tetrahymena* ribozyme It cleaves RNA molecules at sequences resembling the 5' splice site of the rRNA precursor A free guanosine nucleotide is added to the 5' end of the downstream RNA fragment during cleavage This allows one product to be end-labelled during the reaction The reaction is analogous to the first step of pre-rRNA self-splicing (Fig 1) Cleavage does not require nucleotide G414 of the ribozyme, thus unlike the first four activities, it does not involve formation of a covalent enzyme-substrate intermediate

The ribozyme cleaves very specifically after the sequence CUCU, under stringent conditions it discriminates against sites that match three out of four of these nucleotides This specificity approaches that of the DNA restriction endonucleases[6] Site-specific mutations in the active site of the IVS RNA, the internal guide sequence[7,8] or 5' exon-binding site[9-11], alter the sequence specificity of the ribozyme in a predictable manner This will allow us to develop a set of sequence-specific RNA endonucleases that may be useful as tools for studying the molecular biology of RNA

Sequence-specific cleavage of large RNAs

The L-19 IVS RNA enzyme was prepared by incubation of pre-rRNA under conditions that promote self-splicing, circularization, and site-specific hydrolysis[3,4] The 3'-terminal guanosine (G414) was then removed from the L-19 IVS RNA by periodate oxidation followed by β-elimination[12] As expected, the resulting ribozyme (L-19 IVS$_\beta$) has greatly reduced activity as a nucleotidyltransferase, assayed using [^{32}P]-p(C)$_5$ as a substrate (data not shown) But when GTP is added the ribozyme can cleave p(C)$_5$ and large RNA molecules For example, the 504-nucleotide (nt) pAK105 transcript[13], a fragment of mouse β-globin pre-mRNA containing the first intron, is cleaved to give major fragments of 148, 360 and 464 nt, and some minor fragments (Fig 2*a*) As shown below, the 360- and 148-nt fragments can be explained as the 5' and 3' products of cleavage at position 360 The 464-nt fragment is the 3' product of cleavage at position 44, the 5' 44-nt fragment being too small to be observed The fact that little 316-nt RNA (the expected product of cleavage at both position 44 and 360) is observed indicates partial digestion, with few molecules cleaved more than once

Cleavage requires Mg^{2+} (optimum at 10-20 mM MgCl$_2$) and is essentially independent of monovalent cation in the range 0-200 mM NaCl The *p*H optimum is between 7 5-8 0, and the temperature optimum is ~50 °C Although β-eliminated L-19 IVS RNA catalyses the cleavage reaction, the enzyme works at the same rate whether or not G414 has been removed (data not shown) We explain this by supposing that, at saturating GTP concentrations, the attack by GTP on the substrate competes very effectively with attack by G414

When [α-^{32}P]GTP is included in the reaction of pAK105 RNA, the 148- and 464-nt cleavage products are labelled (Fig 2*b*) Direct sequencing of these labelled RNA fragments (Fig 2*c*) showed that cleavage and GTP-addition occur at nucleotides 44 and 360 in the sequence, such that the downstream cleavage products are 5'-GTP labelled The bonds formed by GTP addition are sensitive to RNase T$_1$, confirming that the GTP is covalently added through its 3'-O by a normal 3'-5' phosphodiester bond Reaction of the 841-nt pT7-1 (*Xmn*I) RNA (essentially pBR322 sequences) produced four major labelled fragments These were sequenced in the same manner The pT7-1 RNA with an extra 122 nt at its 3' end was produced by transcription of pT7-1 DNA that had been cleaved at the *Sca*I site, the

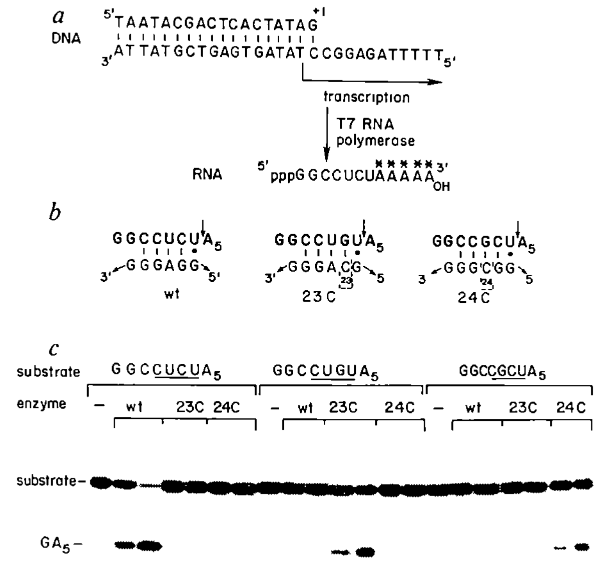

Fig 3 Three different ribozymes can distinguish between sequences that differ by a single base change in the recognition element *a*, Synthesis of defined oligoribonucleotide substrates by the method of Lowary *et al*[19] DNA was transcribed with T7 RNA polymerase in the presence of [α-^{32}P]ATP to produce oligoribonucleotides labelled with ^{32}P in the positions indicated (*) b, Proposed interactions between the three oligoribonucleotide substrates (top strands, bold) and the active sites of the matched ribozymes (bottom strands) Arrows, sites of cleavage and guanosine addition *c*, Cleavage of three oligoribonucleotide substrates by wild-type and variant L-19 IVS RNAs, assayed by 20% polyacrylamide, 7 M urea gel electrophoresis (–), untreated substrate Lanes are run in pairs, 1 0 μM ^{32}P-labelled substrate was incubated with 0 125 μM ribozyme for 15 min (left lane) or 60 min (right lane) at 50 °C in 10 mM MgCl$_2$, 10 mM NaCl, 50 mM Tris-HCl, *p*H 7 5, 0 5 mM GTP (unlabelled), 2 5 M urea Because the ^{32}P is confined to the nucleotides downstream from the cleavage site, only the smaller product is apparent The identity of the GA$_5$ product was confirmed by treatment of the substrate and reaction mixtures with RNase T$_2$ and monitoring the transfer of ^{32}P to Gp A band migrating above GA$_5$ in lanes 2 and 3 appeared in some experiments but has not been identified

Methods Substrates were prepared by transcription of deoxyoligonucleotides synthesized on an Applied Biosystems DNA Synthesizer The same promoter top strand was used in each transcription The bottom strand, which contains promoter and template sequences, was varied to obtain the different RNA substrates The DNA was transcribed with purified phage T7 RNA polymerase[34] as described[19] Variant ribozymes are described by Been and Cech[11] The L-19/23C ribozyme was prepared by transcription of pBG/-2G 23C and treatment of RNA under site-specific hydrolysis conditions[11] The 24C ribozyme was similarly prepared from transcripts of pBG/–3G 24C The variant ribozymes were not subjected to β-elimination to remove their 3'-terminal G

Table 1 Sites of cleavage of large RNA substrates by the wild-type L-19 IVS$_\beta$ RNA

Substrate	Site	Size (nt)*	Sequence†
			–6 –1
pAK-105 (β-globin pre-mRNA)	1	148	UCCUCU↓GCCUC
	2	464	AACUCU AAGAG
pT7-1 (pBR322)	1	145	UCCCUU UUUUG
	2	556	CACUCU CAGUA
	3	603	UAUUUU CUCCU
	4	805	UCCUCU AGAGU
Consensus			
observed			$\mathrm{U}^{\mathrm{C}}_{\mathrm{A}}\mathrm{CUCU}\downarrow\mathrm{N}$
expected‡			$\mathrm{C}^{\mathrm{C}}_{\mathrm{U}}\mathrm{CUCU}\downarrow\mathrm{N}$

* Size of the GTP-labelled fragment

† Sequences are listed in 5'→3' direction Arrows indicate sites of cleavage and guanosine addition

‡ The expected consensus sequence is based on the known sequence at the end of the 5' exon (CUCUCU) modified by the possibility that either a C or a U at position –5 might be able to pair with the G in the active site At position –1, C may work less well than U[7,27,35]

labelled products increased in molecular weight as expected In all reactions, including those in which substrate RNA was omitted, the L-19 IVS$_\beta$ RNA became labelled, perhaps by guanosine exchange[14,15] The sites of self-labelling were heterogeneous

The sequence near the 5' end of each end-labelled product was compared with the known sequence of the RNA to identify the nucleotides preceding the site of cleavage (Table 1) All the cleavage sites are preceded by four pyrimidines, the consensus sequence is CUCU This is exactly the tetranucleotide sequence expected to be an optimal target for the ribozyme The importance of nucleotides at –5 and –6 from the cleavage site is not clear, but the absence of G residues may be significant There is no apparent sequence preference downstream from the cleavage site, all four nucleotides are found at position +1

The potential sites in the RNA that were not cleaved by the ribozyme also provide information about the specificity For the pAK105 RNA, only one CUCU site was not cleaved (Cleavage at this site would produce a labelled 378-nt RNA) Many sites that match CUCU in three out of four positions were not cleaved These include 17 CUMU sequences (where M ≠ C) and 7 CNCU sequences (where N ≠ U) In pT7-1 RNA, cleavage was observed at both of the CUCU sequences in the RNA, but at only one of the 15 UUUU sequences present Thus, the ribozyme has a strong preference for cleavage after the tetranucleotide CUCU

M1 RNA, the RNA subunit of *Escherichia coli* RNase P[16], was not cleaved by L-19 IVS$_\beta$ RNA under standard reaction conditions (Fig 2*b*) M1 RNA contains the sequence UCCUCU, which should be an excellent target site However, this sequence is part of a stable hairpin stem[17,18], which presumably makes it unavailable as a substrate Denaturation of M1 RNA with glyoxal allows this site to be cleaved by L-19 IVS$_\beta$ RNA (unpublished data), in support of the interpretation that RNA secondary structure can inhibit cleavage

Active-site mutations alter substrate specificity

We then studied the substrate specificity in a defined system where the substrate RNA had no secondary structure that might affect the cleavage reaction Oligoribonucleotide substrates were made using the phage T7 RNA polymerase transcription method (Fig 3*a*) One substrate contained a perfect match to the tetranucleotide consensus sequence Two other substrates had single-base changes giving a three-out-of-four match to the consensus

These substrates were tested with the wild-type L-19 IVS$_\beta$ RNA and with two altered ribozymes The two variants have single-base changes in the 5' exon-binding site that alter the sequence specificity of the first step in pre-rRNA self-splicing[11] The 23C variant (G→C at position 23 of the L IVS RNA) is expected to recognize CUGU substrates, and the 24C (A→C at position 24) variant should recognize CGCU (Fig 3*b*) In the presence of 2 5 M urea, each substrate is cleaved exclusively by the ribozyme that can make a perfectly base-paired enzyme-substrate complex (Fig 3*b*, *c*) We find that 2 5 M urea or 15% formamide greatly increases specificity, allowing each ribozyme to differentiate between substrates with a single base change in the recognition sequence Our current model is that these denaturants destabilize the base-pairing between the substrate and the active site nucleotides of the ribozyme, thereby discriminating against mismatched complexes

When variant ribozymes were incubated with the 504-nt pAK105 RNA, each ribozyme gave a different pattern of cleavage products (data not shown) One major cleavage site was mapped for three variant ribozymes, including a 25C variant (G→C at position 25) The sites cleaved by the 23C, 24C and

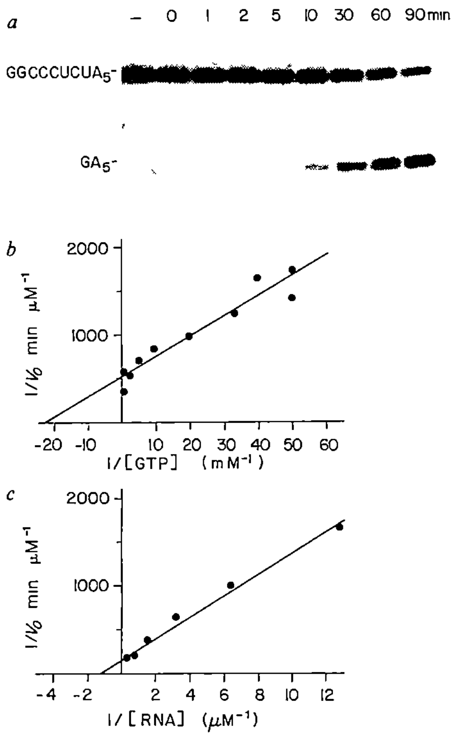

Fig. 4 Kinetic analysis of the RNA endoribonuclease reaction. *a*, The oligoribonucleotide substrate (2.5 µM) was incubated with wild-type L-19 IVS$_\beta$ RNA (0.2 µM) as in Fig. 3, except that urea was omitted. *b*, Kinetics of cleavage of GGCCCUCUA$_5$ as a function of GTP concentration. RNA substrate concentration was kept constant at 2.5 µM. *c*, Kinetics of cleavage as a function of RNA substrate concentration, with GTP concentration kept constant at 0.5 mM.

Methods. Products were separated by polyacrylamide gel electrophoresis. Each gel was cut into strips using the autoradiogram as a guide and the radioactivity in the unreacted substrate and the GA$_5$ product was determined by liquid scintillation counting. The initial rate of cleavage (v_0) was determined from a semilogarithmic plot of the fraction of reaction as a function of time. The graphs are linear least-squares fits to a plot of $1/v_0$ against inverse substrate concentration.

25C ribozymes are preceded by CCCUGU, UCUGCU, and CUGUCU, respectively; the underlining indicates the base that forms a G·C base pair with the mutated nucleotide in the variant ribozyme. Each of these sequences can form 6 continuous base-pairs with the active site nucleotides of the variant ribozyme.

Cleavage is catalytic

The time course of cleavage of the oligonucleotide substrate GGCCCUCU↓AAAAA (the arrow designates the cleavage site) by wild-type ribozyme is shown in Fig. 4*a*. The reaction of 2.5 µM substrate with 0.2 µM ribozyme is 66% complete in 90 minutes. Thus, it is readily apparent that the ribozyme is acting catalytically.

The reaction rate was determined at a series of substrate concentrations. The kinetics are adequately described by the Michaelis–Menten rate law. The dependence of the rate on GTP concentration is shown in the form of a Lineweaver–Burk plot in Fig. 4*b*. The K_m for GTP is 44 µM. The dependence of the rate on RNA substrate concentration at saturating GTP concentration is shown in Fig. 4*c*. The K_m for this oligoribonucleotide substrate is 0.8 µM, and k_{cat} is 0.13 min^{-1}. Thus under V_{max} conditions the enzyme turns over about 8 times per hour.

Discussion

We find that the L-19 IVS RNA acts like an RNA restriction endonuclease. It catalyses the sequence-specific cleavage of other RNA molecules while transferring guanosine to the downstream RNA fragment. The enzyme has a strong preference for cleaving RNA after the sequence CUCU (Table 1), and in a solution containing 2.5 M urea it cleaves after CUCU, but ignores the related sequences CUGU and CGCU (Fig. 3*c*). Additional sequences must be tested to provide a complete picture of the sequence specificity of the ribozyme, and to examine the effect of the nucleotides at positions −5 and −6 on the efficiency of cleavage. Its specificity may approach that of the DNA restriction endonucleases, most of which recognize a particular 4 or 6 base-pair sequence.

The endoribonuclease reaction is analogous to the first step of pre-rRNA self-splicing (Fig. 1). Both the enzymatic and the self-splicing reactions use the same two binding sites, an oligopyrimidine-binding site and a guanosine-binding site, to achieve specificity and to contribute to catalysis. The oligopyrimidine-binding site is also known as the 5′ guide sequence[8] or the 5′ exon-binding site[9-11]. Its role in self-splicing has been defined by analysis of single-base mutations and second-site suppressor mutations[8,11,20]. The same nucleotides bind the substrate in the endoribonuclease reaction, as shown by the change in substrate specificity of the mutant enzymes (Fig. 3). The altered specificity follows the rules of Watson–Crick base pairing. The general features of the guanosine-binding site involved in self-splicing have been described[21,22], but the site has not been localized to a particular set of nucleotides. The endoribonuclease activity appears to use the same guanosine-binding site, as in both cases guanosine is as active as GTP, whereas UTP, CTP, ATP and dGTP have little if any activity (data not shown). In addition, the K_m of 44 µM for GTP observed in this study agrees reasonably well with the value of 32 ± 8 µM determined for self-splicing under somewhat different reaction conditions[22].

The endoribonuclease activity of L-19 IVS RNA does not require the 3′-terminal guanosine (G414). In this respect it differs from the nucleotidyl transfer, phospho transfer and hydrolytic activities, in which a covalent enzyme-substrate complex, apparently necessary for reaction, is formed through G414[4,5]. Thus the L-19 IVS RNA is not restricted to reaction mechanisms involving formation of a covalent enzyme-substrate intermediate. It can also catalyse bisubstrate reactions by a single-displacement mechanism. Ribonuclease P, an RNA enzyme that catalyses cleavage by hydrolysis rather than by transesterification, also appears to act without formation of a covalent intermediate[23,24].

The L-19 IVS RNA endoribonuclease activity reported here appears to require single-stranded RNA substrates. Work recently reported by Szostak[25] suggests that a smaller version of the *Tetrahymena* IVS RNA, lacking the 5′ exon-binding site, may have an endoribonuclease activity that requires a base-paired substrate. The substrate tested[25] was an RNA fragment containing the end of the 5′ exon paired with the 5′ exon-binding site. However, this RNA 'substrate' included a substantial portion of the IVS RNA, so it is unclear whether the ribozyme has endoribonuclease activity with double-stranded RNA substrates in general.

The enzymatic cleavage reaction has some implications for *Tetrahymena* pre-RNA self-splicing. The observed sequence-specificity of the enzymatic reaction provides further evidence that the CUCU sequence immediately preceding the 5′ splice site is both necessary and sufficient to designate the site. RNA structure models[7,26,27] and data from the *trans*-splicing reaction[9,10] and genetic studies[8,11,15] also support this conclusion. Now that the first step of self-splicing can be mimicked using a short oligonucleotide substrate, analysis of this step should become easier. For example, the uridine nucleotide immediately preceding the site of guanosine addition can be replaced with modified uridine This uridine is conserved in Group I intervening sequences[7,27], modifications would allow detailed investigation of the interactions involving this uridine

Sequence-specific endoribonucleases may be useful in the study of RNA, in ways analogous to DNA restriction endonucleases[6] The pattern of restriction fragments could be used to establish sequence relationships between two related RNAs, and large RNAs could be cleaved to fragments of a size more useful for study The 4-nucleotide specificity of the ribozyme is ideal for cleavage of RNAs of unknown sequence, an RNA of random sequence would have an average of 1 cleavage site every 256 bases The automatic end-labelling of one fragment during ribozyme cleavage is a practical advantage

Ribozyme development has only just begun The cleavage efficiency needs improving, so that digestion is complete Denaturants such as urea and formamide appear to increase the specificity of cleavage, they should also melt the secondary structure of the substrate and maximize the availability of target sequences There are 256 possible tetranucleotide cleavage enzymes of which we have investigated only three Further mutagenesis experiments are needed to discover how many of these are both efficient and specific

Protein ribonucleases cleave RNA substrates with high specificity by recognizing a combination of RNA structure and sequence, the structure is more important (for instance RNase III (ref 28) and RNase M5 (ref 29) But proteins that cleave single-stranded RNA substrates are only specific for mononucleotides or dinucleotides (for instance, RNase T_1 cleaves after guanosines[30]) Thus, the L-19 IVS RNA is considerably more sequence-specific than any known protein ribonuclease

RNA sequence recognition usually involves recognition of RNA by RNA Triplet codons in messenger RNA are recognized by anticodons in transfer RNA, and ribosome binding sites in prokaryotic mRNA are recognized using the Shine-Dalgarno interaction with 16S rRNA It is easy to imagine uses for sequence-specific protein ribonucleases in pre-mRNA splicing and 3'-end generation, but there is no evidence for such enzymes Instead, 5' splice sites in pre-mRNA are recognized using the U1 small nuclear RNA[13,31] and the 3'-end cleavage site of histone H3 pre-mRNA by U7 snRNA[32], much of the sequence discrimination is provided by complementary base-pairing Perhaps it is difficult to construct an active site in a polypeptide to bind an unstructured stretch of nucleotides specifically It is possible that in certain reactions involving RNA substrates, RNA catalysis has not been superseded by protein catalysis for the simple reason that RNA does the job better

We thank T Inoue for initiating studies of ribozyme-catalyzed GTP addition in our laboratory, O Uhlenbeck for sharing his technology for synthesis of oligoribonucleotides, B Chabot and J Steitz for providing pAK105, H Sasmor and M Caruthers for DNA synthesis, and A Sirimarco and M Neary for preparation of the manuscript and illustrations This work was supported by grant GM28039 from the NIH, grant NP-374 from the American Cancer Society, and by the National Foundation for Cancer Research

LETTERS TO NATURE

Is CO_2 responsible for the outbursts of comet Halley?

Outbursts are thought to originate from the nucleus of comet Halley; cameras on the Vega and Giotto spacecraft have recorded the images of jets[1,2], and rapid fluctuations are seen in the visible light curve, detected, for example, by the International Ultraviolet Explorer satellite during the time the spacecraft were making their observations[3]. This activity does not appear to be limited to when the comet is near perihelion, but has been reported for heliocentric distances >4.6 AU pre-perihelion[4]. The outbursts are probably triggered by the heating of relatively volatile material within the ice. We report here spectroscopic data from the IUE showing a strong correlation between a visible outburst in the near-nucleus region on 18.8 March 1986 and the sudden appearance of a large column abundance of CO_2^+ ions in the tail. These data suggest that CO_2 may play a significant role in the outburst process This outburst may have been the source of the detached clumps of CO^+ emission recorded by ground-based observers on 19 and 20 March 1986[5,6].

Data were obtained during a combined 16 h US1-US2 IUE shift on 18 March 1986 beginning at 11 00 UT Observations consisted of a large number of relatively short exposures taken at various offset distances from the nucleus with the long-wavelength (LWP) spectrograph to map the spatial distribution of the OH emission farther from the comet than previously[7] and thereby determine the OH scalelength An initial set of exposures was taken with all the offsets (the maximum was 8 arc min) on the sunward side of the nucleus along the Sun-comet line To examine the symmetry of the OH coma, subsequent exposures consisted of sunward-tailward pairs at equal distances, again along the Sun-comet line Three short exposures at the nucleus were also obtained, at the beginning, middle and end of the observational period Near the middle of the period, a moderately long exposure of the LWP spectrograph was carried out

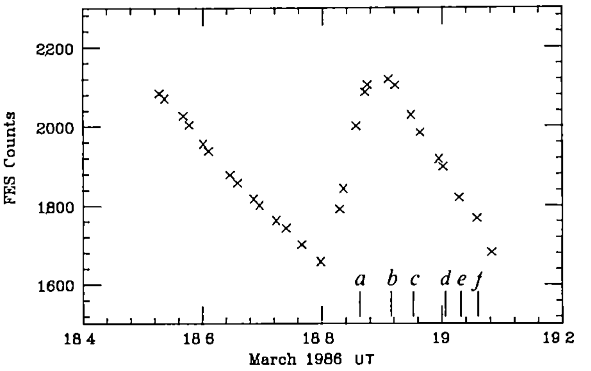

Fig. 1 Light curve of comet Halley for 18, 19 March 1986 derived from the IUE Fine Error Sensor. The effective aperture is ~18 arc s square. *a–f*, Times of the spectrograph exposures listed in Table 1.

to determine the flux of the continuum and weaker features such as CS and C_2.

The IUE fine error sensor (FES) is a slit-jaw camera used to acquire and track a desired target. The FES can also be used as a visible light photometer (wavelength range ~4,000–6,500 Å) sensitive to dust and C_2 and CN emission in a region ~18 arc s square (11,000 km × 11,000 km) around the centre of brightness of the comet. It can provide continuous monitoring of short-term variability[8] not possible at ground-based observatories. The FES data from March 18, 19 are shown in Fig 1, and indicate an outburst beginning at ~19.22 UT, increasing linearly and reaching a maximum about 2.5 h later, and then decaying at a faster rate than before the outburst. The mid-point exposure times of the spectra presented in Table 1 are also shown (*a–f*). At the time of the outburst, the heliocentric distance of Halley was 0.98 AU, the geocentric distance was 0.84 AU, the solar elongation was 63.7° and the phase angle was 66°. Foreshortening along the Sun-comet line was <10%.

Spectra *a–c* are shown in Figs 2 and 3. Spectrum *b* clearly shows the $\tilde{B}$-$\tilde{X}$ doublet of CO_2^+ at 2,884–2,896 Å, at a flux comparable to the nearby OH (1,0) band at a position 4 arc min, or 150,000 km projected on the sky, on the tailward side of the nucleus. The CO_2^+ feature is absent at the same distance on the sunward side (*c*). It is still present (despite the higher camera noise level from the shorter exposure) 1 arc min tailward in *d*, taken 2.25 h after *b*. In the spectrum at the nucleus (*a*) the CO_2^+ emission is masked by the very strong continuum of dust-scattered sunlight, and accounts for only ~15% of the observed emission at 2,890 Å. Festou *et al*[3] have suggested, from earlier IUE spectra of Halley, that this comet appears to show a much lower emission rate of CO_2^+ relative to OH than several other comets observed by the IUE[9]. However, as Fig 2*a* shows, the region of the CO_2^+ doublet contains a maximum in the spectrum of scattered solar radiation (dotted line) which masks the CO_2^+ feature. Subtraction of the solar spectrum, properly reddened[10], clearly shows the CO_2^+ doublet (*b*).

The coincidence of the tailward exposures with the outburst was extremely fortuitous, as was another observation that showed the transient nature of the outburst. The spectra denoted by *d* and *e* in Table 1 were both taken at the same offset of 1 arc min into the tail because of an operational error. A comparison shows more than a fourfold decrease in a period of 37 min for the CO_2^+ emission, whereas the OH brightness remained nearly constant. Note also the decrease in CO_2^+ brightness between spectra *b* and *d* which is all the more striking as *d* was obtained with a fourfold smaller offset into the tail.

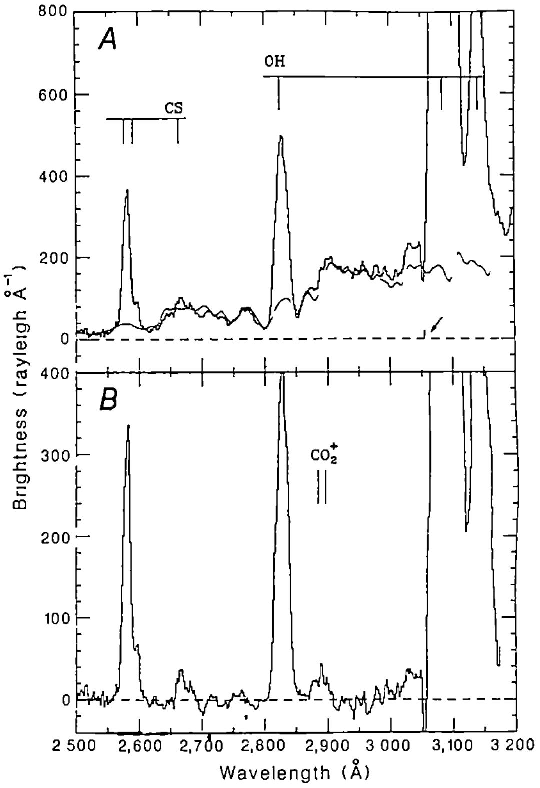

Fig 2 *A*, spectrum *a*, at the centre of brightness, showing the prominent OH and CS emission features. The dotted line is a solar spectrum smoothed to the resolution of the IUE spectrograph. The position of a camera reseau mark is indicated by the arrow. *B*, same spectrum but with a reddened solar spectrum subtracted.

Although the spatial and temporal coverage afforded by the IUE spectrograph is extremely limited, the data strongly imply a sudden enhancement followed by a rapid decrease in the abundance of CO_2^+ ions in the plasma tail in the ~10^4 s after the onset of the outburst detected by the FES. The presence of CO_2^+ suggests the production of a large enhancement of CO_2 molecules at the nucleus, perhaps enough to drive the outburst in terms of propelling grains into the coma. A qualitative estimate of the CO_2 production rate required can be derived from the observed surface brightness of the CO_2^+ emission.

The IUE spectrograph slit is ~10 arc s × 20 arc s with the long axis ~73° to the Sun-comet line for these observations. This long axis is then part of a surface 150,000 km from the nucleus through which all the ions produced inside must flow under the accelerating influence of the solar wind. The 20 arc s dimension corresponds to a linear width $w = 12{,}000$ km, and the uniform spatial distribution of the CO_2^+ emission in the aperture indicates that the width of the ion tail is considerably greater than this slit width. The average column density in the aperture, *N*, is given in terms of the measured surface brightness, *B*, in rayleighs, as

$$N = \frac{Br^2}{g} \times 10^6 \text{ cm}^{-2}$$

where *g* is the fluorescence scattering efficiency in photons per second per molecule at 1 AU and *r* is the heliocentric distance of the comet in AU.

The rate of flow of CO_2^+ ions through that portion of the surface defined by the slit is

$$q = Nvw \text{ ions s}^{-1}$$

where *v* is the outflow velocity at the surface. To estimate a lower limit to *v*, if the ions observed in spectrum *b* were produced at the nucleus at the onset of the outburst, 9,300 s earlier, their mean velocity into the tail would be 16 km s^{-1}. The assumption of uniform acceleration then gives $v > 32$ km s^{-1}. Thus, in the IUE aperture, using $g(CO_2^+) = 2 \times 10^{-3}$ photons s^{-1} ion^{-1} (at 1 AU) (ref 11 and J. L. Fox, personal communication), the observed brightness of 560 R gives $q > 1.0 \times 10^{27}$ s^{-1}. However, the width of the ion tail region is significantly greater than the 12,000 km defined by the IUE aperture, so *q* must be even larger

Table 1 IUE data from 18–19 March 1986

Sequence	Image no	Exposure duration(s)	Mid-point time of exposure (UT)	Position	$B(CO_2^+)$ (R)	B(OH 1,0) (R)	B(OH 0,0) (kR)

* This spectrum is included because the OH bands are saturated in LWP7824

† With continuum subtracted

‡ Uncertainty is standard deviation in camera noise only

Ground-based monochromatic images of other comets at similar heliocentric and geocentric distances[12], suggest that $w>$ 50,000 km, so that the ion flow rate, which is equal to the CO_2^+ production rate, must be $>4.2\times10^{27}\,s^{-1}$.

For comparison, the water production rate, derived from the observed OH (0, 0) band brightness[3], is $3.9\times10^{29}\,s^{-1}$. An upper limit to the CO_2 volume mixing ratio relative to H_2O, derived from the Giotto neutral mass spectrometer data[13], is 0.035, and if this represents a 'quiescent' value, it would imply a production rate, $Q(CO_2)<1.4\times10^{28}\,s^{-1}$. The observed CO_2^+ emission rate would then require efficient ionization and dissociation of all neutral CO_2 produced within a region $<10^4$ km from the nucleus. As the time scales for CO_2 destruction are significantly longer than 10^4 s, the only way to account for the required CO_2^+ production rate is by a large increase in $Q(CO_2)$ during the outburst over the quiescent value. Surprisingly, the OH (0,0) band emission rate does not show an increase after the outburst (see the first and last lines of Table 1), but, in fact, shows a slight decrease, despite the lifetime of the OH parent, H_2O (~1 day). Almost all the IUE data, except for this outburst, show a strong correlation between the FES count rate and the measured OH brightness[14].

The ionization source near the nucleus remains an open question. Photoionization of CO_2 by solar extreme ultraviolet photons is relatively slow (the rate at 1 AU is $\approx7\times10^{-7}\,s^{-1}$)[15] so that 10^4 s after the beginning of the outburst $<10^{-2}$ of the CO_2 molecules produced would have been ionized. Electron impact ionization is also a possible source, particularly within $\sim10^4$ km of the nucleus where significant concentrations of $10–10^3$ eV electrons were measured by the plasma experiment on Vega 1[16]. Evidence for electron impact excitation of forbidden ultraviolet transitions in the inner coma was also obtained in other ultraviolet observations of comet Halley[17]. However, although collisional ionization, in addition to photoionization, could significantly increase the CO_2^+ formation rate, at the required rate the entire neutral molecular coma (principally H_2O) would quickly be converted to ions and atoms contrary to all known observations.

Several ground-based observers[5,6] have reported monochromatic images in CO^+ ($\lambda=4,260$ Å) taken on 20 March 1986 showing a detached condensation of CO^+ at $\sim2.6\times10^6$ km from the head of comet Halley. Pederson and Vio[5] also determined the velocity of the condensation relative to fixed stars, the velocity relative to the comet nucleus was found to be $\sim35\,km\,s^{-1}$. Extrapolating backwards from their observation time of UT 20.295 March 1986, and allowing for changes in velocity of the ion cloud, it is very likely that the origin of this cloud is the outburst detected by the IUE. Unfortunately, although CO^+ is detectable in the wavelength region of the IUE exposures listed in Table 1 through fluorescence in the First Negative system near 2,200 Å (ref 18), the combination of low fluorescence efficiencies[19] and low sensitivity of the IUE camera at 2,200 Å resulted in no detection of CO^+ emission in any of the IUE spectra. However, as CO appears to be the second most abundant parent molecule in the coma of comet Halley[17] and is even more volatile than CO_2, it is likely that both species are released simultaneously during the outbursts (together with the grains that give rise to the increase in FES counts seen in Fig 1) and both the IUE and ground-based observations can be associated with a common event. The presence of CO and CO_2 is also expected on the basis of laboratory experiments that have shown that both CO and CO_2 are likely to be present in comparable abundance in pre-solar cometesimal grains[20].

The role, if any, of the solar wind in the observed outburst is not clear. Measurements of solar wind parameters by the Sakigake spacecraft[21], not too far from Halley, showed a large increase in electron density early on 18 March 1986. However, even at the higher particle flux, the rate for charge exchange ionization of molecules by solar wind protons is at best comparable to the photoionization rate, and the solar wind is stood off by mass loading from the inner coma region where most of the ionization must occur[22]. There is also no evidence in any of the sunward offset exposures taken by IUE before the outburst of

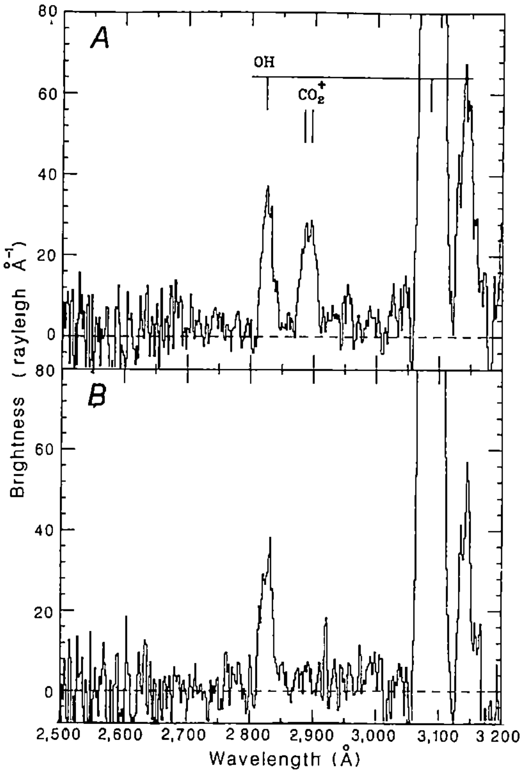

Fig 3 Spectra *b* and *c* (from Table 1) (*A* and *B* respectively) taken 4 arc min tailward and sunward, respectively

any CO_2^+ emission that would indicate enhanced ionization in the coma Thus, while the solar wind may have significantly affected the structure of the ion tail once formed, it is unlikely to have initiated the outburst

We thank the IUE staff at Goddard Space Flight Center for their assistance in the operations and acquisition of data E Roettger assisted in the data analysis This work was supported by NASA grants NSG-5393 to the Johns Hopkins University and NAG 5-252 to the University of Maryland P D F, M F A'H, M C F and H A W were guests observers with the IUE satellite observatory

Rocket ultraviolet spectroscopy of comet Halley and abundance of carbon monoxide and carbon

T. N. Woods, P. D. Feldman, K. F. Dymond & D. J. Sahnow

Department of Physics and Astronomy, Johns Hopkins University, Baltimore, Maryland 21218, USA

The ultraviolet spectrum of a comet's coma is dominated by emissions from the dissociation products of water, OH, H and O, and from secondary species: C, C^+, CO, CO^+, CO_2^+, S, and CS (ref. 1) We report here two far ultraviolet observations of comet Halley made on 26 February 1986 and 13 March 1986 with a sounding rocket experiment. This is the first time that long-slit spectroscopy, a standard technique for the study of extended objects such as comets and nebulae, has been applied to the far ultraviolet study of a comet. The observed CO spatial profiles can be modelled by a radial outflow model[2] for a parent molecule and suggest that the CO is produced directly from the nucleus of the comet Using the observed O I emission profile to deduce the H_2O production rate, the abundance of CO relative to H_2O is found to be 20±5% for the first flight and 17±4% for the second flight, making CO the second most abundant parent molecule in the coma The derived production rate of atomic carbon is consistent with that expected from the photodissociation of carbon monoxide.

Atomic carbon is a common feature in the ultraviolet spectrum of many comets, yet its origin remains unclear In comet West (1976 VI), the observed C I emission was consistent with a model of carbon as a daugher of CO which is vaporized from the nucleus as a parent molecule[3] However, for comet Bradfield (1979X) the C I brightness and spatial distribution were not consistent with models of carbon either as the daughter of the observed CO or as the granddaughter of CO_2 (ref 4) The differences may reflect intrinsic compositional differences between comets, or deficiencies in the models used to interpret the observations Festou[5] has discussed this 'carbon puzzle' in the context of similar results on other comets observed by the International Ultraviolet Explorer (IUE) satellite

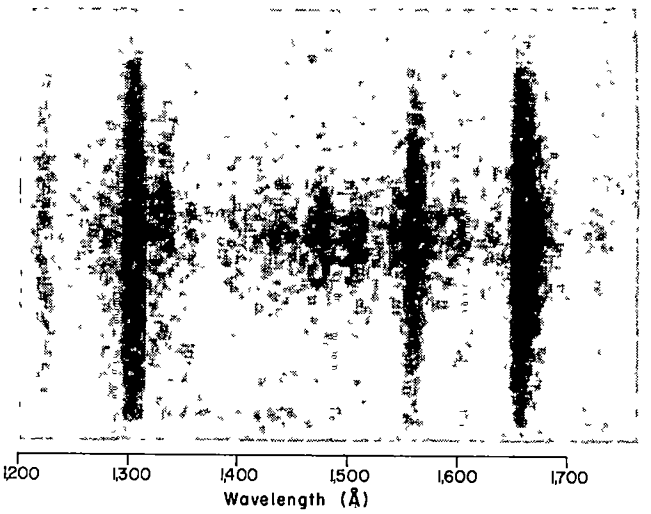

Fig 1 A photographic representation of the raw counts from the spectrograph on NASA 21 093UG is shown for a 72 2-s exposure of comet Halley centred in the entrance slit of the spectrograph The horizontal axis is the wavelength dispersion from ~1,150 to 1,800 Å, and the vertical axis is along the 7 7 arc min slit with the sunward direction pointing down The three brightest lines are O I λ1,304, C I λ1,561, and C I λ1,657 H I λ1,216 appears as a weak feature due to the heavy attenuation below 1,230 Å by a CaF_2 filter in front of the entrance slit

The spectral range for the sounding rocket observations, 1,200-1,750 Å at 12 5 Å resolution, is well suited for studying the carbon chemistry of the coma as it includes C I λ1,657, C I λ1,561, C II λ1,335, and the CO fourth positive system whose strongest bands are at 1,478 and 1,510 Å. While these observations augment the many ultraviolet observations of comet Halley made with IUE[6], the sounding rocket payload is specially designed for the study of the emission profiles in the coma because the spectrograph provides 10 arc s spatial resolution along the 7 7 arc min slit In addition, a higher sensitivity, needed because of the short observing time (~300 s) available with a sounding rocket experiment, is achieved using a photon-counting detector

The faint object telescope (FOT) payload flown previously[7] was modified for long-slit spectroscopy of extended emission objects The basic structure of the FOT is a Dall-Kirkham telescope, a Rowland circle spectrograph and a slit-jaw camera The spectrograph modifications included the use of an ellipsoidal grating to reduce astigmatism at the focal plane and a two-dimensional resistive anode detector The first launch of the experiment, NASA 21 093UG, was on 26 February 1986 at 12 02 UT, 17 days after perihelion, when the heliocentric distance, *r*, was 0 70 AU and the geocentric distance, Δ, was 1 32 AU The payload was recovered, refurbished, and flown again on 13 March 1986 at 11 20 UT when *r* was 0 90 AU and Δ was 0 98 AU This flight, NASA 21 095UG, preceded the Giotto encounter by ~13 h Both launches were from the White Sands Missile Range, New Mexico (106 3° W, 32 4° N)

During both flights a central exposure was taken with the entrance slit (16 arc s wide by 7 7 arc min long) of the spectrograph centred on the brightest part of the coma and with the long axis of the slit oriented along the Sun-comet line The first flight also included a tail exposure that was obtained with the slit centred 8 arc min away from the comet in the anti-sunward direction, again with the slit along the Sun-comet line

Table 1 The brightness *B* and the derived column density *N* of the species in the central coma (10×16 arc s) observed in both flights

* The uncertainty is a combination of the 20% uncertainty in the absolute calibration of the instrument and the counting statistics

† The solar fluorescence efficiencies (or *g*-factor) are based on earlier values[14] which are adjusted for the heliocentric velocity of comet Halley and the solar flux (G Rottman, personal communication) during the observation The CO *g*-factors are from ref 8 scaled to 1 AU and corrected by 0 5 to account for the variation of the solar flux

‡ The average of IUE data from 12 and 13 March 1986, the CO brightness is from 13 March only

A spectrogram of the central exposure taken during the first flight is represented as a two-dimensional photographic image in Fig 1 The vertical axis depicts the spatial distribution of the emissions from the coma The extended and brighter features in the spectrogram are H I λ1,216, O I λ1,304, C I λ1,561, and C I λ1,657, which have been observed in almost all comets studied in the far ultraviolet region[1] The spectra of the central coma (16×72 arc s centred on the nucleus) are shown in Fig 2 for both flights Other features identified in the spectra include the emissions from C II λ1,335 and the CO fourth positive system At least 11 bands of CO are clearly identified by comparison with a synthetic spectrum based on CO fluorescence of ultraviolet solar radiation[8] While a few of these bands are seen in the IUE spectra of comet Halley[6], the poor signal-to-noise ratio in the IUE spectra makes it difficult to extract reliable band intensity ratios from those data

A tentative identification of O I λ1,356 at a level of 60 R in the 26 February spectrum can be made This intercombination line is not excited by solar fluorescence as the other emissions are, and suggests the presence of a region of electron excitation within the inner coma Other indications for a collisional destruction mechanism within ~10^4 km of the nucleus besides solar photodissociation and photoionization are given by the IUE observations of CO_2^+ during an outburst[9] and by the unexpectedly high C^+ abundance measured by Giotto[10] An enhanced flux of keV electrons at 15,000 km measured by Vega 1 and Vega 2[11] and a maximum in the total ion current at 12,000 km as measured by Giotto[12] indicate that a region in the inner coma could exist where collisional excitation or destruction mechanisms are significant Additional modelling is needed to verify this identification of O I λ1,356

The brightnesses of the strongest emission features for both flights are listed in Table 1, and are given for an area of 10×16 arc s centred on the nucleus of comet Halley Table 1 also gives the derived column densities and the fluorescence efficiencies used to derive them The IUE data in Table 1, given for comparison with NASA 21 095UG, are the average of observations made on 12 and 13 March 1986 at 22 UT on each day The IUE data are reduced to an effective aperture of 10×15 arc s These brightnesses are consistent within the uncertainty in the two measurements, which results from a combination of calibration errors and the different spatial resolution and tracking stability of the two instruments Although the visual brightness of the comet varied by a factor of two over a period of a day during many of the IUE observations[6], the O I and C I emissions should not vary as rapidly as their parents' lifetimes are longer than a day Because the visual brightness was reasonably constant from 12 to 13 March, only a small effect due to the intrinsic variability is expected in comparing the two data sets

As the composition of the comet's nucleus cannot be directly inferred from the given brightnesses, modelling of the coma to fit the observed radial distributions of the emissions is performed to determine the production rates of the molecular species A radial outflow model of CO with a production rate of 2 4×10^{29} s^{-1} for the first flight and 1×10^{29} s^{-1} for the second flight yields a good fit to the observed CO distributions (Fig 3*a*) This

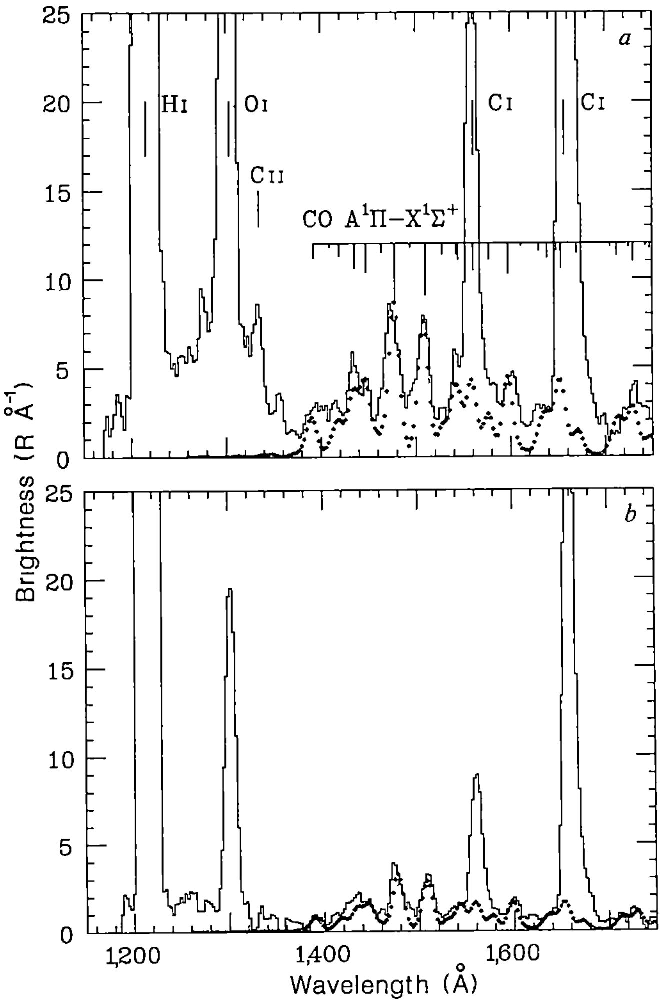

Fig 2 The central coma spectrum from *a*, the first flight on 26 February 1986, and *b*, the second flight on 13 March 1986 The synthetic CO spectrum (diamonds), convolved to our instrument resolution, is based on the *g*-factors of CO fluorescence of ultraviolet solar radiation given by Durrance[8] The feature at 1,356 Å in *a* has been tentatively identified as O I λ1,356 excited by electron collisions in the inner coma

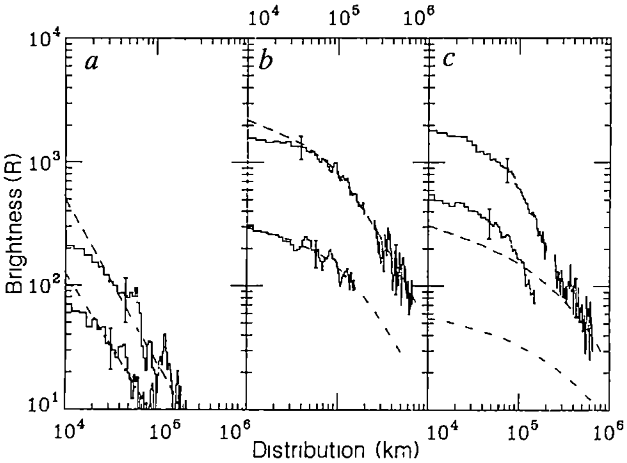

Fig. 3 The observed radial distribution of *a*, the 1,478-Å CO band, *b*, O I λ1,304, and *c*, C I λ1,657 for both flights with the data from the first flight being the upper curve in each panel. The dashed lines are emission profiles, for comparison with the data from the first flight, convolved to our instrument resolution, from a radial outflow model with the production rate of $2.4\times10^{29}\,s^{-1}$ for CO and $1.2\times10^{30}\,s^{-1}$ for H_2O. The dot-dash lines, for comparison with the data from the second flight, are emission profiles from a model with the production rate of $1\times10^{29}\,s^{-1}$ for CO and $6\times10^{29}\,s^{-1}$ for H_2O.

strongly suggests that the CO is vaporized directly from the nucleus, but cannot exclude the possibility of a parent species which has a lifetime <1,000 s. A possible parent for CO is H_2CO, but it is improbable because a radial outflow model of H_2CO that reproduced the observed CO profile would require a production rate greater than the water production rate and would produce a detectable level of H_2 fluorescence in our spectral range. By fitting an outflow model with H_2O and CO parents to the observed oxygen distributions in Fig. 3*b*, a production rate for water of $1.2\times10^{30}\,s^{-1}$ is derived for the first flight and $6\times10^{29}\,s^{-1}$ for the second flight. The average water production rate derived from the OH (0, 0) band brightness measured by IUE, using a vectorial model[2], is $5\times10^{29}\,s^{-1}$ for comet Halley on 12 and 13 March 1986. The water production rate derived from the Giotto neutral mass spectrometer data[12] is $5.5\times10^{29}\,s^{-1}$ with an estimated 50% uncertainty. Because of the uncertainties in the parameters (lifetime and velocity of each species) used in the model, the H_2O production rates derived from a coma model have at least a 30% uncertainty. Therefore, these water production rates are consistent within the uncertainties in the models, instrumental calibrations and the solar fluxes used in deriving the fluorescence efficiency for O I λ1,304 (G. Rottman, personal communication). Note that because CO appears to be a parent molecule and is modelled with fewer parameters, the uncertainty in the derived CO production rate is smaller than the uncertainty in the H_2O production rate.

While data from the Giotto ion mass spectrometer gave an upper limit of 20% for the ratio of CO to H_2O abundance[10], and a rough estimate from the IUE observations in March for this ratio is 10-20%[6], the results from the rocket data give a relative abundance of CO to H_2O as 20±5% for the first flight and 17±4% for the second flight. The uncertainty in these ratios includes the errors from the absolute calibration of the instrument and the fit of the models to the observed radial profiles. Krankowsky *et al.*[12] consider CO_2, NH_3 and CH_4 to be the second most abundant molecules in the coma, however, our results indicate that CO is the second most abundant parent molecule with a mixing ratio of ~18% relative to H_2O. For comparison, a 27% abundance of CO to H_2O was derived for comet West[3], and 1% for comet Bradfield[4].

While these data strongly suggest that the CO is vaporized directly from the nucleus, an unresolved difference remains between the observed radial distribution of carbon shown in Fig. 3*c* and the predictions of the CO outflow model. The data seem to require an additional source of carbon. An outflow model with a small additional source of carbon from the nucleus, at ~2% of the H_2O production rate, improves the fit to the observed carbon profile, but it is not adequate to identify firmly a direct source of carbon from the nucleus. An alternative evaluation of the atomic carbon production rate can be obtained if the total flux in a C I emission multiplet is known. Although the present experiment did not measure the total flux, a reliable estimate can be obtained from the observed radial profiles because the measurements in the tailward exposure on the first flight extend to 7×10^5 km. Circular symmetry of the carbon emission, necessary for this derivation, is a safe assumption as the observed carbon emissions are symmetrical on the sunward and anti-sunward sides of the nucleus. The derived carbon production rate, Q_C, is $4.3\times10^{28}\,s^{-1}$ for the first flight. As the carbon scale length is ~2.5×10^6 km at 0.70 AU, this production rate is only a lower limit. Extrapolating the observed carbon radial distribution to 3×10^6 km yields $Q_C=6.4\times10^{28}\,s^{-1}$, while extrapolation to 1.5×10^7 km gives $Q_C=6.6\times10^{28}\,s^{-1}$. Thus, a reasonable estimate for the total carbon production rate for the first flight is $7\times10^{28}\,s^{-1}$, which gives a ratio of Q_{CO}/Q_C of 3.4±1.2. Because our derived carbon production rate is a lower limit, we consider this ratio to be consistent with the expected ratio of 2.1, assuming that C is produced only through the photodissociation of CO (ref. 13).

The apparent contradiction between the need for an additional carbon source and the result that the Q_{CO}/Q_C ratio is consistent with photodissociation of CO may be resolved by the inclusion of an electron impact source in the models. Evidence for such a source, including the OI λ1,356 emission in Fig. 2, has been cited above. If electron impact enhanced the dissociation of CO in the inner coma, without destroying a significant fraction of the total CO, then the radial distribution of C would exhibit a steeper slope in agreement with the observations, while the radial distribution of CO and the Q_{CO}/Q_C ratio would not be significantly altered. Quantitative modelling using the *in situ* plasma measurements[10,11] is needed to evaluate the possible importance of this mechanism. In addition, improved coma models, such as the vectorial model[2], or models based on the *in situ* measured abundances of CO_2, CH_4, and other carbon-bearing molecules may also provide better agreement with the observed radial distributions of the carbon emissions.

Wide-field ultraviolet imagery of comets provides a useful means of determining such fundamental parameters as production rates, lifetimes and outflow velocities of daughter photodissociation products in the coma. Far-ultraviolet imagery has been used to measure the production rates and outflow characteristics of hydrogen for comets Bennett[1], Kohoutek[2,3] and West[4,5], for C and O in comet Kohoutek[6], and for C, S and CS in comet West[7]. Ultraviolet spectroscopy has also revealed the presence of C^+ ions and CO molecules[8] in comet West. Other comets have been observed spectroscopically in the ultraviolet from the International Ultraviolet Explorer (IUE) spacecraft[9]. Here we present far-ultraviolet images of comet Halley obtained from sounding rockets launched from White Sands Missile Range, New Mexico, on 24 February and 13 March 1986. We gained direct electrographic images of the hydrogen coma of the comet at the Lyman-α wavelength (1,216 Å), and objective spectra containing images of the coma at the oxygen (1,304 Å), carbon (1,561 and 1,657 Å) and sulphur (1,814 Å) resonance multiplets. Analysis of the Lyman-α images yields hydrogen atom production rates of $1.9\times10^{30}\ s^{-1}$ and $1.4\times10^{30}\ s^{-1}$ for the two observations. Images of oxygen, carbon and sulphur emissions obtained with the objective grating spectrograph are presented for the first set of observations and preliminary production rates are derived for these elements.

Preliminary results of two far-ultraviolet rocket imaging experiments are reported here. The first rocket (NASA 36 010 DL), was launched as soon after perihelion as practical to observe the comet at high luminosity. The payload was refurbished at the Naval Research Laboratory between launches. The second rocket (NASA 36 017 DL) was launched just before the Giotto spacecraft flyby of comet Halley. Both experiments were coordinated with rocket observations of comet Halley by Johns Hopkins University experimenters (accompanying paper)[10]. The relative solar and cometary positions at the time of the two flights are given in Table 1.

The rocket payload instruments were similar to those used previously in sounding rocket observations of comet Kohoutek[2]. The payload contained a direct-imaging camera covering the wavelength range 1,050–1,600 Å (which includes the hydrogen Lyman-α line at 1,216 Å), and an objective grating spectrograph covering the range 1,230–2,000 Å. Also included was a Lyman-α airglow calibration photometer using a photoionization chamber filled with nitric oxide as a detector.

Table 1 Observation parameters

	36 010 (24 February 1986)	36 017 (13 March 1986)
Time of launch	11 53 30 UT	10 54 00 UT
Apogee (km)	312	312
Comet zenith angle (apogee)	91°	87°
Solar zenith angle (apogee)	112°	120°
Comet-Sun distance (AU)	0.672	0.895
Comet-Earth distance (AU)	1.356	0.975
Comet-Sun velocity (km s^{-1})	17.97	25.57
Comet-Earth velocity (km s^{-1})	−32.11	−43.32
Sun-comet-Earth angle	44.0°	64.1°
Sun-Earth-comet angle	28.2°	54.1°

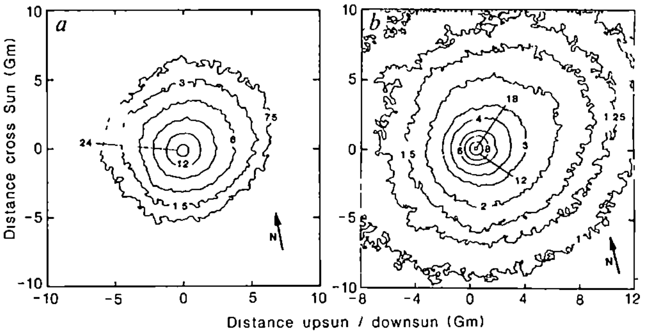

Fig. 1 Isophote contours (kR) of Lyman-α images of comet Halley. Exposure times are 2.5 s for the 24 February (a) and 9.5 s for the 13 March (b) data. The distance scales are the same and the Sun is to the left. The dotted contours on the 24 February plot are reconstructions of isophotes marred by static discharges on the film. Backgrounds due to the terrestrial Lyman-α airglow of an effective 7 kR for the first observation and 6.5 kR for the second have been subtracted.

The direct imaging camera had a 75-mm focal length, $f/1$ Schmidt optical system (LiF corrector plate) and a KBr photocathode, it was identical to Lyman-α cameras used in previous rocket observations of comets Kohoutek and West[2-4]. The camera field of view was 20° in diameter with an angular resolution of ~3 arc min.

The objective grating spectrograph was based on an electrographic Schmidt camera with a focal length of 150 mm, $f/1.5$ focal ratio, CaF_2 corrector plate and CsI photocathode. A objective grating with 1,200 lines per mm was used that gave a spectral dispersion at the photocathode of 30 Å mm^{-1}. The spectrograph had a 12° square field of view and angular resolution of ~1 arc min. The corresponding point-source spectral resolution was ~1 Å. This camera was much more sensitive than that used in the previous objective spectroscopy of comet Kohoutek because it incorporated a microchannel plate (MCP) intensification stage[11,12]. The MCP was operated at a gain of ~100, giving a corresponding increase in effective diffuse-source sensitivity.

Laboratory calibrations consisted of measurements of relative wavelength sensitivity in the 1,150–1,850 Å range combined with absolute measurements of a monochromatic 1,304 Å spot source of diameter 0.27°. For the Lyman-α camera, in-flight calibration was obtained from the ion chamber, and a relative calibration between the two flights was obtained from simulated aperture photometry of the image of the star π Capricornis, which in both cases was in the field of view. Laboratory and in-flight calibrations agreed closely, and the estimated absolute accuracy of the Lyman-α measurements is ±20%. The reduction of the laboratory calibration data for the spectrograph data is complex and has not been completed, consequently an in-flight calibration based on the spectrum of τ Capricornis, which was adjacent to the comet spectrum, was used. The observed τ Cap spectrum was calibrated using the OAO-2 photometer measurements at 1,910 Å (ref. 13), to which was normalized an OAO-2 spectrum of the star ζ Draconis[14] which has the same spectral type and colour (B6 III, $(B-V)=-0.12$). The wavelength scale in the stellar spectrum was based on an IUE spectrum of HD 182255 (ref. 15), that also has the same spectral type and reddening. The TD-1 spectrophotometry of τ Capricornis[16] is available down to 1,380 Å, but is about 15% below the OAO-2 measurement at 1,910 Å. The absolute accuracy of the spectral data is ~±35%, including the uncertainty in the comparison star spectrophotometry, but the relative (wavelength) accuracy is ~±10%.

The flight and calibration exposures were scanned and digitized using a microdensitometer at the University of Texas, Austin, using a 16×16 μm aperture on a 2048×1536 array. The measurements were then summed on a 2×2 basis to form a

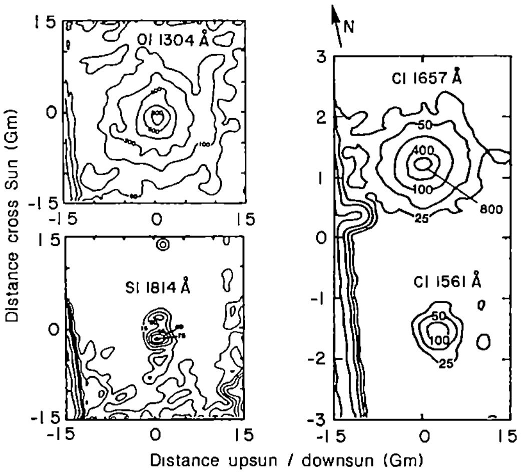

Fig. 2 Brightness in rayleighs of the objective spectral images of C, O and S resonance multiplets seen during the flight of 24 February. The images have been compressed in the spectral direction to correct for the non-isotropic plate scale of an objective spectrograph. The brightness contours have been oriented so that the Sun is positioned to the left. A background derived from an average in the vicinity of each feature was subtracted from all four images. The vertical streaks on the left are from the spectrum of τ Capricornus which was used for calibration. The right sides show a small amount of contamination from another stellar spectrum, and contours from zero order star images are seen.

1,024×768 array for final analysis, the resultant sampling was 2–3 pixels per resolution element. Nonlinearities are small in the electrographic process below a film density of ~4.0, and were avoided by using data from shorter exposures for the brighter features.

Images of the Lyman-α coma of comet Halley were obtained on both flights with 0.5, 2.5, 9.5 and 29.5 s exposure times. Contour plots of the Lyman-α isophotes from images obtained on the two periods of observation are given in Fig. 1. Only the 0.5 and 2.5 s exposures from the first flight could be used because of instrumental difficulties.

The intensity contours show approximately circular isophotes within 2 Gm of the nucleus but also show noticeable elongation away from the Sun at increasing distance. The surface brightness during the February observations was higher, but the outer isophotes of the March image are better developed due to the longer exposure time and decreased Earth-comet distance.

In both rocket flights, objective spectral images of the comet were obtained with exposure times of 2.5, 9.5 and 29.5 s. Grayscale reproductions of images from the first flight have been published[17]. Contours of the surface brightness of the O 1,304 Å, C 1,561 Å and 1,657 Å, and S 1,814 Å multiplets are shown in Fig. 2. Because the inner regions of the O 1,304 Å and C 1,657 Å images were saturated on the film for exposure times >2.5 s, the isophote contours shown for these features are a combination of images with long and short exposure times. Isophotes for contours >100 R were taken from 2.5 s exposures for both features. The outer isophotes of the 1,304 Å image were taken from a 9.5 s exposure and those of the 1,657 Å images were taken from a sum of six 29.5 s images. The C 1,561 Å and S 1,814 Å isophotes were also taken from the sum of six images.

The production rates of C, O, S and H were calculated using a simple radial-outflow model similar to that used previously to analyse hydrogen imagery[2,4]. Atoms are assumed to expand outwards isotropically from a negligibly small source region. The atoms are ultimately lost to photoionization or charge exchange with the solar wind, however, in the inner regions losses can be ignored and the column density of atoms at projected distance ρ from the nucleus can be related to the production rate Q, and mean outflow velocity $\bar{v}$, by

$$N(\rho) = Q/(4\rho\bar{v})$$

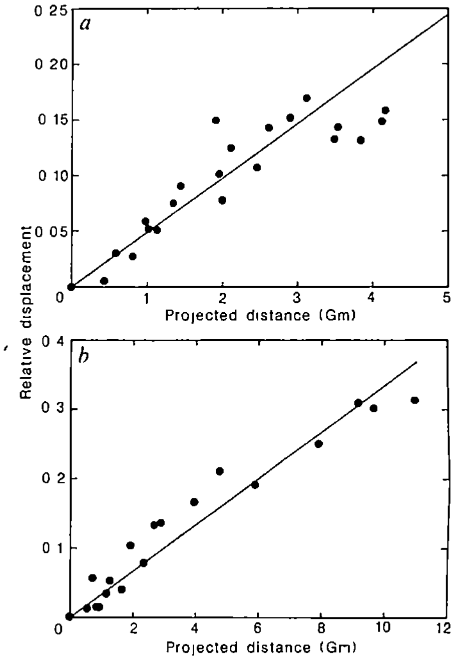

Fig. 3 Relative shift of isophote centre, S/ρ, versus ρ, the projected radius of the isophote. *a*, 24 February; *b*, 13 March. The lines show the predictions for a simple radial outflow model with $\bar{v} = 8\ \mathrm{km\ s^{-1}}$ and the acceleration due to solar Lyman-α radiation pressure produced by a solar flux of 2.3×10^{11} photons $\mathrm{cm^{-2}\ s^{-1}\ Å^{-1}}$ at 1 AU.

The brightness of the comet in rayleighs at ρ is

$$B(\rho) = 10^{-6}\, N(\rho)\, (g_o/R^2)$$

where g_0 is the g-factor, or scattering probability per (atom-second) at 1 AU, and R is the Sun-comet distance in AU. Thus, if the mean outflow velocity is known, the production rate can be determined by measuring the brightness at a distance ρ that is large compared to the instrument resolution but small compared to the scale length of the loss processes.

The radial outflow velocity for heavy constituents is typically $1\ \mathrm{km\ s^{-1}}$, and is the value adopted here for C, O and S to be consistent with previous calculations. For hydrogen, because of its small mass, a high outflow velocity is imparted during dissociation which can range from a few $\mathrm{km\ s^{-1}}$ to over $20\ \mathrm{km\ s^{-1}}$ depending on the dissociation channel. A mean outflow velocity for H can be determined by measuring the shift of the inner Lyman-α isophotes caused by solar radiation pressure[2,4]. The shell of hydrogen emitted at time t before the observation will have been accelerated downsun a distance $S = at^2/2$, where a is the acceleration due to radiation pressure. Because of limb brightening most of the contribution to the observed radiation from a given shell is from a ring of projected distance equal to the radius $\rho = \bar{v}t$. A plot of relative isophote shift versus radius then gives the velocity (Fig. 3). The prediction for $\bar{v} = 8\ \mathrm{km\ s^{-1}}$ is shown, this is in good agreement with results obtained for comets Bennett, Kohoutek and West. In spite of the many simplifying assumptions, this model tends to give production rates similar to those obtained from more realistic computations.

Production rates derived for the four species on 24 February and for H on 13 March are summarized in Table 2. The formula above was used, taking the average brightness of the coma at the radius indicated in Table 2 and assuming an outflow velocity of 1 or $8\ \mathrm{km\ s^{-1}}$ as appropriate. The sulphur brightness listed is the sum from the two bright lines that are resolved, and is the least reliable because of the poor signal-to-noise ratio for this multiplet.

The Lyman-α observations on 13 March give production rates of H_2O, (assuming all H comes from water), of $7\times10^{29}\ \mathrm{s^{-1}}$, in

Table 2 Production rates

Species	ρ (Gm)	$B(\rho)$ (R)	g_0 (1 AU) (s^{-1})	Outflow velocity (km s^{-1})	Q (s^{-1})
H (24 Feb)	2 0	7,850	$1\ 22\times10^{-3}$	8	$1\ 9\times10^{30}$
O	0 2	406	$3\ 7\times10^{-6}$	1	$5\ 9\times10^{29}$
C	0 2	535	$2\ 3\times10^{-5}$	1	$8\ 4\times10^{28}$
S	0 12	51	$5\ 9\times10^{-5}$	1	$2\ 4\times10^{27}$
H (13 Mar)	1 0	6,680	$1\ 22\times10^{-3}$	8	$1\ 4\times10^{30}$

Values for g_0 for C and O from ref 21, g_0 for H from ref 4, g_0 for S from ref 7 The 1,657 Å emission was used for the C production rate

good agreement with results from optical and mass spectrometers on the Vega[18,19] and Giotto[20] spacecraft The 24 February observations given an H/O ratio of >3, perhaps indicating that not all the hydrogen is produced from water (uncertainties could be as large as 50% for O) Our C production rate is consistent with results from the other rocket observations[10], and indicates that gaseous carbon is relatively scarce in this comet Our C/S ratio is not very different from the value of 22 given by ref 7 The cosmic ratio is 21

Further reduction of the data is in progress Future analyses of the spectral images will involved the use of more complex models, and comparisons will be made with Lyman-α observations from the Suisei, IUE, Dynamics Explorer and Pioneer Venus spacecraft

We thank D King and H Merchant for assistance with the development of the experiment payload, and the NASA Wallops payload team and the research rocket group at White Sands Missile Range for their assistance Solar Lyman-α fluxes were provided by G Rottman Supported by NASA grant S21601D

Our previous pre-perihelion observations[1] of comet Halley from the NASA Kuiper Airborne Observatory (KAO) resulted in the first definite detection of water vapour in a comet. This success allowed us to carry out an ambitious post-perihelion KAO observing programme which significantly extended the scope of our Halley water investigation. The spectral bandwidth of the post-perihelion data included essentially all of the ν_3 band. Fifteen spectral lines of water were detected, including three previously undetected lines in the ν_3 band ($\lambda \simeq 2.65$ μm) and three lines in the (011–010) band. The observed relative intensities illustrate that water in the cometary coma is rotationally relaxed, as predicted by recent nonthermal-equilibrium models[2,3]. An *ortho/para* ratio of ~3 is consistent with both pre- and post-perihelion data. The water spatial brightness profile can be fit by that of a parent molecule, and a significant sunward–tailward brightness asymmetry was observed which suggests ejection primarily into the sunlit hemisphere. Comet Halley exhibited marked temporal activity on timescales as short as 2 h. The largest water production rate measured was 2.3×10^{30} mol s^{-1} on 24:18 UT March 1986, which is about an order of magnitude (or more) larger than the production rates we measured pre-perihelion at the same heliocentric distance (~1 AU), indicating a large pre- to post-perihelion asymmetry in gas production.

Spectra were obtained on 20, 22, 24 and 26 March 1986 using the University of Arizona high-resolution Fourier-transform spectrometer (FTS) The heliocentric distance (R) was ~1 AU for all dates while the geocentric distance (Δ) decreased from 0 8 to 0 6 AU during our investigation Observations from airplane altitudes (~12 km) and large cometary geocentric radial velocities ($\Delta \simeq -43$ km s^{-1} for the period of our observations) were required to obtain good atmospheric transmittance at the positions of cometary H_2O emission lines Comet Halley was in the airplane's observing 'window' for up to 2 5 h during our flights For monitoring the temporal variability of the comet, at least one spectrum was taken each flight through a narrow filter ($\Delta\lambda \leq 0\ 06$ μm) using the relatively modest spectral resolution of ~1 4 cm^{-1} Approximately 15 min were required to obtain these data when our aperture (~41 arc s diameter) was centred on the nucleus Spatial mapping was accomplished using the same instrumental setup, but with the aperture offset by known amounts from the centre of brightness of the comet On 26 March we observed comet Halley at ~0 75 cm^{-1} resolution through a much wider filter ($1\ 9 \leq \lambda \leq 2\ 7$ μm), which transmits essentially the entire ν_3 band of H_2O On 22 March we used the narrow filter at ~0 014 cm^{-1} resolution ($\Delta v = 1\ 2$ km s^{-1}), but these data will be discussed elsewhere[5]

Figure 1 shows the spectra acquired through our wide bandpass filter Fig 1*a* is a spectrum of the Moon showing the atmospheric transmittance, and Fig 1*b* is the cometary emission spectrum Figure 1*a* is characteristic of an H_2O absorption line spectrum in thermal equilibrium at ~216 K and shows significant absorption for rotational levels up to $J=8$ ($J\equiv$total angular momentum quantum number) In contrast, the cometary spectrum is heavily weighted towards low J, with all detectable emission originating from transitions having $J\leq3$ as the lower level

The intensities for all observed H_2O lines are given in Table 1 At least six new H_2O lines were detected post-perihelion that were not observed pre-perihelion Most of these were not observed pre-perihelion simply because the comet had significantly stronger emissions post-perihelion (that is, Q_{H_2O} was

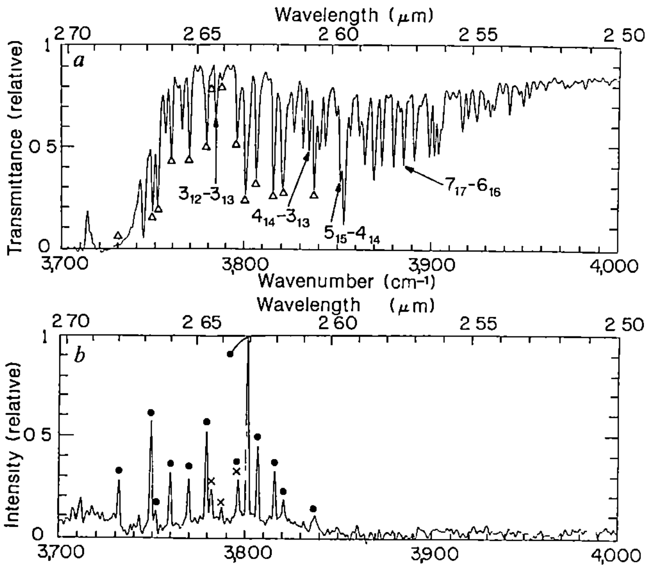

Fig. 1 *a*, A spectrum of the Moon. *b*, The spectrum of comet Halley. Both spectra, taken on 26 March 1986, are apodized to a resolution of 1.5 cm^{-1}, and are uncorrected for atmospheric transmission and instrumental response. For the Halley spectrum, R = 1.096 AU and Δ = 0.646 AU. The absorption lines in the lunar spectrum are due to H_2O and CO_2 in the Earth's atmosphere. Terrestrial H_2O lines corresponding to observed cometary lines are indicated (Δ). The relative strengths of the H_2O lines are characteristic of thermal equilibrium with $T \sim 216$ K. Four H_2O lines whose lower states are the upper states for rotational transitions which have been suggested as probes of H_2O in comets are also identified. These lines are not present in the cometary spectrum. The cometary spectrum is due primarily to molecular line emission produced in solar infrared fluorescence (a little cometary continuum may also have been detected). Most lines are in the (001-000) vibrational band (●), but three lines can be seen in the (011-101) band (×). Note the contrast between the LTE (low thermal emission) terrestrial transmittance spectrum (*a*), which shows significant H_2O absorption for $J \leq 8$, and the non-LTE cometary spectrum (*b*) which sharply cuts off with $J \leq 3$. ($J \equiv$ lower state total angular momentum quantum number)

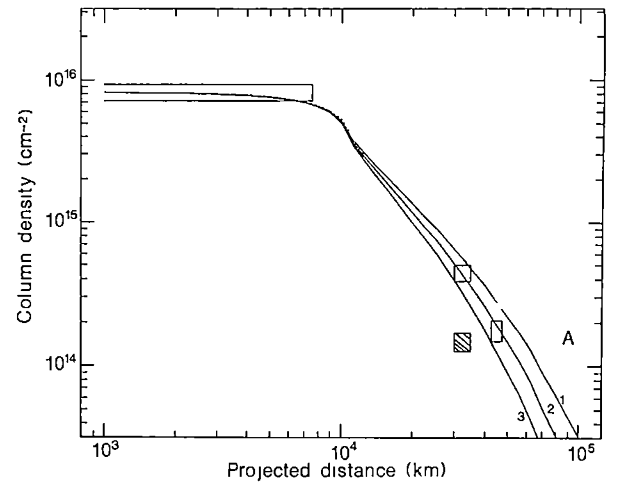

Fig. 2 Assuming that the H_2O emission in the ν_3 band is proportional to the H_2O column density, the boxes represent the observed H_2O spatial brightness distribution. The width of each box is the estimated pointing uncertainty for each observation and the height is the error in the measured relative intensities. The largest component of this error (~10%) is the uncertainty in deriving the relative ν_3 band emission for the nucleus pointings versus the offset pointings (the excitation changes with position in the coma). Two of the offset pointings were towards the Sun while the hatch box represents a tailward pointing. A significant sunward-tailward brightness asymmetry was measured, so only the sunward points are used to determine the H_2O scale-length. Although Q_{H_2O} was varying significantly over the time required for molecules to flow from the nucleus to the offset points, we have ignored this effect. Comparison of KAO and IUE data suggest that Q_{H_2O} was increasing before our observations, which implies that the scale-length derived from our data is a lower limit to the actual value. The curves represent steady-state radial outflow models which have been convolved with a 41 arc s diameter aperture. Scale-lengths: model A, 8.2×10^4 km, model 1, 4.4×10^4 km, model 2, 3.2×10^4 km, model 3, 2.4×10^4 km.

much larger) and/or the lines were not transmitted by our pre-perihelion filter. There are three lines in our spectra which belong to the (011-010) 'hot' band of H_2O. Our calculations of the *g*-factors for this band yield predicted intensities which match the observed values. One of these lines is so strong that it should have been detected in the pre-perihelion spectrum given similar excitation conditions pre- and post-perihelion. The absence of this line pre-perihelion remains to be explained.

The lines originating from levels other than the lowest *ortho* and *para* states (1_{01} and 0_{00}, respectively) have become relatively stronger post-perihelion. This behaviour seems consistent with the hypothesis that larger post-perihelion water production rates cause the pure rotational transitions (which allow relaxation of the H_2O molecules to the lowest states) to become extremely optically thick, thereby 'pumping up' the higher J levels. We note, however, that this mechanism apparently still does not significantly populate levels with $J > 3$. In fact, assuming that the 4_{04}-3_{03} line is pumped only from 3_{03}, we use the measured post-perihelion intensity of this line to derive a relative (to the total) population of 4.3 ± 1% in the 3_{03} level, confirming our previous conclusion[1] that the population in 3_{03} must be small.

Figure 1*a* shows the positions of several strong terrestrial H_2O lines in the ν_3 band whose lower states are the upper states of some rotational transitions which have been suggested as probes of cometary H_2O (6_{16}-5_{23} at 22 GHz, 3_{13}-2_{20} at 183 GHz, and 4_{14}-3_{21} at 380 GHz). The absence of cometary infrared fluorescence (Fig. 1*b*) in these lines (3_{12}-3_{13}, 4_{14}-3_{13}, 5_{15}-4_{14} and 7_{17}-6_{16}) suggests that the rotational levels 3_{13}, 4_{14} and 6_{16} are not significantly populated. This may explain some past failures to detect H_2O rotational lines in comets. We observe ν_3 band transitions which pump the levels 3_{13} and 4_{14} of the ground vibrational state, but the equilibrium populations achieved by the pumps are insufficient to produce detectable infrared fluorescence from those levels. If the rotational transitions 3_{13}-2_{02} and 4_{14}-3_{03} are optically thin, then the emission in two of the above rotational transitions can be estimated directly from the infrared emission rate. We calculate aperture-averaged intensities of 2.3×10^{-16} W cm^{-2} sr^{-1} for the 183 GHz line and 2.4×10^{-16} W cm^{-2} sr^{-1} for the 380 GHz line. Using a Haser model, these intensities can be used to predict the fluxes in a diffraction-limited (for a 0.9-m telescope) aperture. We obtain 28 Jy and 10 Jy for the 183 GHz and 380 GHz lines, respectively, which are below detection limits. However, these predicted fluxes should be considered as lower limits to the actual values because optically thin conditions were assumed and other possible pumping mechanisms were not considered.

The ratio of *ortho*-H_2O to *para*-H_2O in comets may be indicative of the temperature of the cometary ice[1]. Our post-perihelion data give an *ortho*/*para* ratio of 3.23 ± 0.37, compared with our revised pre-perihelion value of 2.73 ± 0.17 (the pre-perihelion value has been revised slightly due to a reassessment of the atmospheric transmittances). Within the present $\pm 2\sigma$ statistical error limits, both the pre- and post-perihelion data are in agreement that the *ortho*/*para* ratio in comet Halley is ~3. More precise determination of the atmospheric transmittances is in progress, and should lead to reduced error estimates for the cometary line intensities, and for the *ortho*/*para* ratio.

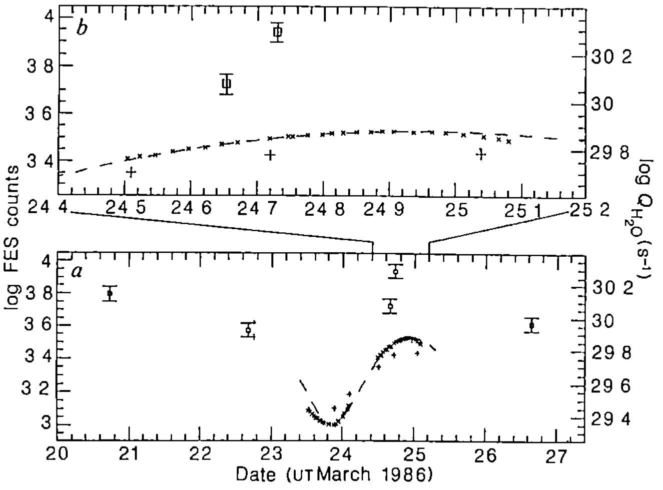

Fig. 3 *a*, Water production rates (using model A parameters) derived for all KAO observations (☐). The error bars are determined solely by our estimate of how pointing inaccuracies can affect our individual observations. The statistical error in the measurements is negligible by comparison. IUE data for 23 and 24 March are also shown. The IUE water production rates (+) are derived from measurements of OH. The integrated visual intensities measured by the IUE fine error sensor (FES) are also given (×). The dashed curve is a sinusoid of period 2.2 days and gives a fairly good match to the FES curve. Propagating this sinusoid forward and backward in time would yield peaks in activity at the positions of the dotted vertical lines. *b*, An expansion of *a* during the time of simulaneous KAO and IUE observations. The temporal variability of the KAO data seems to be substantially larger than that of the IUE data for the time around 24.17 March UT.

Table 1 Intensities of H_2O lines

† From ref. 12.

‡ Relative intensities are listed. The integrated line intensity for the 202-101 (001-000) transition was 9.24 (±0.09)×10^{-10} W cm^{-2} sr^{-1} on 24.18 UT March 1986. The estimated ν_3 band intensity in this case was 1.18 (±0.11)×10^{-8} W cm^{-2} sr^{-1}. The quoted errors are 1σ statistical errors plus our estimate of the uncertainties in the atmospheric transmittances.

Spatial information on the H_2O emission is required for determining the H_2O scale-length. On 24 March 1986 we made observations with sunward and tailward (approximately) offsets of 65 arc s (3.3×10^4 km at the comet) relative to the nucleus, and bracketed these by two exposures centred on the nucleus. On 26 March we made an observation centred on the nucleus and one offset by 97 arc s sunward.

As illustrated in Fig. 2, a significant sunward-tailward brightness asymmetry is observed, which suggests ejection of H_2O primarily from the sunlit hemisphere. The Giotto multi-colour camera[6] pictures of Halley showed an asymmetry in nucleus activity directly, and our data demonstrate that the asymmetry persists far from the nucleus. We will ignore this asymmetry and derive an H_2O scale-length using only the sunward brightness profile and a spherically symmetric model.

Assuming that the measured brightnesses are linearly proportional to the H_2O column density, we show predicted brightness profiles for several scale-lengths in Fig. 2. The observed H_2O spatial brightness distribution is consistent with that of a parent molecule. The scale-length which best matches our data is ~3.2×10^4 km (model 2, R = 1 AU). Taking 1 km s^{-1} as the nominal outflow velocity implies an H_2O lifetime which is 2.8 times shorter than the photochemical value at solar maximum[7]. Our very high resolution data[5] are consistent with an H_2O velocity of ~1.4 km s^{-1}, indicating that the H_2O lifetime could be shorter still.

The scale-length derived from the Giotto neutral mass spectrometer[8] is given approximately by model 1 and is marginally consistent with our data. However, our data are not consistent with model A, which is based on the calculated photochemical lifetime. The short H_2O lifetime implied by both the Giotto and KAO observations is surprising because the Halley apparition occurred near the time of solar minimum when the H_2O lifetime should have its largest value (even larger than that of model A).

Temporal variation in Q_{H_2O} may explain why our data give short apparent scale-lengths. For a pointing centred on the nucleus, ~70% of the observed H_2O molecules are in a sphere whose radius is equal to the projected size of our aperture radius at the comet (1.04×10^4 km). If the molecules are moving at ~1 km s^{-1}, then it takes ~2.9 h for an H_2O molecule to move from the nucleus to the edge of this sphere. Thus, the nuclear pointings mainly represent an integral of Q_{H_2O} over the previous 3 h. As ~9 h and ~13 h are required for H_2O molecules to reach the two offset positions. These pointings represent an integral of Q_{H_2O} over a period beginning much earlier than the time sampled by the nucleus pointing. Analysis of KAO and International Ultraviolet Explorer (IUE) data[9] suggests that Q_{H_2O} was rising during the 12 h preceding our observations. If this is true, then the scale-length derived from our data will be a lower limit to the actual value.

Using a nominal H_2O velocity of 1 km s^{-1}, and the scale-length given by model 2 of Fig. 2, we obtain a water production rate of 2.3×10^{30} mol s^{-1} for the observation with the largest H_2O emission (24.18 UT March). Below, we compare our data with water production rates derived from IUE measurements of OH, which also assume isotropic production and use the H_2O parameters of model A (v = 1 km s^{-1}). For this model, the KAO data imply a production rate of 1.9×10^{30} mol s^{-1}.

The model A water production rates derived from our observations are plotted in Fig. 3. Simultaneous IUE observations[9] were made on 24 March, and the derived H_2O production rates are plotted in Fig. 3, along with the count rate from the IUE fine error sensor (FES, this is an acquisition camera being employed essentially as a photometer during these Halley observations).

The FES data display an apparent harmonicity with a period which is tantalizingly close to the value suggested by others[10] as the rotation period of the comet (2.2 days). Assuming that there is a fundamental period of 2.2 days, we have indicated by the dotted vertical lines in Fig. 3 where the peaks in cometary activity should occur. The post-perihelion KAO data show clearly that the cometary activity cannot be described so simply, a peak in activity would be expected on 22 March, while the data show no evidence for this. Similar departures from simple periodicity were observed for IUE observations made during the week of the spacecraft encounters[11].

All the data illustrate the extremely dynamical behaviour of comet Halley, but the KAO H_2O data show the largest variability At a time when the H_2O brightness increased by ~64%, the FES counts and OH brightness increased by only ≤6% (see Fig 3*b*). These results indicate that the H_2O line brightnesses are very sensitive remote indicators of nucleus activity

The post-perihelion KAO production rates seem to be systematically larger than those derived from the IUE measurements (a factor of ~2) However, the discrepancy between the KAO and IUE numbers may be due in part to absolute calibration uncertainties Based on a comparison of the signal-to-noise ratio achieved on our data, the nominal instrument sensitivity, and the absolute fluxes produced in our calibration process, we expect that the KAO absolute intensities (from which we derive Q_{H_2O}) should be accurate to within ±50% Because the IUE absolute calibration uncertainty is ±10%, the peak water production rates derived from the IUE measurements are actually consistent (at the 1σ level) with the average KAO value

Besides absolute calibration difficulties, several other factors must be considered when comparing the KAO and IUE results Both the KAO and IUE data have been reduced assuming that all cometary emissions are optically thin The aperture-averaged optical depths for the strongest lines are ~1 for both the KAO and IUE observations, so this assumption is not valid However, a more important consideration is the effect of temporal activity on the derived Q_{H_2O} Our data indicate that Q_{H_2O} derived from the KAO observations is more sensitive to temporal activity than Q_{H_2O} derived from the IUE observations Until time-dependent effects are treated properly, strict comparisons of water production rates derived from the two sets of data are not valid Similar comments should apply to water production rates derived from radio OH observations

Finally, we note that both our pre- and post-perihelion KAO observations were made when the comet was at a heliocentric distance of ~1 AU A significant pre- to post-perihelion asymmetry in the water production rate is observed Our largest post-perihelion rate is a factor of ~10 larger than that derived for 24 December 1985 (this was near the time of an outburst in cometary activity), and a factor of ~25 larger than the value derived for 22 December 1985 In contrast, the water production rates derived from the IUE observations[9] of Halley near 1 AU suggest that there is virtually no pre- to post-perihelion asymmetry Because only relative measurements using the same instrument are important in determining the pre- to post-perihelion asymmetry, the discrepancy cannot be attributed to absolute calibration uncertainties Different sensitivities of the infrared and ultraviolet data to temporal activity may account for the discrepancy, but, failing this, the relationship between OH and H_2O in the cometary coma may require reinterpretation

We thank Lou Haughney and the staff of the Kuiper Airborne Observatory for excellent support The help of Mike Williams was crucial for the smooth operation of the spectrometer We thank Paul Butterworth and William Jackson for performing the IUE OH observations on 24-25 March and for permission to use these data Conversations with Paul Feldman contributed valuable insights into the effects of Halley's temporal variability Financial support from NASA grants NAG 2-356 to The Johns Hopkins University and NAG 2-206 to the Lunar and Planetary Laboratory (The University of Arizona), and from NASA RTOP's 188-41-55, 196-41-54 and 352-02-03 to the Goddard Space Flight Center, is gratefully acknowledged

Solar ultraviolet spectra have been obtained with high spectral and spatial resolution using the Naval Research Laboratory's high-resolution telescope and spectrograph[1] (HRTS) flown on rockets since 1975 and most recently on the Spacelab 2 Shuttle flight. Because the solar spectrum between ~1,170 and 1,719 Å has been well observed for some years, few lines of substantial intensity remain unidentified. (See for example the recent compilation by Sandlin *et al.*[2]). The longest exposures during the first rocket flight of the HRTS, which obtained spectra with a spatial resolution of ~1 arc s along the slit, of length ~1 solar radius, and a spectral resolution of ~0.05 Å, showed a number of weak emission lines at the solar limb, in particular between 1,570 and 1,600 Å (see Plates 16 and 17 in ref. 3), that could not readily be identified. Improved observations of these lines were obtained during the flight of HRTS on the Spacelab 2 Shuttle flight in July–August 1985, by making longer exposures (60, 100 and 250 s) The scope of the data obtained has been described[4]. We have now identified the emission lines concerned as forbidden (electric quadrupole and magnetic dipole) transitions in Fe III, the first detection of these particular transitions in any source. They must now be considered potential candidates for previously unidentified lines in other low-density ($N_e \leq 10^{10}$ cm^{-3}) astrophysical sources.

The wavelengths of the emission lines are given in Table 1 Three groups of lines occur, the strongest between 1,575 and 1,598 Å, the others between 1,503 and 1,518 Å and between 1,431 and 1,452 Å The wavelengths were determined on a scale established from nearby lines of neutral atoms For the group around 1,575 to 1,598 Å these were lines of Si I (ref 5) The wavelength accuracy is estimated as ±0 02 Å for lines in this group and ±0 04 Å for the weaker lines Where Sandlin *et al*[2] include the lines their wavelengths agree with those listed to within these limits Several of the lines under discussion are at wavelengths close to those of lines that appear on the disk or in plage and sunspot spectra from the HRTS I flight However, their behaviour at the limb is quite distinct and unlike the typical appearance of the species, such as neutral atoms, with which they could be blended The lines are observed only at and above the solar limb and are not detectable more than ~20 arc s inside the limb It was this unusual feature that first attracted attention In the Spacelab 2 spectra the lines are most clearly observed when the spectrograph slit was set to pass radially through the north solar polar coronal hole They then extend farther above the limb then in 'quiet' regions Figure 1 shows one such spectrum (HRTS Spacelab plate 266, 60 s exposure) Although weak, the lines extend farther above the limb than nearby stronger lines of C I and Fe II, indicating a degree of ionization greater than that of Fe II This conclusion is supported by a series of spectra, also obtained during the Spacelab mission, where the spectrograph slit was set tangential to the limb, centred close

* Accuracy estimated as ±0.02 Å for lines in a^5D–a^5G, and ±0.04 Å for other lines.

to the boundary of the north polar coronal hole. The slit was stepped from inside the limb (at −5 arc s) to above the limb (up to +17 arc s) in increments of 1 arc s (up to +5 arc s) and then 2 arc s. Although the absolute pointing accuracy has yet to be determined, the stigmatic spectra obtained show clearly the reduction in the extent of the chromospheric continuum and successive reduction in the length of lines from different stages of ionization as the slit was moved to greater heights. The Si I recombination continuum ($\lambda \leq 1,520$ Å) and lines of Si I, formed in the solar chromosphere, are restricted to the lowest heights. Higher ionization or excitation lines (for example those of C IV at 1,548 and 1,550 Å and He II at 1,640 Å) extend farthest out into the corona. The lines of Fe II and Si II are intermediate in their behaviour. The lines of [Fe III] can be seen only near the edges of the spectra, indicating strong limb brightening. They extend farther than Si II lines of comparable strength, are broader than the Si I lines and extend at least as far as much stronger lines of Fe II.

The strong limb brightening of the lines shows that they are optically thin transitions, behaviour shared with semi-forbidden electric dipole lines, for example the ^3S–^5S lines of O III at 1,661 and 1,666 Å. This indicates transitions either in an abundant species of low oscillator strength or in a species of low abundance. The spatial behaviour suggests at least a second or third stage of ionization. The available spatial information is consistent with the present proposal of lines of [Fe III].

The term scheme of Fe III[6,7] is illustrated in a partial way in Fig. 2. It is unusual in that states of even parity in the $3d^6$ and $3d^54s$ configurations extend to 80,000 cm^{-1} above the ground state before the first term of odd parity occurs. Thus permitted resonance transitions (to the ground a^5D term) do not begin until wavelengths ≤1,132 Å. Permitted transitions at longer wavelengths occur only to even parity states well above the ground state. The solar lines are transitions within the multiplets $3d^6\ a^5D$ to $3d^5\ (a^4G)\ 4s\ a^5G$, to $3d^5\ (a^4P)\ 4s\ a^5P$ and to $3d^5\ (a^4D)\ 4s\ b^5D$ and include both electric quadrupole and magnetic dipole transitions. (Only one other quintet term, $3d^3(^6S)4s\ ^5S$, lies between a^5G and the ground a^5D term. Transitions between a^5D and a^5S would lie between 2,439 and 2,502 Å, outside the range of the HRTS instrument.) Fe III is a well-known emitter of forbidden lines in the optical spectra of gaseous nebulae and peculiar stars (see for instance refs 8 and 9). However, this is the first identification of [Fe III] in the vacuum ultraviolet region. Table 1 shows the observed and predicted wavelengths. The strongest line is in the a^5D–a^5G multiplet between $J=4$ and $J=6$, as one might expect for a quadrupole transition where $\Delta L=2$ (see ref. 8).

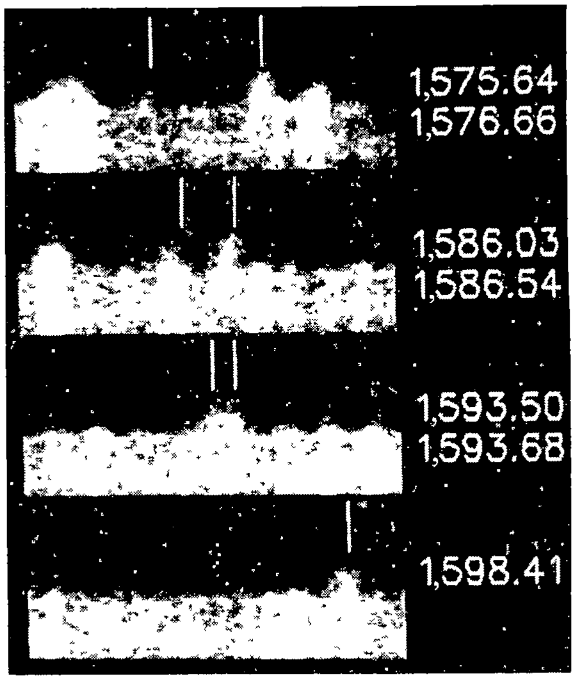

Fig. 1 Sections of a solar limb spectrum obtained with the HRTS instrument on the Spacelab 2 Shuttle flight. HRTS plate 266, a 60 s exposure with the slit radial, crossing the north polar coronal hole. The spectra as illustrated extend about 25 arc s on to the Sun. The wavelengths are given in ångstroms. The wavelength increases to the right.

The intensity calibration of the Spacelab 2 spectra is still in progress, but the order of magnitude of the line intensities can be found from previous spectra[2]. The strongest [Fe III] lines have intensities at the limb ~15 erg cm^{-2} s^{-1} sr^{-1}, about an order of magnitude weaker than the strongest lines of Fe II and a factor of ~100 weaker than the C IV resonance lines.

Until transition probabilities and collision cross-sections are available it is not possible to make definitive statements concerning the excitation of the lines. At present these atomic data have been calculated only for optical forbidden transitions[8,9] or for electric dipole transitions[10]. The [Fe III] lines are likely to be formed at $T_e \approx 20$–30 kK according to ion-balance calculations[11]. The electron density in a coronal hole at this temperature is $N_e \approx 10^{10}$ cm^{-3} (see for instance ref. 12). From the calculations by Garstang *et al.*[9], collision strengths, Ω, between ~1 and 0.3 are typical for transitions with $\Delta L=0$, 1 and 2 and $\Delta J=0$, 1 and 2. If a mean value of $\Omega=0.5$ is adopted then it can be shown that collisional de-excitation of the upper levels will exceed spontaneous radiative decay unless $A>40$ s^{-1}. The transitions listed in Table 1 can occur either by electric quadrupole radiation ($\Delta J=2$) or by both magnetic dipole and electric quadrupole radiation ($\Delta J=0$, 1). The largest transition prob-

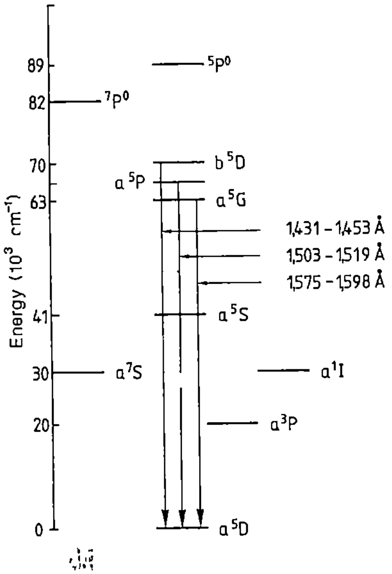

Fig. 2 A partial term scheme for Fe III, showing the observed transitions, some lower-lying terms of the same even parity and the first two terms of odd parity Term energies are given in cm^{-1}

abilities found by Garstang[8] for lower-lying levels are in each case ~1 Thus it is likely that the upper levels have populations close to their Boltzmann values with collisional de-excitation rates exceeding radiative decay rates Then the ratio of the [Fe III] line fluxes to those of permitted transitions would be sensitive to the electron density Detailed calculations of the atomic data are required to establish the collisional-radiative regime for the individual lines The upper levels may attain only a pseudo-Boltzmann population if collisional excitation to higher states of odd parity exceeds the rate for collisional de-excitation to lower levels In any case the new [Fe III] identifications will provide more information on the structure of the solar chromosphere-corona transition region

If the a^{5}G, a^{5}P and b^{5}D levels are collisionally de-excited in the solar atmosphere, they could become stronger, relative to permitted transitions of species of similar excitation, in astrophysical sources of lower electron density For this reason their presence is being investigated in such sources, including the Seyfert galaxy NGC 4151, which has unidentified emission features around 1,575, 1,581 and 1,518 Å (refs 13 and 14) [Fe III] emission is observed in the optical spectrum of NGC 4151[15,16] The relative intensities of the quintet transitions in NGC 4151 and other sources cannot be predicted until collision cross-sections and transition probabilities are known, and these are urgently required to establish whether or not the [Fe III] lines are of wider astrophysical significance

A hierarchical $O(N \log N)$ force-calculation algorithm

Josh Barnes & Piet Hut

The Institute for Advanced Study, School of Natural Sciences,
Princeton, New Jersey 08540, USA

Until recently the gravitational N-body problem has been modelled numerically either by direct integration, in which the computation needed increases as N^2, or by an iterative potential method in which the number of operations grows as $N \log N$. Here we describe a novel method of directly calculating the force on N bodies that grows only as $N \log N$: The technique uses a tree-structured hierarchical subdivision of space into cubic cells, each of which is recursively divided into eight subcells whenever more than one particle is found to occupy the same cell. This tree is constructed anew at every time step, avoiding ambiguity and tangling. Advantages over potential-solving codes are: accurate local interactions; freedom from geometrical assumptions and restrictions; and applicability to a wide class of systems, including (proto-)planetary, stellar, galactic and cosmological ones. Advantages over previous hierarchical tree-codes include simplicity and the possibility of rigorous analysis of error. Although we concentrate here on stellar dynamical applications, our techniques of efficiently handling a large number of long-range interactions and concentrating computational effort where most needed have potential applications in other areas of astrophysics as well.

Until recently, the dynamics of a system of self-gravitating bodies (the gravitational N-body problem) has been modelled numerically in two fundamentally different ways The first one, direct N-body integration, involves the computation of all $\frac{1}{2}N(N-1)$ forces between all pairs of particles This allows an accurate description of the dynamical evolution but at a price that grows rapidly for increasing N[1] The second way involves a two-step approach after fitting the global potential field to a special model with a number of free parameters, each particle is propagated in this background field for a short time before the same procedure is reiterated The potential method involves a number of operations that grow only as $N \log N$ Thus calculations can be performed more quickly, but with a loss of accuracy and generality The special nature of each potential-solving code is caused by the need to use some technique that is tuned to the geometry of the problem being considered (such as Fourier transforms or spherical or bispherical harmonics[2])

Recently, some of the advantages of both approaches have been combined by using direct integrations of force while grouping together increasingly large groups of particles at increasingly large distances This corresponds to the way humans interact with neighbouring individuals, further villages and increasingly further and larger states and countries—driven by increasing cost and decreasing need to deal with more removed groups on an individual basis The first implementation of such a hierarchical grouping of interactions was given by Appel[3], who used a tree structure to represent an N-body system, with the particles stored in the leaves of the tree An independent implementation by Jernigan[4] and Porter[5] incorporated regularization of close encounters However, in both codes the logarithmic-growth gain in efficiency comes at the price of introducing additional errors that are hard to analyse because of the arbitrary structure of the tree Nearby particles may be grouped as leaves of nearby branches, but the phase-space flow of realistic self-gravitating systems demands a continuous updating of the tree structure to avoid tangling and unphysical grouping, requiring complicated book-keeping It is not at all clear how to understand and estimate the errors caused by the process of approximating lumps of particles together as single pseudo-particles, because individual lumps can take more or less arbitrary shapes and sizes

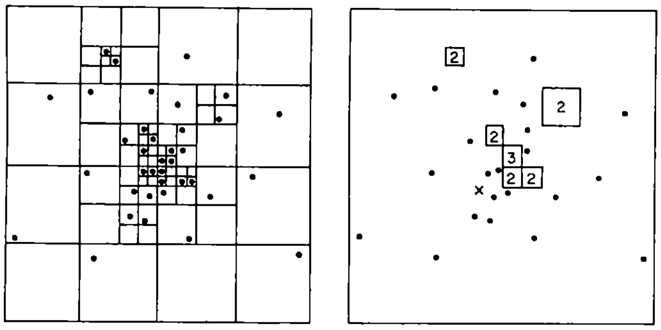

Fig 1 Hierarchical boxing and force calculation, presented for simplicity in two dimensions On the left, a system of particles and the recursive subdivision of system space induced by these particles Our algorithm makes the minimum number of subdivisions necessary to isolate each particle On the right, how the force on particle *x* is calculated Fitted cells contain particles that have been lumped together by our 'opening angle' criterion, each such cell represents a single term in the force summation

We present here a new way of realizing a tree-based force calculation with logarithmic growth of force terms per particle that avoids the tree-tangling complications mentioned above, allows rigorous upper bounds for errors that arise from neglecting internal lump structure, and also offers a well-defined procedure for estimating more typical, average errors The essential ingredients are (1) a virtual cubical division of empty space in (sub)cells with daughter cells having exactly half the length, breadth and width of their parent, (2) the construction of the actual tree of cells from the virtual one by (i) discarding empty subcells, (ii) accepting subcells with one occupant, and (iii) recursively dividing shared occupancies in sub-subcells, and (3) performing this reconstruction *ab initio* at every time step

Given this book-keeping structure, the dynamics are implemented by assigning to every non-empty cell, as well as to higher-order cells containing more than one particle, a (pseudo-)particle that contains the total mass in the cell located at the centre-of-mass of all the particles it contains Any single real particle feels the force of all (pseudo-)particles in the system that represent a cell small enough and far enough to forego the need of further division, thereby screening all its component (pseudo-)particles

A computer program that implements the hierarchical force calculation is available from us upon request It contains less than a thousand lines of C code 150 lines of definitions, 150 lines for tree construction, 100 lines for force calculation and 100 lines for a simple integrator, the remaining lines handle input-output book-keeping

In what follows we summarize some of the more technical details The method we use to compute a force in time of $O(\log N)$ is based on a representation of the mass distribution as a hierarchical tree structure, constructed as follows Begin with an empty cubical cell big enough to contain the system One by one, load particles into this 'root' cell If any two particles fall into the same cell, divide that cell into eight cubical subcells (thus the first such division occurs as soon as the second particle has been loaded in, splitting the system into at least eight pieces) Each divided cell is represented by a data structure that holds information about the subcells it contains a summary of global physical quantities (mass and centre-of-mass position) as well as pointers to the daughter cells, which may be referenced to obtain more detailed information Continue this process of subdividing to as high a level as required When all N particles have been loaded, the system space will have been partitioned up into a number of cubical cells of different sizes, with at most one particle per cell These particle-bearing cells are grouped together into larger cubical cells, which are grouped together into still larger parent cells, and so on down to the root cell, which contains the entire system The average size of a particle-bearing cell is of the order of the interparticle spacing, so the 'height of the tree' (that is, the number of subdivisions required to reach a typical cell, starting at the root), is of $O(\log_2 N^{1/3}) = O(\log N)$, and the time required to construct the tree is of $O(N \log N)$ The final step in constructing the tree is to tag the subdivided cells with the total mass and centre-of-mass position of the particles they contain, by propagating information down the tree from the particles towards the root, this step may also be accomplished in a time of $O(N \log N)$

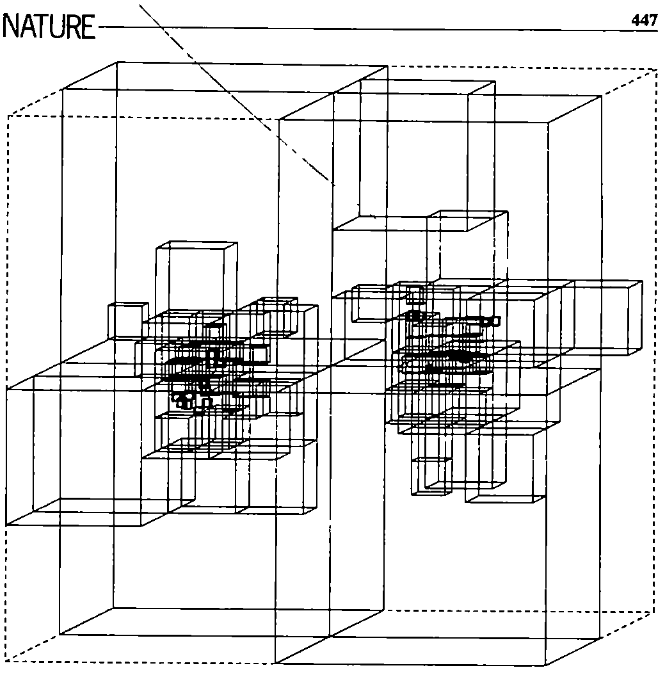

Fig 2 Box structure induced by a three-dimensional particle distribution This example was taken from the early stages of an encounter of two $N = 64$ systems, and shows how the boxing algorithm can accommodate systems with arbitrarily complicated geometry The particle distribution corresponding to a system with 32 times as many members is shown in Fig 3

Having constructed such a tree, the force on any particle p may be approximated by a simple recursive calculation Start at the root cell of the tree, which contains the entire system Let l be the length of the cell currently being processed and D the distance from the cell's centre-of-mass to p If $l/D < \theta$, where θ is a fixed accuracy parameter ~1, then include the interaction between this cell and p in the total being accumulated Otherwise, resolve the current cell into its eight subcells, and recursively examine each one in turn The core of the force calculation routine may be compactly expressed in SCHEME, a dialect of LISP

```
(define (acceleration particle ensemble)
  (cond ((singleton?  ensemble)
         (newton-acceleration particle (the-element ensemble)))
        ((< (/ (diameter ensemble)
               (distance particle (centroid ensemble)))
            theta)
         (newton-acceleration particle (centroid ensemble)))
        (else
         (reduce sum-vector
                 (map (lambda (e) (acceleration particle e))
                      (subdivisions ensemble))))))
```

Note that in LISP, a function with arguments $f(x, y, \quad)$ is written as $(f\,x\,y \quad)$ For example, (newton-acceleration p_1 p_2) calls a function to compute the acceleration of particle p_1 due to p_2 The (cond) form is a three-way conditional, computing the acceleration directly in the first two cases, and by recursion in the final (else) clause Elements of the SCHEME programming language are presented in Abelson *et al*[6] Figure 1

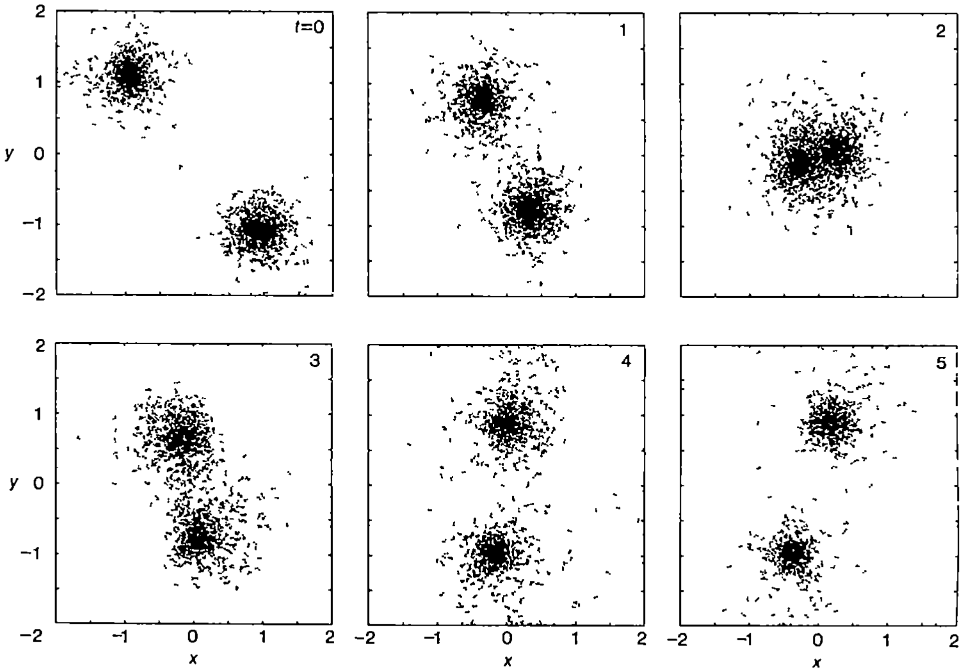

Fig 3 Encounter of two spherical systems, simulated by using our hierarchical acceleration technique in combination with a simple leap-frog integrator The incoming systems were launched on parabolic orbits, but become bound because of dynamical friction Note the striking wakes lagging behind the density centres of the two systems at $t=3$, 4 (in our units the gravitational constant, the mass of each galaxy and the total binding energy of the whole system all equal unity) With a total of $N=4{,}096$ particles in the system and an opening angle criterion of $\theta=1$, the number of two-body interactions computed by our technique is less than 0 1 of the $\frac{1}{2}N/(N-1)$ required by a direct-summation force calculation The calculation took 10 h on a VAX 11/780 (in double precision because of compiler limitations, a single-precision calculation would take half as long) With a time step $\Delta t = 0\ 05$ and softening parameter $\varepsilon = 0\ 025$, energy was conserved to ~1%

illustrates this process for a small number of particles in two dimensions, increasing the number to $10^4 \sim 10^5$ in three dimensions typically increases the number of interactions per particle to only of order 10^2

The number of interactions considered by this procedure in computing the force on p is of order log N for large N Suppose the mass distribution is homogeneous within the root cell Increasing the total number of particles eightfold is roughly equivalent to adjoining eight similar root cells together The seven new cells not containing p will contribute some 'relatively small' number ΔN_t of additional terms to the force approximation Now the expectation value $\langle \Delta N_t \rangle$ depends on θ, but not on the total number of particles or the size of the system Thus the time required to calculate the force on a particle increases by a constant increment (of $\langle \Delta N_t \rangle$), whereas N increases by a constant factor (of eight) In other words, the time required by the CPU (central processing unit) to compute the force on a single particle is on the scale of $O(\log N)$

A rigorous error analysis of the force-calculation algorithm is possible because our prescription yields a unique, well-characterized tree structure based on up-to-date particle positions Each compound cell that we choose not to subdivide introduces a small error due to quadrupole and higher-order moments of the mass distribution within the cell (the dipole term vanishes when expanding around the centroid) The magnitude of this error may be bounded by a 'worst-case' analysis for which the quadrupole moment is maximized (for example, two lumps placed in opposite corners of the cell), and estimated from an analysis of root-mean-square fluctuations within each cell together with estimates of the coherence time scales for these fluctuations We shall present this analysis in a more detailed paper In practice, forces computed even with an opening angle parameter as large as $\theta = 1$ are still accurate to ~1% with little dependence on N Empirically, we find the force error scales approximately as the −1 5 power of the computing time These errors are only weakly correlated from one time step to the next, resulting in a build-up close to a random walk rather than a steady drift

As a test of our new method, we have written a simple N-body code using our force-calculation scheme with a time-centred leap-frog integrator, in which positions and velocities are alternately advanced A parabolic encounter of two galaxies is initiated at a distance of several galactic radii, leading to a box structure as shown in Fig 2 The results of a 4096-body calculation of such an encounter are shown in Fig 3 This calculation took 10 h of CPU time on a VAX 11/780 with a floating point accelerator

There are several ways in which the code can be made more efficient We are now investigating these, and we shall discuss our results in detail elsewhere We just mention three possible improvements (1) using a higher-order integration scheme such as Aarseth's fourth-order polynomial method rather than our second-order leap-frog method, which will require careful adjustments to avoid glitches caused by discrete differences between the grouping of particles in cells from one time step to the next (for example by multiply covering space in partly overlapping virtual grids), (2) including quadrupole moments in the description of cells as pseudoparticles characterized by the total mass in the cell as located in the centre of mass, (3) introducing individual time steps for particles which undergo strongly changing interactions, which could be accomplished by subsequently halving the time step when needed—thus extending the three-dimensional spatial halving of cells to a four-dimensional space-time division in rectangular subcells

An interesting aspect of our new code is the different emphasis it places both on software and hardware, in comparison with other codes On the hardware side, the hierarchical structure of our code does not lend itself easily to vectorization (although this may well be worth exploring) In contrast, we expect our code to be most useful on computers with highly parallel architectures (with one processor per particle, computer time is reduced approximately by a factor of N) On the software side, the hierarchical decomposition of the problem is best realized by using recursive descriptions Recursive function calls and other general control and data structures are not well supported or clearly represented in FORTRAN This has led us to consider other programming languages such as C, PASCAL and LISP Another advantage offered by these languages is that they permit a clarity of presentation of our ideas, which makes the underlying techniques available to other researchers Of course, if a particular computer has a FORTRAN compiler which is an order of magnitude faster than other compilers, it makes sense to translate a version of our program into FORTRAN, trading clarity and modularity for efficiency

Our application to N-body calculations is only one in a range of possibilities including the calculation of radiation fields (replacing particles with sources) and self-gravitating fluid flow (cell division being governed by the complexity of the local flow pattern) Thus our technique forms a general tool for simultaneously handling a large number of long-range interactions and for concentrating computing resources locally where most needed

The 400-km seismic discontinuity and the proportion of olivine in the Earth's upper mantle

Craig R. Bina & Bernard J. Wood

Department of Geological Sciences, Northwestern University, Evanston, Illinois 60201, USA

The 400-km seismic discontinuity has traditionally been ascribed to the isochemical transformation of α-olivine to the β-modified-spinel structure in a mantle of peridotitic bulk composition[1-6]. It has recently been proposed[7,8] that the observed seismic velocity increase at 400 km depth is too abrupt and too small to result from a phase change in olivine but instead requires that the transition zone be chemically distinct in bulk composition from the uppermost mantle. By requiring phase relations in the Mg_2SiO_4-Fe_2SiO_4 system to be internally consistent thermodynamically, we find that the α–β transition in olivine of mantle $(Mg_{0.9}Fe_{0.1})_2SiO_4$ composition is extremely sharp, occurring over a depth interval (isothermal) of ~6 km. The magnitude of the predicted velocity increase is in agreement with that observed seismically[9,10] if the transition zone is composed of ~60–70% olivine. Thus, our results indicate that seismic velocities across the 400-km discontinuity are consistent with a transition zone of homogeneous peridotitic composition and do not require chemical stratification.

The 400-km seismic discontinuity reflects a change in elastic properties of the mantle and has been attributed to a phase transformation of olivine to a spinel-like structure at high pressures[1] Subsequent work has given rise to a generally accepted model in which the discontinuity is attributed to such an isochemical phase change in a mantle of homogeneous olivine-rich, or peridotitic, composition[2-6] This model has the advantage of simplicity and can be tested experimentally

Recently, it has been suggested[7,8] that a phase transition in olivine would produce a gradual velocity increase over an appreciable depth interval—rather than the abrupt increase observed seismically—and that the magnitude of the increase would be more than twice that actually observed It was proposed that the seismic data require the transition zone to be chemically distinct in bulk composition from the uppermost mantle, with the transition zone consisting of a pyroxene-garnet rich 'piclogite' composition containing either 16%[7] or 30%[8] olivine The 400-km discontinuity is ascribed to either a change in chemical composition from peridotite to underlying piclogite or—if this periodotite/piclogite boundary is referred to shallower depths—to the transformation of pyroxene to a garnet-like structure

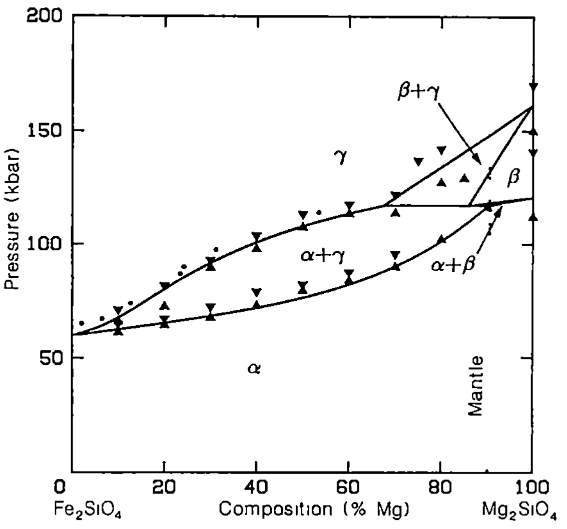

Fig 1 Isothermal pressure–composition diagram showing calculated boundaries for olivine polymorph stability fields at 1,273 K Also shown are experimental data points[12-14,18-20] delimiting the high-pressure stability limits of the low-pressure assemblages (▲), the low-pressure stability limits of the high-pressure assemblages (▼), and the compositions of γ phase which coexist with α phase at the indicated pressures (●) Dashed line shows $(Mg_{0.9}Fe_{0.1})_2SiO_4$ composition

In a previous study[11], we showed that the transformation of pyroxene to a garnet structure would produce a smooth and gradual increase in seismic velocity, rather than the discontinuity observed at 400 km In the present study, we have examined the olivine–spinel phase transitions to determine whether the observed seismic velocity variations may be attributable to such a phase change The α-olivine to β-modified-spinel transition has been commonly represented by a broad 'α+β divariant loop', a region in which both phases coexist in stable equilibrium. If this representation were accurate, the α phase would transform to the β phase in a continuous and gradual manner, and this phase change would not produce a sharp discontinuity in seismic velocity However, the available experimental data (Fig 1) do not constrain the width of this α+β loop, since no high-pressure experiments have yet produced both phases together in equilibrium for olivine of mantle $(Mg_{0.9}Fe_{0.1})_2SiO_4$ composition We have used available thermoelastic and calorimetric data on the olivine polymorphs (α-olivine, β-modified-spinel, and γ-spinel) to constrain the width of the α+β divariant loop By requiring the phase diagram for the Mg_2SiO_4-Fe_2SiO_4 system to be internally consistent thermodynamically, we have attempted to determine the sharpness and magnitude of a seismic discontinuity resulting from a phase change in olivine

If the partial molar free energies of Mg_2SiO_4 and Fe_2SiO_4 components are known as functions of pressure, temperature, and composition, then the boundaries of the stability fields for the various phase assemblages (α, α+β, β, β+γ and so on) can be calculated explicitly To compute the free-energy functions, we require knowledge of the enthalpies, entropies, volumes, and solution activities of the components in the various phases at the pressures, temperatures and compositions of interest We used the available experimentally-measured values of the enthalpies and entropies[5,12-14], heat capacities[15], molar volumes and coefficients of thermal expansion[4], elastic moduli[16], and activity coefficients[17] for the phases and components in question Where measured values were extremely uncertain or

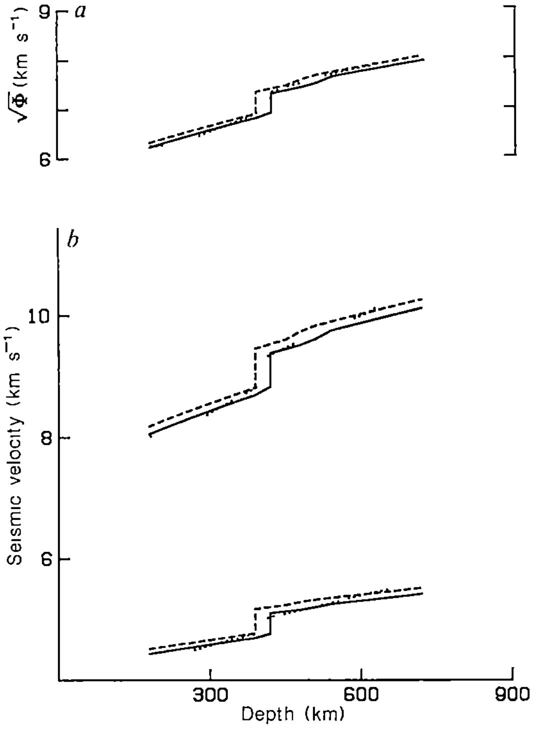

Fig. 2 *a*, Calculated bulk sound velocity ($\sqrt{\Phi}$) as a function of depth for a mantle consisting of pure olivine of $(Mg_{0.9}Fe_{0.1})_2SiO_4$ composition, along 1,700 K (dashed line) and 2,000 K (solid line) isotherms. Composite seismic profile GCA+TNA[9,10] (dotted line) is shown for comparison. *b*, Calculated P- and S-wave velocities (V_P and V_S, respectively) as functions of depth for a mantle consisting of pure olivine of $(Mg_{0.9}Fe_{0.1})_2SiO_4$ composition, along 1,700 K (dashed line) and 2,000 K (solid line) isotherms. Composite seismic profile GCA+TNA (dotted) is shown for comparison.

unavailable (such as for the metastable β-Fe_2SiO_4 component), we estimated them by formally inverting the calculation procedure and requiring the estimated values to reproduce the observed phase relations as constrained by the available synthesis data[12-14,18-20]. (Detailed discussions of the experimental data, the methods of computation and the requirements of thermodynamic consistency are presented elsewhere[21].) Using the Gruneisen thermal state equations[22] and the third-order Birch-Murnaghan isothermal state equation[23] to compute the temperature and pressure dependencies, respectively, of the molar volumes, we computed the boundaries of the stability fields in pressure-composition space for the various assemblages along the Mg_2SiO_4-Fe_2SiO_4 join, as shown in Fig. 1.

The resulting phase diagram is internally consistent thermodynamically and is consistent with the available calorimetric, thermoelastic and synthesis data, within their experimental uncertainties. Note that the $\alpha+\beta$ divariant loop is extremely narrow, ~2 kbar wide, so that the $\alpha \rightarrow \beta$ transition in mantle olivine would be quite sharp, occurring over a depth interval of ~6 km. The width of this transition is extremely robust to uncertainties in the data set, extreme perturbations of the various parameters yield a variation in transition width of only ±1 kbar (~3 km).

Using the method of free-energy minimization[24], we have calculated stable phase assemblages and associated (Voigt-Reuss-Hill averaged[25]) bulk sound velocities ($\sqrt{\Phi}$) as functions of pressure (depth) along 1,700 K and 2,000 K isotherms for a model mantle consisting of pure olivine of $(Mg_{0.9}Fe_{0.1})_2SiO_4$ composition (Fig. 2a). The model bulk sound velocities for a pure olivine mantle agree quite well (within ±0.06 km s^{-1}) with those calculated from the representative high-resolution P-wave and S-wave velocity profiles GCA[9] (Gulf of California) and TNA[10] (Tectonic North America), respectively. (As we are not attempting to model the 670-km discontinuity, we have not included the effects of any higher pressure phases, such as the silicate perovskite, which might contribute to velocity increases at that depth[2].) A sharp jump in velocity occurs at ~400 km depth due to the $\alpha \rightarrow \beta$ transition. A small kink in the velocity profile occurs at ~550 km due to the $\beta \rightarrow \gamma$ transition, but this slight velocity change is barely detectable due to the similarities of the elastic properties of the β and γ phases[16]. The ratio of the magnitude of the observed (GCA+TNA) velocity increase at 400 km (4.9%) to that calculated for the model pure olivine mantle (6.6%) suggests that the mantle in the transition zone contains ~74% olivine.

We have separated our values of bulk sound velocity ($\sqrt{\Phi}$) into P- and S-wave velocities for a model pure olivine $(Mg_{0.9}Fe_{0.1})_2SiO_4$ mantle (Fig. 2*b*). This requires additional assumptions because the temperature and pressure derivatives of the shear moduli of the high-pressure polymorphs are unknown[26]. To perform the decomposition, we first computed velocities by assuming that the behaviour of the shear moduli at high pressures and temperatures follows the same pattern as that of the bulk moduli, namely that the pressure derivatives and the logarithmic temperature derivatives, respectively, are the same[22] for all the phases of a given component. In a second approach, we followed previous workers[27] in extracting P- and S-wave velocities by assuming that Poisson's ratio for our model pure olivine mantle was the same, at corresponding depths, as that observed (GCA+TNA) seismically. These independent approaches yielded virtually identical results and provide support for our conclusions. The magnitudes of the observed (GCA+TNA) velocity increases at 400 km (4.8 and 4.5% in P- and S-wave velocity, respectively), and those calculated for the model pure olivine mantle (7.2 and 8.1%), are indicative of a mantle composed of ~62% olivine (a peridotitic mantle), in excellent agreement with the results of Weidner[6].

Thus, an isochemical phase change from α-olivine to β-modified-spinel in olivine of mantle composition would produce a sharp 400-km seismic discontinuity ~6 km wide. In fact, our computed velocity increase is even sharper than that required by current seismic observations. The actual sharpness of this discontinuity is difficult to resolve seismically[28,29]. Leven[30] suggests that the discontinuity occurs over a depth interval of ~6 km, other studies[31] suggest that the discontinuity is at least 10 km wide. Our transition width of 6(±3) km is computed for isothermal conditions, temperature gradients through the transition could broaden the discontinuity[4] by up to ~7 km.

Thus, seismic velocities above and below a 400 km depth for a model mantle consisting of pure olivine of $(Mg_{0.9}Fe_{0.1})_2SiO_4$ composition are in good agreement with those observed seismically[9,10]. The magnitudes of the abrupt increases in bulk sound velocity and in P- and S-wave velocities at 400 km are consistent with a mantle composed of between 62 and 74% olivine. Since phase transformations from pyroxene to garnet would not produce such a discontinuity[11], a mantle dominated compositionally by olivine appears necessary for the generation of a sharp 400-km discontinuity unless arbitrary changes in bulk chemical composition are invoked. We therefore conclude that seismic observations are consistent with a peridotitic mantle to a depth of at least 650 km and thus do not require the transition region to be chemically distinct from the overlying mantle.

We thank Jim Leven and Hiroshi Sawamoto for providing preprints of papers before publication. We also thank Ray Jeanloz for providing experimental data from the dissertation of Kawada[13], Masaki Akaogi for critical comments, and Don L. Anderson, Jay Bass, Seth Stein and Emile Okal for helpful discussions. This material is based upon work supported under a NSF Graduate Fellowship (to C.R.B.) and NSF grant EAR-8416793 (to B.J.W.).

Controversy has arisen over the recent acidification of lakes[1–4], ascribed by many to anthropogenic acid deposition from the atmosphere[5,6], and by some to natural processes of soil acidification enhanced by the regrowth of forests after cutting and burning[7–10]. Here we show, by analysing the chemistry of Nova Scotian lakes and ponds on base-poor terrains, that both anthropogenic and natural acidification can be important We calculated correlations and regressions between hydrogen ion (H^+) concentrations and each of four predictors: dissolved organic carbon (DOC) (a surrogate for complex coloured organic acids, often of high molecular weight[11,12]), non-marine sulphate (denoted by the prefixed asterisk as $^*SO_4^{2-}$; a surrogate for acid deposition[13]), non-marine calcium ($^*Ca^{2+}$; the major basic cation from soil weathering and ion exchange), and the sum of the other non-marine base cations sodium, magnesium and potassium ($^*(Na^+ + Mg^{2+} + K^+)$). The results indicate that acidity in these waters is affected both by organic acids from peatland catchments and by acid deposition from long-range and local sources (see ref. 14).

Previous investigators ascribed acidity of lakes on diverse geological substrates in Halifax County to either peaty inflows[15] or acid deposition[16] Both used methods inadequate for measuring SO_4^{2-} in coloured waters[17], so another study was needed We sampled lakes on granite and quartzite terrains between 2 5 and 42 km around the Halifax-Dartmouth power plant, whose annual emissions declined from 21 5 kton SO_2 in 1980 to 8 3 kton in 1984 (ref 18) Thirty-seven surface waters were collected during 7-18 December 1984 after a dry period (September-November precipitation, 42% normal) and filtered through Reeve-Angel no 934AH glass-fibre filters before analysis H^+ was measured by a Radiometer combination electrode, DOC by photo-oxidation, gas dialysis and colorimetric titration with phenolphthalein, and Ca^{2+}, Mg^{2+}, Na^+ and K^+ by atomic absorption spectrophotometry SO_4^{2-} was analysed by ion chromatography and colorimetrically by methyl thymol blue after photo-oxidation, results were averaged (Ion chromatography yielded a mean 1 2% above that of colorimetry, r^2 was 0 97, the slope of the relation departed by only 2 5% from the 1 1 line, and the average difference between techniques was 6 μequiv $^{-1}$) $^*SO_4^{2-}$, $^*Ca^{2+}$ and $^*(Na^+ + Mg^{2+} + K^+)$ were estimated as differences between total and marine concentrations, the latter from ratios to chloride (Cl^-) in sea water Cl^- was measured by ion chromatography and colorimetrically by mercuric thiocyanate, results were averaged (Colorimetry yielded a mean 1 4% above that of ion chromatography, r^2 was 0 99, but the slope of the relation departed from the 1 1 line by 8%, so that at very low concentrations colorimetric values were 15% below those of ion chromatography, whereas at very high concentrations colorimetric values exceeded those of ion chromatography by almost 5% Average difference between techniques was 17 μequiv $^{-1}$) Colour was measured as absorbance at 320 nm in a 1-cm cell (A_{320}^{1cm}), and in Pt/Co units Because of plant uptake and microbial reduction, nitrate and ammonium ions—important components of acid deposition—were negligible (N usually <0 01 mg l^{-1}) Alkalinity was usually <2 and always <25 μequiv l^{-1} Ranges of chemical properties were DOC, 0 7-27 mg l^{-1}, colour (A_{320}^{1cm}), 0 001-0 574 and (Pt/Co units), 7-200, H^+, 1-98 μequiv l^{-1}, Cl^-, 90-832 μequiv l^{-1}, $^*SO_4^{2-}$, 12-203 μequiv l^{-1}, $^*Ca^{2+}$, 17-239 μequiv l^{-1}, and $^*(Na^- + Mg^{2+} + K^+)$, 2 4-105 μequiv l^{-1} In the last case, mean percentages were $^*Na^+$, 64, $^*Mg^{2+}$, 23, $^*K^+$, 13

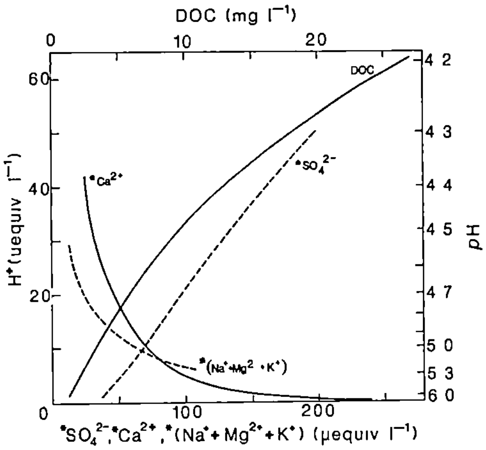

Fig 1 Partial regressions of H^+ on DOC, $^*SO_4^{2-}$, $^*Ca^{2+}$ and $^*(Na^+ + Mg^{2+} + K^+)$

We analysed the chemistry of 33 waters statistically, excluding four lakes by standard diagnostic criteria for regressions[19] Data were transformed to linearize relationships between H^+ and the predictors, error distributions were also normalized H^+ was transformed to its square root, other data to natural logarithms Transformed means were H^+, 3 93, DOC, 1 50, $^*SO_4^{2-}$, 4 43, $^*Ca^{2+}$, 4 03, and $^*(Na^+ + Mg^{2+} + K^+)$, 3 60

In the transformed scales, DOC is the best of the four predictors of H^+ its correlation coefficient is 0 746 and its partial correlation coefficient—in an equation including $^*SO_4^{2-}$, $^*Ca^{2+}$ and $^*(Na^+ + Mg^{2+} + K^+)$—is 0 908 (Except where specified, all correlation coefficients are significant at $p < 0 01$) For $^*SO_4^{2-}$ the corresponding statistics are lower, with a correlation

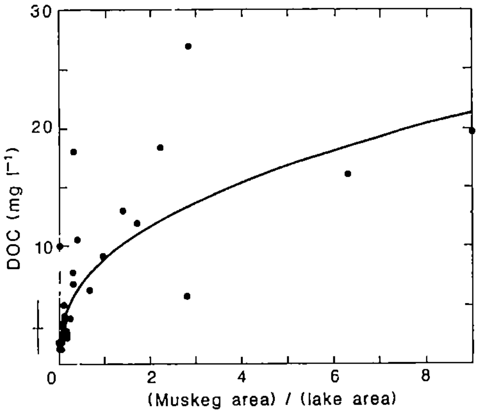

Fig. 2 Relation between DOC and the ratio (muskeg area)/(lake area) ($n = 30$). Cross at lower left indicates mean and range of sites without muskeg. Logarithmic regression, $\ln DOC = 0.395 \ln$ {muskeg area)/(lake area)} $+ 2.19$, correlation, $r^2_{ln} = 0.605$.

coefficient of 0.095 (not significant) and a partial correlation coefficient of 0.742. $^*Ca^{2+}$ predicts H^+ better than $^*SO_4^{2-}$, with correlation coefficients of -0.385 ($p < 0.05$) and -0.849 respectively, negative because of alkalinity associated with $^*Ca^{2+}$ released from soils and sediments. Coefficients for $^*(Na^+ + Mg^{2+} + K^+)$ shift sign after partial correlation, from 0.386 ($p < 0.05$) to -0.558. The multiple regression equation, including both natural and anthropogenic acidifying agents and neutralizing base cations as predictors, is

$$\sqrt{H^+} = 1.33 + 2.26 \ln DOC + 3.66 \ln {}^*SO_4^{2-} - 2.97 \ln {}^*Ca^{2+} - 1.40 \ln {}^*(Na^+ + Mg^{2+} + K^+) \qquad (1)$$

(DOC in mg l^{-1}, other variables in μequiv l^{-1}). The multiple correlation coefficient ($R^2 = 0.878$) accounts for most of the variance in H^+, and is distinctly greater than that ($R^2 = 0.823$) for H^+ on DOC, $^*SO_4^{2-}$ and $^*Ca^{2+}$.

Another possible cause of lake acidification is the deposition of sea salts, whose metal cations can displace adsorbed H^+ episodically and seasonally from soils and peats into streams and lakes[20]. Cl^- can be used as a predictor of the sea-salt effect on H^+, and when substituted for $^*(Na^+ + Mg^{2+} + K^+)$ in equation (1), it too yielded a correlation ($R^2 = 0.857$) distinctly greater than that with three predictors. However, when Cl^- was added to equation (1) as a fifth predictor, the correlation ($R^2 = 0.885$) did not improve appreciably.

Figure 1 illustrates partial relations of H^+ to DOC, $^*SO_4^{2-}$, $^*Ca^{2+}$ and $^*(Na^+ + Mg^{2+} + K^+)$ over their observed ranges of concentration, holding the other three predictors at their mean values in equation (1). DOC has a broader range of effect than $^*SO_4^{2-}$ on H^+, which rises from 1 to 64 μequiv l^{-1} over the full range of DOC increase and from 1 to 50 μequiv l^{-1} over the full range of $^*SO_4^{2-}$ increase. $^*Ca^{2+}$ has a negative effect upon H^+, which declines from 42 to <1 μequiv l^{-1} over the full range of $^*Ca^{2+}$ increase. The decline is curvilinear, reflecting the rapid drop in pH as bicarbonate alkalinity (associated primarily with $^*Ca^{2+}$) is exhausted. A smaller decrease in H^+, from 29 to 6 μequiv l^{-1}, occurs with increasing $^*(Na^1 + Mg^{2+} + K^+)$.

Correlations among DOC, colour and absorbance are highly significant, indicating humic substances, chiefly fulvic acids[11,12], produced by decomposition of plant remains in the catchments. DOC also correlates with the ratio (catchment area)/(lake area), because larger catchments generally contain larger areas of the peatlands that are the major sources of DOC input (see below) and the area of the lake is a major determinant of the volume in which the input is dissolved. The correlation between DOC and the ratio is logarithmic and highly significant ($r^2_{ln} = 0.392$). The prediction equation is $\ln DOC = (-0.095) + 0.634 \ln$ {(catchment area)/(lake area)}. Catchments have been mapped (by the Nova Scotia Department of Lands and Forests) as muskeg, rock

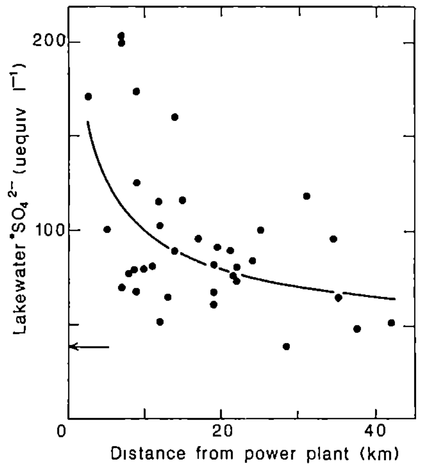

Fig. 3 Decline of lakewater $^*SO_4^{2-}$ outward from the Halifax-Dartmouth power plant ($n = 36$, rejecting one outlier). $\ln {}^*SO_4^{2-} = 5.35 - 0.321 \ln$ km, $r^2_{ln} = 0.266$. Horizontal arrow, background from long-distance transport.

barren, softwood (>75%) forest, hardwood (>75%) forest and mixed forest. Muskegs (which we remapped from air-photos, adjusting other areas appropriately) represent open peatland, sometimes with stunted trees, and are commonly dominated by *Sphagnum* moss. Rock barrens include large patches of ericaceous shrubs over acid mor humus on rock or shallow sandy soil, and small patches of *Sphagnum*. Muskegs and softwood forests on peat are the most likely sources of DOC to lakes[21,22]. Rock barrens are also possible sources because they often have patches of peat, and also lack deeper, less acid B soil horizons capable of precipitating humic substances with oxides of iron and aluminium[23].

For the 16 waters with all three cover types, analysis indicated significant correlation of DOC only with the ratio (muskeg area)/(lake area). For all 30 catchments with muskeg (Fig. 2), the logarithmic correlation and regression of these two variables are highly significant, the correlation accounting for 60% of the variance in DOC. Restriction to lakeside ($n = 14$) and lakeside plus streamside muskeg ($n = 26$) does not improve the correlation. The arithmetic scatter is, however, substantial, and softwood (black spruce and tamarack) swamps, which could not be mapped separately from upland softwood forests, deserve investigation in this context. The rate of water-flow through peatlands also influences DOC concentrations[21].

The $^*SO_4^{2-}$ in these lake waters comes chiefly from acid deposition. (Maps of soil and bedrock geology were inspected carefully to exclude the Halifax slate formation, in which local occurrences of pyrite are a source of $^*SO_4^{2-}$. However, there is a remote possibility that some $^*SO_4^{2-}$ is supplied through the use of crushed Halifax slate on gravel roads beyond the extent of its geological exposure[24].) Figure 3 shows the influence of Halifax-Dartmouth (population 191,000), an oil-fired generating station at Tufts Cove (360 MW) is the reference point for distance. The correlation between $^*SO_4^{2-}$ and distance is relatively low. Differences in vegetation cover, fluctuations in precipitation, wind speed and direction, and differences in water retention time and reduction of SO_4^{2-} in anoxic bottom waters also influence $^*SO_4^{2-}$ inputs and concentrations. The curve in Fig. 3 approaches a baseline (39μequiv $^{-1}$) representing long-distance transport of air pollutants, it was calculated by interpolating Halifax along a line connecting average $^*SO_4^{2-}$ concentrations in lakes at Kejimkujik National Park (46 μequiv l^{-1}) and Cape Breton Highlands National Park (20 μequiv l^{-1}), respectively 140 km SW and 350 km NE of Halifax[25].

Interaction of acid deposition with soil organic matter is claimed to decrease the solubility of humic compounds[8]. Halifax County, with a broad range of lake DOC and moderate levels of acid deposition, shows no evidence of this, the correlation between DOC and $*\mathrm{SO}_4^{2-}$ ($r_{\mathrm{ln}}^2 = 0\ 03$) being insignificant (see ref 26)

Coloured organic acids from catchments strongly influence the acidity of lakes on base-poor substrates, so that even small amounts of humic DOC affect lakewater pH greatly, between minimum DOC at $<1\ \mathrm{mg\,l^{-1}}$ and the log-normal mean at $4\ 5\ \mathrm{mg\,l^{-1}}$, pH declines more than one unit to 4 8 (Fig 1) This conclusion probably applies throughout Nova Scotia, 769 lakes, mostly on base-poor substrates, exhibit a log-normal distribution of colour (J K U unpublished observations) greater than that of Halifax County lakes (antilog mean = 35 Pt/Co units in Nova Scotia, 27 units in Halifax County) Moreover, in 234 Nova Scotian lakes[27], organic anions average 49 μequiv $\mathrm{l^{-1}}$ and $*\mathrm{SO}_4^{2-}$ 60 μequiv $\mathrm{l^{-1}}$ The influence of coloured organic acids is likely in other areas (for example much of the Precambrian Canadian Shield) on comparably base-poor substrates with an abundance of acid peatlands, and with similar concentrations of organic anions (see ref 28) Their significance for lake-acidification models[6,29] is not known and should be evaluated

Despite the influence of coloured organic acids from natural sources (see refs 14, 26 and 30), the effect of acid deposition on surface waters in Nova Scotia is clear (Fig 3) and especially important at snow-melt and other periods of high flow[14,26] It has probably caused naturally acidified waters to acidify further and beyond thresholds for losses of diatoms[31] and salmon[32,33] The degree of natural acidification, as well as the amount of wet $*\mathrm{SO}_4^{2-}$ deposition from the atmosphere, should be taken into account in determining target loadings for acid deposition

A 40,000 year-old human occupation site at Huon Peninsula, Papua New Guinea

‡ Department of Physics, The Faculties,
Australian National University, Canberra, Australia

The geographical position of the island of New Guinea suggests that it may have been an early staging post in the Pleistocene settlement of Australia from the Indonesia–Indochina region. Previous data have not supported this, as archaeological sites 35,000 to 40,000 years old occur in southern Australia[1,2], whereas the earliest previously known in Papua New Guinea is 26,000 years old[3–5]. We now report evidence that the north coast of Papua New Guinea was occupied at least 40,000 years ago Sahuland, which is the greater land area of Australia and New Guinea plus their connecting continental shelf exposed as land when Pleistocene sea levels were lower than now[6,7], was occupied by humans in several widely separated areas at that time. A distinctive 'waisted axe' culture appears to have existed in New Guinea and probably in Australia in the Late Pleistocene, but antecedents are not yet known from east and southeast Asia. There is evidence for hafting of these tools at a date which is earlier than known elsewhere in the world.

Our evidence is found at the southeast end of Huon Peninsula (Fig 1), where a flight of raised coral terraces preserves the former coastal environment of a succession of Upper Pleistocene stages The terraces have been described and dated by ^{14}C and ^{230}Th/^{234}U methods, showing continual tectonic uplift of the coast[8–11] Each coral reef terrace formed when a glacio-eustatic rise of sea level overtook the rising land[9] During each period of reef formation, the coastal environment included local lagoons and fringing reefs By analogy with the present coastal fringe with its Holocene reefs, these provided a productive and hospitable habitat for human occupation[9,12] Figure 1 shows the terrace flight in the vicinity of the archaeological site described here

The archaeological site occurs in a stream gully running into a small palaeo-lagoon on the reef complex labelled IIIa by Chappell[9], which is dated as 45,000 to 53,000 years by ^{230}Th/^{234}U This age and the ^{230}Th/^{234}U chronology of the entire terrace sequence is supported by correlation with deep-sea core records[13] In the area shown in Fig 1, reef IIIa overlies seaward-dipping bedded sandy tuffs that are exposed in several streams and are seen to pass inland beneath the front of the next reef higher in the sequence A set of three strongly weathered tephras occur in the depression behind reef IIIa and on the lower front of the rise to reef IVb (Fig 1) Artefacts found in the excavation described below occur within the tephra sequence The tephras are considerably altered by pedogenesis All are clay-like and the upper two are dark brown to black, and each contains fine sand to fine silt-size angular tephric quartz in greater concentrations towards their bases The tephra pile varies from 1 5-2 8 m thick due to slope wash and redeposition after each fall, as well as to downslope creep which is indicated by small slip planes visible in the excavation

The age of the tephras is critical to our conclusions about the age of the artefacts The tephras do not occur on 6,000-year-old (Holocene) reef I, which is broad and contains potential tephra-trapping palaeo-lagoons (Fig 1) They have not been found on reef II, which is dated to 28,000 to 30,000 years[9,11], nor on reef IIIb which is 40,000 years old[9–11], although the possibility they

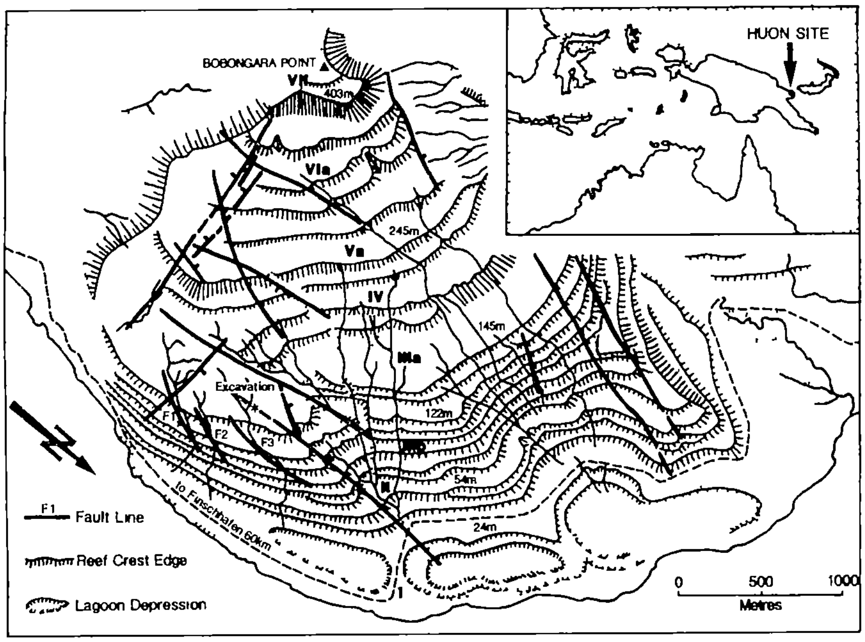

Fig 1 Bobongara area of Huon Peninsula coral terraces Archaeologic site marked * Excavation Inset shows land exposed at times of Pleistocene low sea levels (white areas), and location of Huon Peninsula site in Papua New Guinea

were on these reefs and subsequently were stripped cannot be eliminated The inference that the tephras are older than 40,000 years is supported by thermoluminescence (TL) dating of the quartz particles within each unit This dating was done at Australian National University, using the fine-grain technique[14] All samples show well-defined TL plateaux from about 350° to 475 °C Laboratory-induced TL growth curves were linear, and fading tests (1 month) found no TL loss Hence, we are confident of the calculated archaeologic doses Dose rate, based on laboratory analyses of potassium (K) and total α count rate for each tephra, is less certain due to a peculiarity in the K-values Measured K_2O content of the tephras ranges from 0 05–0 11% This is very low for tephra, and K-leaching is suspected to have occurred during strong pedogenesis The nearby Bismark volcanics average K_2O of 1 2%[15] Hence, dose rates are estimated on the basis of (1) measured K_2O, and (2) $K_2O = 1\ 2\%$ The latter is almost certainly greater than the average value over the history of the deposits The alpha dose rate is taken as measured, which may also be higher than the historical average due to thorium growth in the neighbouring reefs, which are in U-series disequilibrium[8,10]

TL data and calculated ages are shown in Table 1 Ages based on measured K_2O and assumed K_2O (=1 204%) are both consistent with stratigraphic order, showing that T1 is significantly younger than T2 and T3, which are similar to each other Ages based on measured K_2O are higher than those based on assumed K_2O because the K_2O values are lower We believe that ages based on assumed K_2O are almost certainly too low, first because they are based on much higher K_2O than measured, and second because the assumption that $H_2O = 0$ is unrealistic as annual rainfall at the site is 2,500 mm and the soil has been found to be generally wet during excavation Soil moisture reduces dose rate, and the zero H_2O assumption leads to unduly low age estimates We conclude that the T2 and T3 are at least 40,000 years old, and probably T1 as well, consistent with their occurrence on Reef IIIa but not on the younger reef terraces

Stratigraphy of the archaeological excavation is shown in Fig 2 The site is adjacent to an ephemeral channel (Jo's Creek) which descends the front of reef IVb and crosses the depression behind the crest of reef IIIa Two sections were excavated, one along the southeast creek bank and the other at right angles to this ('trench section' in Fig 2) The creek section was excavated as a vertical face cut slowly back into the slope from the channel, and the trench was cut slowly downwards maintaining a horizontal floor until basal tuff and limestone was encountered Sieving was not possible in the sticky clay-like tephras, and most work was by trowel Figure 2 shows that the tephras are continuous but vary in thickness Some variation is due to mass creep, as mentioned, and some reflects infilling of temporary channels which are thought to have formed by runoff before and between tephra falls Such a channel is seen beneath findspot 2 in the trench section (Fig 2)

Artefacts were recovered at several points indicated in Fig 2, the most important being at the interface between T2 and T3 at findspots 1 and 2 These and that from findspot 3 are waisted axes, described shortly A stone core and 2 flakes were found at and near findspot 4 All were recovered from *in situ* positions by direct excavation The waisted axe at findspot 2 was in several pieces with interstitial tephra T2, attesting to burial after breakage with little subsequent displacement The waisted axe from

Table 1 Thermoluminescence dating results

			TL age (yr BP)			
Tephra unit	Archaeological dose (rad)	Measured $K_2O\%$	Minimum ADR (rad yr^{-1})	Age*	Maximum ADR (rad yr^{-1})	Age
T1	12,600	0 0543	0 299	42,100	0 402	31,300
T2	9,430	0 1076	0 156	60,500	0 254	37,100
T3	8,732	0 1372	0 146	59,800	0 241	36,200

Column 5 shows ages based on measured K_2O and column 7 ages based on assumed $K_2O = 1\ 204\%$ Other assumed parameters are Rb = 110 ppm, $H_2O = 0$, and cosmic dose = 0 015 rads yr^{-1} Standard errors of measurement are not shown as these are much less than K_2O uncertainty Tephra units are labelled T1 to T3 in descending stratigraphic order

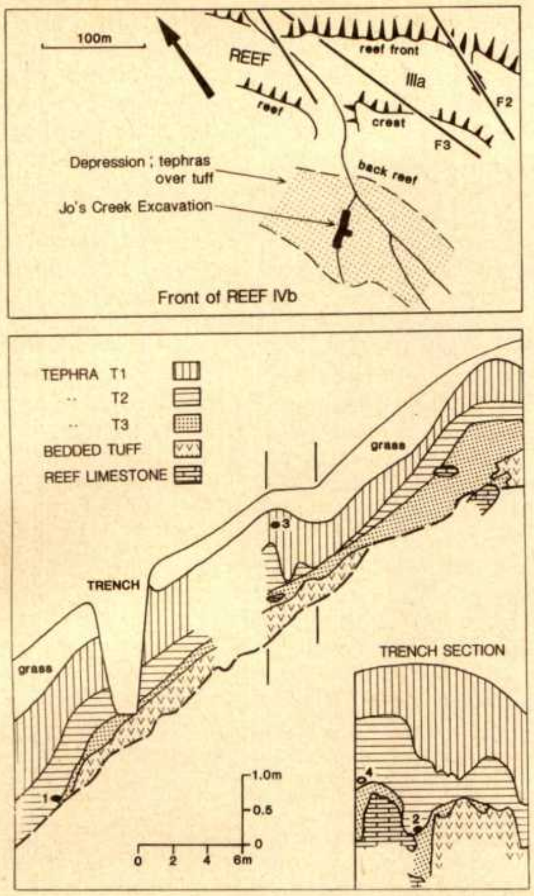

Fig. 2 Location of excavation (Jo's Creek) on Terrace IIIa at Bobongara, and stratigraphic sections at excavation. Main section follows creek; trench section at right angles to this. Numbered spots show locations of artefacts described in text.

spot 1, shown in Fig. 3*a*, is heavy (1.68 kg) and is marked by a distinct groove between the waisting notches. It is made of 2-pyroxene andesite comparable with boulders in the nearby Masaweng River. It has a skin of semi-opalline cristobalite (X-ray diffraction determination) and a thin section from a 1-cm core from the underside shows the albitic groundmass to be altered to microcrystalline quartz. These features are consistent with long burial in a weathering tephric environment. We refer to the tool as a waisted 'axe' on the grounds of its similarity in terms of size, weight, strength, and edge characteristics to axes. We interpret the groove across the waist as due to haft-lashing, by analogy with ethnographic examples from Melanesia[16] and Australia.

In addition to the artefacts found *in situ*, over 100 waisted axes of similar dimensions and pattern, although without hafting grooves, were found loose in creek beds around the site, mostly on or somewhat above reef IIIa. All are unifacial, of similar material to that in Fig. 3*a*, apparently manufactured by spallation from rounded river boulders followed by flake retouching, often very steep, of the flake-scar surface. A typical example is

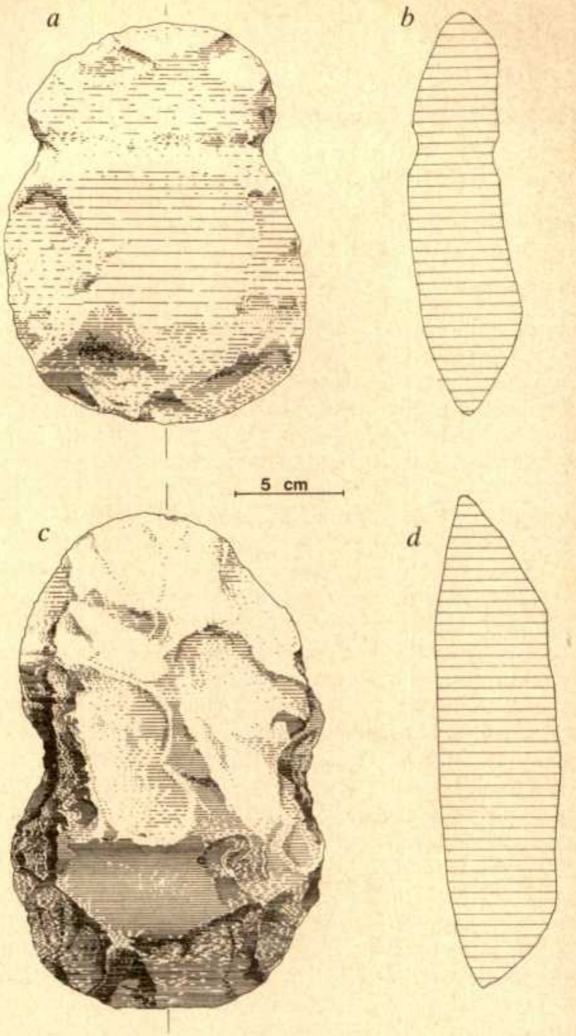

Fig. 3 *a, b*, Grooved waisted axe from findspot 1 in excavation. *c, d*, Typical non-grooved waisted axe from near to excavation.

shown in Fig. 3*b*. Other loose artefacts in creeks at or above the site include a chert core, various flakes, and one 'stemmed' and one 'knobbed' axe, both unifacial and made of andesite. Our waisted axes have similarities with artefacts discovered elsewhere. In highland New Guinea, waisted axes at 26,000 years are reported at Kosipe[4] and occur from 6,000 to over 10,000 BP at Yuku[17]. Pleistocene ages are inferred for waisted axes at Kangaroo Island in south Australia and at Mackay in north Queensland[18]. Waisted axes of inferred Holocene age occur at Botal Tobago[19] and Japan[20], in east Asia, although these appear to be smaller than the Huon Peninsula tools.

We thank the people of Hubegong village and the Tewai local government for assistance, the University of Papua New Guinea for support and the Australian Department of Foreign Affairs for financial assistance. We also are grateful to Professor J. Golson for assistance with the manuscript.

Reproductive failure in common seals feeding on fish from polluted coastal waters

Peter J. H. Reijnders

Research Institute for Nature Management, Department of Estuarine Ecology, Postbus 59, 1790 AB Den Burg, Texel, The Netherlands

The population of common seal *Phoca vitulina* in the westernmost part of the Wadden Sea, The Netherlands, has collapsed during the past few decades[1,2]. Between 1950 and 1975 the population dropped from more than 3,000 to less than 500 animals. Comparative studies of common seal populations from different parts of the Wadden Sea reveal that pup production has declined sharply only in the western (Dutch) part[2-4]. A comparative toxicological study[5] on the levels of heavy metals and organochlorines in tissues of seals from the western and northern parts of the Wadden Sea shows that only the polychlorinated biphenyl (PCB) levels differ significantly. This is predominantly a result of PCB pollution from the river Rhine[6-9], which mainly affects the western (Dutch) part. PCBs are thought to be responsible for the low rate of reproduction in Dutch common seals on the basis of epidemiological and experimental data on the ability of PCBs to interfere with mammalian reproduction[5,10]. Here I report that reproductive failure in common seals from the Dutch Wadden Sea is related to feeding on fish from that polluted area. This is the first demonstration of a causal relationship between naturally occurring levels of pollutants and a physiological response in marine mammals.

An experiment with two groups of 12 female common seals was carried out to test the detrimental effects of PCBs on seal reproduction. Each group, consisting of 7 seals from the east coast of the United Kingdom and 5 seals from the Museum of Natural History at Texel, was fed a diet containing different levels of pollutants. Group 1 received fish (predominantly plaice, flounder and dab, with some eelpout and hooknose) caught in the western part of the Wadden Sea. Group 2 received fish (mainly mackerel) from the north-east Atlantic. The fish were maintained at −28° C and thawed before being fed to the seals. The diets are comparable with respect to nutritional quality, except for fat levels; this was compensated for by a high daily intake. Residue analysis for aldrin, dieldrin, endrin, heptachlor, hepox, α,β,γ-hexachlorocyclohexane, pentachlorobenzene, hexachlorobenzene, *pp'*-dichlorodiphenyl-dichloroethylene (DDE), *op'*-dichlorodiphenyl-dichloroethane, *pp'*-dichlorodiphenyl-dichloroethane and PCBs showed statistically significant differences between the two diets for PCBs and *pp'*-DDE. The average daily intake (during ~2 years) was 1.5 mg PCBs and 0.4 mg *pp'*-DDE for group 1, and 0.22 mg and 0.13 mg for group 2 (J. P. Boon, P.J.H.R., J. Dols, and P. F. Wensvoort, unpublished data). Three males receiving Atlantic fish were alternated between both groups during the mating period. To detect whether hormonal regulation was affected by pollutants, blood samples were taken regularly and serum concentrations of progesterone and oestradiol-17β were determined. Because the timing of oestrus differs for individuals, all profiles have been synchronized by taking the day of previous delivery as day zero and adjusting the profiles of non-pregnant animals accordingly. Although there is some published information about the hormonal changes during reproduction in seals[11,13], none of these studies reported the changes during a complete annual reproductive cycle in a specific group of females. The oestradiol-17β and progesterone concentration profile of the control group (Fig. 1*e,g*) illustrate the normal annual cycle. The number of non-pregnant animals in the control group is too small to consider their reproductive cycle as 'normal' for non-pregnant females.

No statistically significant differences (Spearman, $p < 0.005$) were found in the progesterone and oestradiol-17β profiles of pregnant seals from groups 1 and 2. Identical tests for the non-pregnant animals in both groups gave the same result. This is important as it implies that the differences in diet do not influence hormone patterns. The patterns resemble those for eutherian mammals in general[14,15]. Pinnipeds are classified as having an obligate and seasonal embryonic diapause[16,17]. In common seals in this study implantation probably occurred at

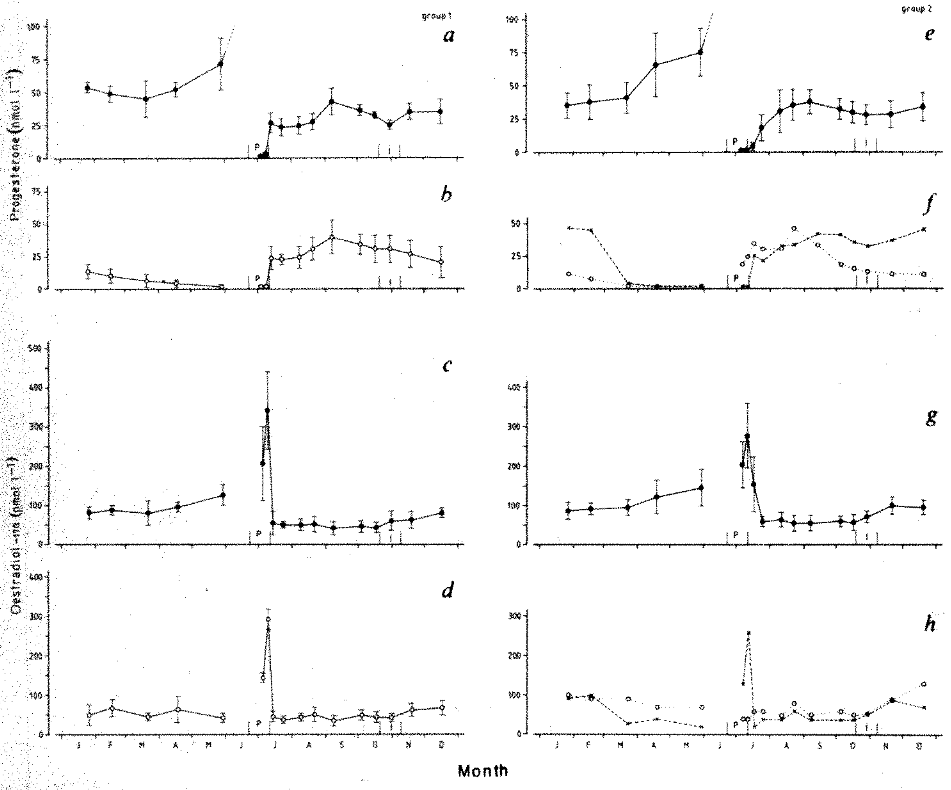

Fig. 1 Circulating serum concentrations of progesterone and oestradiol-17β during the reproductive season 1983–84, in common seals feeding on fish from the Wadden Sea (group 1) and on Atlantic fish (group 2). *a–d*, Group 1 (*a,b,c,d*): (● - - - ●), pregnant seals ($n = 4$); (○—○), non-pregnant seals ($n = 8$). *e–h*, Group 2: (● - - - ●), pregnant seals ($n = 10$); (× - - - ×) and (○—○) non-pregnant seals. Vertical bars, 1 s.d.; p = period over which previous parturitions occurred; i = implantation period. Blood samples were obtained from veins in the hind flippers after restraining the animals on a V-shaped bench. The blood (~8 ml) was collected in vacutainers, centrifuged and the serum stored frozen at −20 °C. Serum concentrations of progesterone and oestradiol-17β were determined by radioimmunoassay. The intra run coefficients of variation for progesterone and oestradiol-17β were consistently below 3.0% and 3.05% respectively.

the end of October or beginning of November, and was characterized by an increase in oestradiol-17β levels (Fig. 1, *c*, *g*).

The reproductive success was significantly lower in group 1 than in group 2 (Table 1; $p<0.02$, Fisher's exact probability test). The hormone profiles of the non-pregnant animals in group 1 show that the effect occurs at a stage of the reproductive process around implantation; the follicular, luteal and post-implantation phases until the end of gestation are not affected. These findings corroborate the results from experiments with mink[18,19] where PCBs impaired reproduction: ovulation, mating and implantation occurred but were followed by early abortion or resorption. These results may be due to hormonal disturbance, to direct dominant-lethal action or to an embryo lethal effect caused by toxicants. Hormonal disturbance may be caused by disruption of the steroid synthetic pathway resulting in reduced circulating levels of hormones. PCBs are known to cause microsomal enzyme induction, accelerating hydroxylation of body steroids such as oestrogens[5]. To determine if pollutants suppress circulating levels of hormones during the implantation period, the four subgroups (pregnant and non-pregnant seals in groups 1 and 2) are compared. A statistical test revealed no difference between progesterone levels of pregnant animals in group 2 and non-pregnant animals in group 1. It is concluded that progesterone levels were not reduced in group 1. The rise in oestradiol levels of the non-pregnant seals in group 2—indicating follical growth—is lacking in non-pregnant seals of group 1, which suggests that the nature of non-pregnancy differs between the groups. Because there were only 2 non-pregnant animals in group 2, this could not be tested statistically. The results also demonstrate that the levels of oestradiol in all group 1 seals are lower than those in group 2 combined, ($p<0.05$, Wilcoxon), although the initial rise in some of the animals of group 1 (Fig. 1*c*) was apparently sufficient to ensure reproductive success. The mechanisms behind the smaller increase in oestradiol levels and its consequences for the priming effect on the endometrium, as well as the maternal rejection response[20-22], will be discussed in detail elsewhere. Hypotheses about impaired steroid binding capacity by PCBs[23], a dominant-lethal action and an embryo lethal effect cannot be tested with the information available.

I conclude that the reproductive success of the seals receiving the diet with the highest level of pollutants was significantly decreased. No circumannual reduction in levels of circulating hormone levels was observed. The reproductive process is disrupted in the post-ovulation phase. The period around implantation seems to be the most sensitive stage, but no conclusions about the mechanism of action can be drawn. A similar experiment was simultaneously carried out with the American mink *Mustela vison*, a fish-eating mammal with a comparable reproductive physiology. It was designed to test whether pure PCBs had the same effect as the PCB-polluted fish. Three groups of 'Standard' type mink were fed either a basic diet of commercial mink cereal, or the same basic diet supplemented with livers from fish caught in the western part of the Wadden Sea or with Clopen A-60 or A-30. The results show that reproduction is inhibited at very low (25 μg per day) levels of PCB intake and that the effects of the pure PCB diet were identical to those of contaminated fish diet[18].

Irrespective of the precise mechanism involved, the results from this study show that the reproductive failure in common seals from the Dutch Wadden Sea is related to feeding on fish from that polluted area. The available epidemiological experimental data on effects and levels of PCBs in seals and mink fed on fish from this area[5,27] suggest that these organochlorines are the main cause of this failure.

I thank A. Grijzen, H. Jansens and G. van Weert of De Wever Hospital, Heerlen, for carrying out the radioimmunoassays; J. Schoonheden for the illustrations, M. C. Vleugel for care of the animals and J. Zegers for his assistance throughout the whole experiment.

A common mammalian plan of accessory optic system organization revealed in all primates

H. M. Cooper & M. Magnin

Laboratoire de Neuropsychologie Expérimentale, INSERM U-94,
16 Avenue Doyen Lépine, 69500 Bron, France

The accessory optic system (AOS), which was described as early as 1870 by Gudden[1], constitutes a distinct midbrain visual pathway in all classes of vertebrates[2]. In non-primate mammals, retinal fibres of this system project to a set of three nuclei[3,4]: the dorsal (DTN), the lateral (LTN) and the medial (MTN) terminal nuclei. Whereas all AOS cells respond to the slow motion of large visual stimuli, the neurons are tuned to complementary directions of movement[5]: horizontal temporo-nasal direction for the DTN, vertical up and down for the LTN and vertical down for the MTN. It has thus been suggested that these nuclei establish a system of retinal coordinates for the detection of whole field motion[6]. As the AOS provides direct and indirect pathways to both oculomotor and vestibular structures[7,8], each of these nuclei is thought to be an essential link in the co-ordination of eye and head movements in relation to movement within the visual field. One problem for the generalization of this theory is that the medial terminal nucleus has never been found in primates. In this report we establish both the existence of this nucleus and its afferent input from the retina in all major groups of primates (prosimians, New and Old World monkeys and apes), indicating a common anatomical plan of organization of the AOS in mammals.

We used both autoradiographic and histochemical anterograde tracing techniques to study the retinal projection to the AOS in the two primate suborders[9] Strepsirhini (prosimians: lemurs and lorises) and Haplorhini (simians: New and Old World monkeys, apes and man). For the Strepsirhines we studied five mouse lemurs (*Microcebus murinus*) and one bushbaby (*Galago demidovii*). Haplorhine species included two marmosets (*Callithrix jacchus*), three macaques (*Macaca fascicularis*) and two gibbons (*Hylobates concolor*). Most animals were injected with a radioactive amino acid mixture (500–

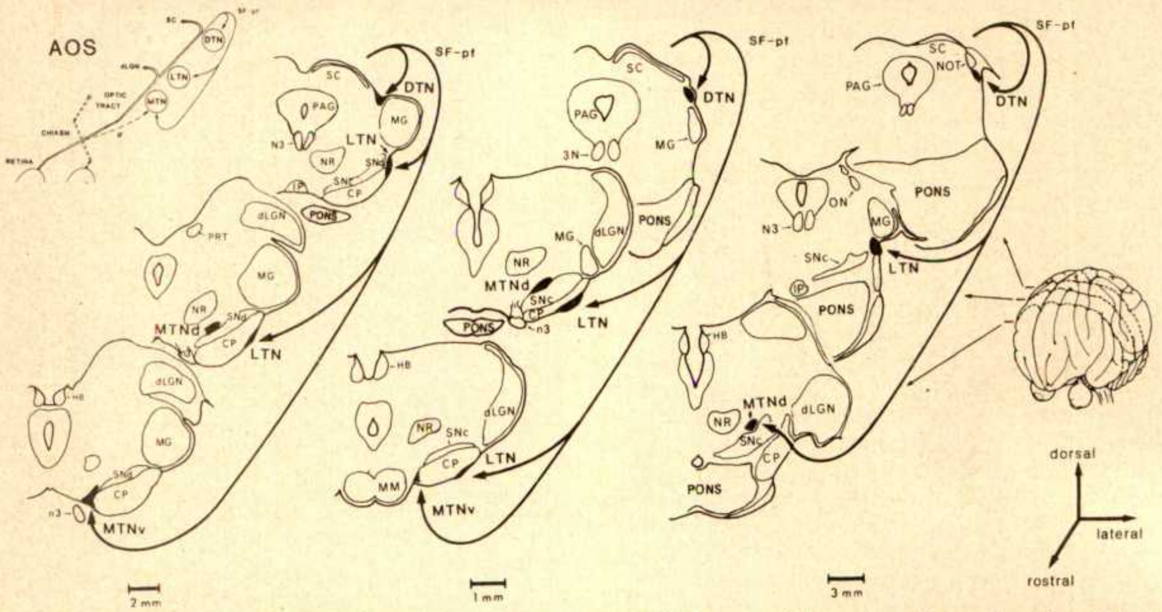

Fig. 1 Organization of the accessory optic system compared in a non-primate (cat), a strepsirhine primate (mouse lemur) and a haplorhine primate (gibbon). Animals received an intraocular injection of radioactive amino acids to reveal the distribution of retinal fibres and terminals. Drawings, scaled to the same size, are from coronal sections (lower right: approximate section levels shown on brain of gibbon) showing the relative positions of the three terminal nuclei (MTN, LTN, DTN, dark shading) of the AOS. Arrows, course of the superior fasciculus (SF-pf) (the main component of the AOT). As shown in the simplified schema in the upper left, this fasciculus separates from the main optic tract in the region of the brachium of the superior colliculus and then courses rostrally. The AOS in strepsirhine primates is similar to that of other mammals, but the MTNv is reduced in size. In haplorhine primates a retinal projection to the MTNv is lacking, and AOS fibres show a shortened trajectory through the cerebral peduncle to the MTNd. The extensive rostral development of the pons and pyramidal tracts in primates suggests that the reduction of the MTNv in Strepsirhini and its absence in Haplorhini is the consequence of a resulting morphological reorganization in the anterior region of the midbrain. AOS, accessory optic system; CP, cerebral peduncle; dLGN, dorsal part of the lateral geniculate nucleus; DTN, dorsal terminal nucleus of the AOS; HB, habenular nucleus; IF, inferior fasciculus; IP, interpeduncular nucleus: LTN, lateral terminal nucleus of the AOS; MG, medial geniculate nucleus; MM, mamillary nucleus; MTNd, dorsal division of the medial terminal nucleus of the AOS; MTNv, ventral division of the medial terminal nucleus of the AOS; n3, oculomotor nerve; N3, oculomotor nucleus; NOT, nucleus of the optic tract; NR, red nucleus; ON, olivary pretectal nucleus; PAG, periaqueductal gray; PRT, pretectum; SC, superior colliculus; SF-pf, posterior fibre branch of the superior fasciculus; SNc, substantia nigra, pars compacta; SNd, substantia nigra, pars diffusa.

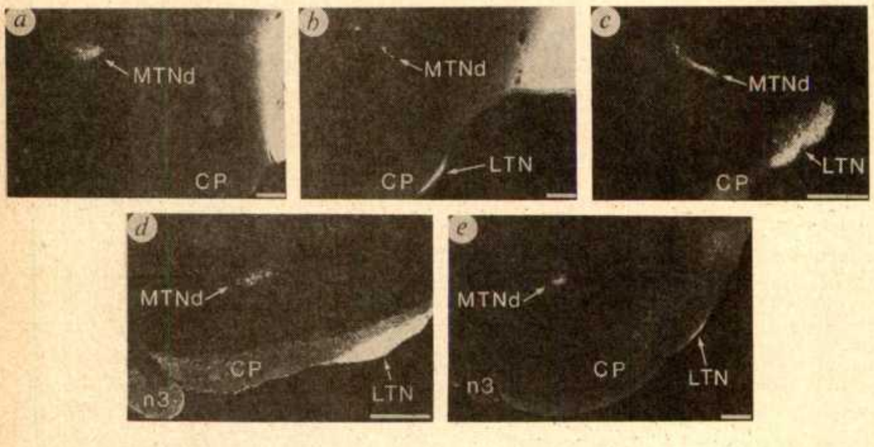

Fig. 2 Distribution of anterograde label transported from retinal ganglion cells to the MTNd (and the LTN) in: *a*, gibbon; *b*, macaque; *c*, marmoset; *d*, lemur; *e*, cat. The microphotographs of these coronal sections are viewed under dark-field illumination. Note the similar topographic location of the MTNd medial to the cerebral peduncle and the substantia nigra (towards upper left) in all species. Scale, 500 μm. CP, cerebral peduncle; LTN, lateral terminal nucleus of the accessory optic system; MTNd, dorsal division of the medial terminal nucleus; n3, oculomotor nerve.

1,000 μCi of ^{3}H-proline and ^{3}H-leucine) in the posterior vitreal chamber of the eye. After survival times of 24–60 hours the brains were processed according to the usual autoradiographic procedures for frozen or paraffin sections. In other primates, the eye was injected with 10–20 μl of a 40% solution of the anterograde tracer horseradish peroxidase (HRP; Sigma type VI) dissolved in sterile saline with 2% DMSO. Survival time was 36–60 hours. Frozen sections of the brains from these animals were treated with the tetramethylbenzidine method[10]. Brains from each series were sectioned in either frontal, sagittal, or horizontal planes and stained with cresyl violet to study cytoarchitecture. Retinal projections to the AOS were compared in species from eight other orders of mammals: Carnivora, Rodentia, Chiroptera, Dermoptera, Hyracoidea, Pholidota, Marsupiala and Edentata.

In all mammalian species studied, fibre tracts and the three terminal nuclei of the AOS were labelled by anterograde transport of the neuronal tracer from retinal ganglion cells. The majority of retinal fibres that form the accessory optic tract (AOT) cross in the optic chiasma, although a small component remains uncrossed. The AOT diverges from the main optic tract at the level of the brachium of the superior colliculus. The tract becomes visible on the superficial aspect of the brainstem as it retraces a rostral pathway to the anterior base of the midbrain[11], terminating in each of the AOS nuclei along its course (Fig. 1).

The MTN is the most conspicuous of the three AOS nuclei in non-primates and can be divided into a ventral division (MTNv) located at the ventromedial base of the cerebral peduncle, and a dorsal division (MTNd) extending into the region of the substantia nigra[3,12]. In primates, a retinal projection to the ventral division was observed only in Strepsirhines but the dorsal division receives retinal terminals in all species studied.

The projection to the MTNd is remarkably similar in primates and non-primates (Fig. 2). It is located in a similar position in all species (medial to the substantia nigra pars compacta and ventro-lateral to the medial lemniscus and the red nucleus). The distribution of terminal label (silver grains or HRP granules) in the MTNd is often reticular in appearance, as synaptic contacts of retinal axons are mainly situated on dendrites rather than on the cell bodies[13]. Fibres of the AOT course to the nucleus by penetrating directly through the cerebral peduncle, forming a characteristic obliquely-oriented fibre bundle in the region of the substantia nigra.

In some primates (*Macaca*, *Callithrix*) the MTNd is rather small, whereas in the gibbon (*Hylobates*) the nucleus extends rostrocaudally in the midbrain for >2.0 mm. The MTNd is partially embedded within the substantia nigra and in some instances the cells of these two structures actually intermingle. Several cytological features allowed us to distinguish the cells of each nucleus, however. The MTNd neurons are typically pale stained, and ovoid or fusiform in shape. In contrast, nigral cells are comparatively large sized, polygonal shaped, and intensely stained with cresyl violet; they also have a large clear cell nucleus and a dense compact nucleolus. Depending on the species, the two populations of cells are also distinguished by additional features. For example in the gibbon, as in other apes and man, the cytoplasm of nigral cells is densely packed with black granules of melanin[14]. These cells show an endogenous red fluorescence under dark-field illumination due to the presence of melanin whereas the MTNd cells, which lack pigment, do not fluoresce. Anterograde label was distributed only over the cells of the MTNd.

In the strepsirhine primates *Microcebus*[15], *Galago*[15] and *Nycticebus*[16], there is also a small but distinct ventral division of the MTN, which receives retinal afferents. As in other mammals, such as the cat, the MTNv is located at the base of the cerebral peduncle, immediately rostral to the emergence of the oculomotor nerve. The cells in this part of the MTN are densely stained, small and round in shape (average diameter 14 μm), and thus differ from those of the dorsal division, which are highly elongated (typically 8 μm × 40 μm). The cytoarchitecture and pattern of retinal projections to the two subdivisions of the MTN in *Microcebus* closely resemble those of the cat. In the cat the ventral and dorsal subdivisions clearly form a topographically continuous nucleus, whereas in *Microcebus* these two parts are interconnected by a few fine fibres. In haplorhine primates we could not identify either terminal label or a cell group typical of the MTNv.

The absence of a distinct ventral portion of MTN in haplorhine primates has been interpreted as the result of a simple regression of the nucleus during primate evolution[17,18]. However, we suggest that the neurons of the MTNv have migrated in position to a more dorsal location and form a single constituent nucleus with the MTNd. Such a dorsal shift of the MTNv in primates could be a consequence of the extensive development of the pyramidal tract[19] (related to precise motor control of the limbs), resulting in a rostral extension of the pons below the cerebral peduncle which influences the topographical relations between the nuclear groups in this region. Since in other mammals the neurones of the ventral and dorsal divisions of the MTN differ in cytoarchitecture[12], efferent connections[7,8] and histochemical properties[12], the hypothesis of a dorsal topological shift of the MTNv in primates could be experimentally verified if the same distinctions exist in this single constituent of the MTN.

Our results unequivocally demonstrate that in primates at least one subdivision of the MTN is present and receives a monosynaptic retinal projection. This conclusion is supported by the presence of retinal terminals to a well defined cellular aggregate located in a homologous region of the midbrain tegmentum and by the typical course of accessory optic fibre tracts to the nucleus. Preliminary results[20] also provide evidence that, as in the rat[7,8], the rabbit[7,8] and the cat[21], the MTN in *Macaca* also sends an efferent projection to the vestibular nuclei. Thus the intrinsic organization of the AOS and its relations with other sensory systems are constant features in all mammalian species.

We thank C. Blakemore for helpful criticism of the text and N. Boyer, P. Giroud, M. Rouvière and S. Bello for technical assistance. This work was supported by grants from INSERM, the DGRST and the Ministère de l'Education Nationale.

A cell surface molecule distributed in a dorsoventral gradient in the perinatal rat retina

Brain topography may have its earliest expression as spatial gradients of molecules controlling the deposition of neurones and neuronal processes[1,2]. In the vertebrate visual system there is evidence that the stereotyped alignment of central retinal projections relies on an initial spatially organized distribution of molecules in both the retina and its central target nuclei[3-6]. We used an immunological approach to look for molecules that are so organized and produced a monoclonal antibody (JONES) which shows a pronounced dorsal to ventral gradient of binding in the rat retina throughout the period when retinal ganglion cell axons are forming topographically organized projections within the central nervous system (CNS). Binding is present throughout the radial thickness of the retinal epithelium in regions where postmitotic neurones are generated but is not associated with any consistent histological characteristic of the tissue. The antibody was shown to bind on the cell surface of freshly dissociated retinal cells, and dorsal retinal quadrants were found *in vitro* to have nearly twice as much antigen as ventral retinal quadrants. Initial biochemical characterization of the target epitope reveals that it is a lipid present in chloroform/methanol extracts from perinatal retina and is sensitive to neuraminidase digestion.

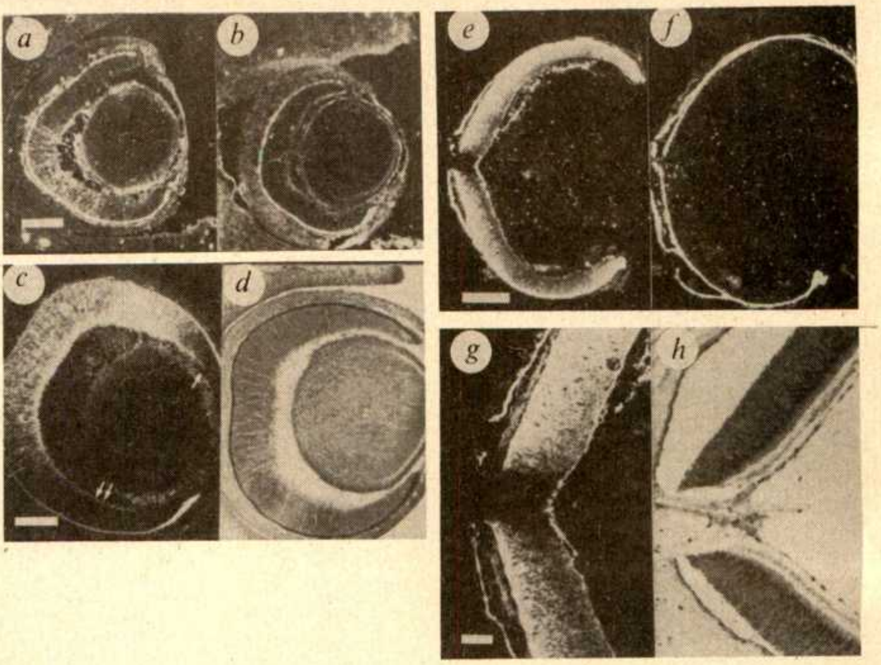

Fig. 1 Immunocytochemical distribution of JONES antibody binding in retinas sectioned parallel to their dorsoventral axes. *a*, Staining of central retina in the E13 eye; *b*, an adjacent 'blank' section reacted with second antibody alone; *c*, the dorsoventral gradient in the E17 eye. Arrow in dorsal retina, the initial expression of the antigen in the region adjacent to the zone at the ciliary margin that still contains only proliferating cells; double arrow, JONES binding in the optic fibre layer of both dorsal and ventral retina; *d*, an adjacent section counterstained with toluidine blue. Scale bars a–$d = 150\ \mu$m; *e*, the retinal epithelium at P0; JONES binding is now distributed throughout the epithelium but a dorsoventral gradient is still apparent; *f*, adjacent 'blank' section. Scale bar e, f $= 500\ \mu$m. In the P0–P3 retinas, the zone of neuroblast proliferation extends to the ciliary margin of the eye[7,8]. JONES binding also extends to the ciliary margin at these ages; *g*, higher magnification of the dorsoventral difference in JONES binding in the P0 eye. Horizontal sections of eyes at equivalent stages of development fail to show this pronounced anistropy in JONES binding; *h*, the equivalent region of another PO eye from a pup pulsed with ^{3}H-thymidine (1 μCi per g body wt., NEN, specific activity 6.7 Ci mmol^{-1}) two hours before it was killed. The most vitreal border of the proliferative zone in central retina is delineated by high grain densities over nuclei synthesizing DNA, post-mitotic amacrine and ganglion cells are present in inner retina. No differences between dorsal and ventral retina are apparent. Scale bar g, h $= 50\ \mu$m.

Methods. The JONES antibody was obtained by innoculation of a BALB/c mouse with retinal epithelia from fetal rats killed 14–21 d after sperm positive vaginal flushes, (E13–E20) rats. The mouse received three intraperitoneal injections of a crude homogenate of 6–10 lightly fixed retinas (2% paraformaldehyde for 30 min). For the first inoculation the retinal homogenates were suspended in complete Freund's adjuvant. Incomplete Freund's was used for the subsequent inoculations spaced two weeks apart. A final boost of ~5 retinas homogenized in phosphate buffered saline (PBS) was given intravenously four d before the fusion of spleen cells with P3-NSI/1-Ag4-1 plasmacytoma cells[33–35]. Screening of antibodies was performed with indirect immunofluorescence using tissue culture supernatants and sections of retina in which E13–E14 retinal epithelia had been nested inside P1 eyes. The JONES monoclonal antibody was sub-cloned three times by limiting dilution and shown by Ouchterlony analysis with subclass-specific sera to be immunoglobulin class M (IgM). Its binding has been examined using indirect immunofluorescence with goat anti-mouse IgG (H+L) (Cappel) or silver-intensified colloidal gold staining using a specific goat anti-mouse IgM (Janssen). Both procedures gave a staining pattern in the form of puncta that appeared to outline the perimeter of cell bodies. The retinal immunocytochemical staining above uses the silver intensified immunogold procedure in dark field illumination. Tissue was fixed overnight at 4 °C, cryoprotected in 30% sucrose in PBS and aligned in OCT mounting medium (Tissue-Tek, Miles) either as a whole fetal head or with the dorsal retinal pole indicated by a single remaining flap of skin. Sections were cut at 10 or 15 μm on a Hacker cryostat.

The JONES antigen was first detected in the rat at embryonic day 12 or 13 (E12–E13) where it was localized to central retina (Fig. 1*a*). By E17–E18 binding was observed along regions of the vitreal surface of the retina next to where an optic fibre layer had formed. In cellular regions of the epithelium the antigen was clearly distributed in gradient (Fig. 1*c*). JONES binding was invariably high in dorsal retina, decreasing gradually in more ventral retinal regions. In the E16–E17 rat a zone of postmitotic amacrine and ganglion cells is apparent in all but the peripheral rim of retina[7,8]. In dorsal retina the JONES antigen was expressed close to the boundary where these post-mitotic cells first appeared (Fig. 1*c*, *d*; arrows), but in ventral retina expression decreased to background levels well within the zone of post-mitotic ganglion and amacrine cells. The dorsal to ventral gradient of JONES binding was retained in the post-natal day 0 (P0) eye (Fig. 1*e*), and was still apparent, though less pronounced, at P3. Throughout the E17–P3 period ventral retina was indistinguishable from its dorsal counterpart on the basis of histological criteria or thymidine uptake (Fig. 1*d*, *g*, *h*).

Cells freshly dissociated from the neonatal eye expressed the JONES antigen on their surfaces (Fig. 2). Differences in JONES binding to different retinal quadrants were subsequently quantified using an *in vitro* assay (Fig. 3*a*). The small size of the early rodent eye precluded reliable dissections of the retina into subquadrant pieces and quantification of the absolute amount of binding was difficult because the degree to which the antibody penetrated the full thickness of the epithelium was unknown. Consequently the results of this assay do not give the maximal differences in antigen concentration between dorsal and ventral retina, but even so JONES binding was found to be ~1.5× higher in dorsal than in ventral retinal quadrants (Fig. 3*b*). This shows that the immunocytochemical differences in JONES binding do not result from fixation artefacts or variations in tissue mass.

Binding of JONES to aldehyde-fixed sections of late fetal and neonatal retina was removed by pretreatment of the fixed tissue with organic solvents and detergents, suggesting that the molecule recognized was a lipid. No antibody binding was observed on Western blots of late fetal or neonatal retinal extracts. Figure 4*a* illustrates immunoblots from thin layer chromatographic (TLC) plates of chloroform/methanol extracts of P4 retinas run in a chloroform: methanol solvent system. When such extracts were partitioned into aqueous and organic phases, all the immunoreactivity was found in the aqueous phase as a discrete band that migrated slightly below ganglioside G_{M2}. A single band of immunoreactivity was also found when the TLC plates were developed in a 1-propanol: aqueous calcium chloride solvent system (data not shown). No immunoreactivity suggestive of binding to lipoproteins or phospholipids was observed at the origin or in the upper regions of these lanes. The immunoreactive band was eliminated by treatment of the retinal extracts with neuraminidase (Fig. 4*b*). These results imply that the JONES epitope is carried on a relatively simple polar lipid, probably a minor species of ganglioside.

Position-dependent cell surface differences between dorsal and ventral retinal cells are suggested by preferential adhesion

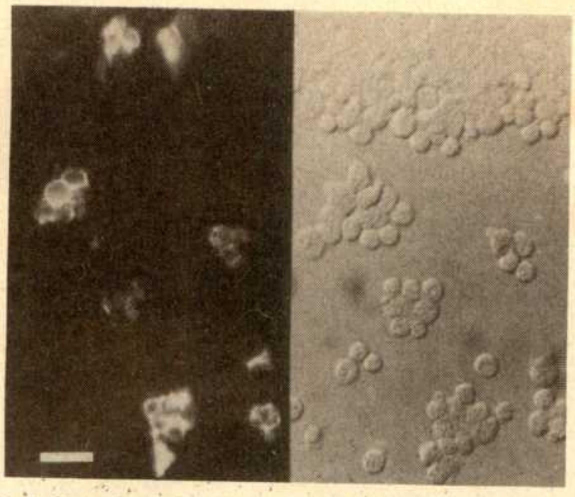

Fig. 2 Cells freshly dissociated from P2 retinal epithelia incubated with the JONES monoclonal antibody and then with rhodamine-labelled goat anti-mouse second antibody. Left, epifluorescent photomicrograph showing JONES labelling on the plasma membranes of cells; right, interference contrast photomicrograph of the same field. Scale bar = 20 μ.

Methods. Twenty P2 retinas were incubated for 20 min at 37 °C in 0.01% trypsin (Gibco 1:150), washed in PBS, titurated in PBS with DNase (5 μg ml^{-1}), centrifuged for 10 min, resuspended in 1 ml PBS and incubated for 1 h with the IgM fraction of JONES ascites fluid (1:100). The cells were then washed 3 times in PBS by centrifugation, resuspended in 1 ml PBS, incubated for 1 h at room temperature in goat anti-mouse IgG (1:50, H + L, Cappel), washed 3 times in PBS by centrifugation, pipetted onto a slide, covered and photographed immediately.

Fig. 3 *a*, Diagrammatic representation of the assay for differential JONES binding to P3 retinal quadrants; *b*, the results of three replicates of this experiment using the quadrants from three retinas per assay point D, dorsal; V, ventral; N, nasal; T, temporal retinal halves. The difference between the summed counts for both dorsal and both ventral retinal quadrants was highly significant ($P < 0.0025$) by paired sample Student's *t*-test. Control experiments without JONES antibody or with other known non-reactive IgM antibodies revealed only low levels of binding and no differential binding to the retinal quadrants.

Methods. A large blood vessel running approximately horizontally along the back of the eye immediately ventral to the optic nerve head was used to distinguish dorsal from ventral retina. A cut perpendicular to this vessel running through the optic nerve distinguished nasal from temporal retinal halves. The pigment epithelium and inner limiting membrane were dissected from each retinal quadrant. The corresponding quadrants from three eyes were placed in one of 4 wells of a well culture plate containing 250 μl of minimal essential medium (MEM, Gibco), 10 μCi ^{3}H-leucine (specific activity 110 Ci mmol^{-1}) and 0.5 μl of ascites fluid from JONES hybridoma tumours. The retinal quadrants were incubated in this medium for 6 h at 37 °C, washed thoroughly in MEM and incubated for 1 h with ^{125}I-labelled F(ab)$_2$ fragments of an affinity-purified rabbit anti-mouse IgG directed against both heavy and light chains. The tissue was washed and processed for γ and β counting. ^{125}I counts were subsequently normalized to the amount of ^{3}H-leucine taken up and incorporated in each quadrant to control variations in the tissue volume in each well.

among cells from dorsal or ventral regions of chick retina[10]. Topographically appropriate binding of retinal cells to tectum was also observed[11], in experiments providing evidence for a double gradient where a protease-sensitive molecule controls the preferential adhesion of ventral retinal cells to dorsal tectum and a protease-insensitive molecule mediates the preferential adhesion of dorsal retinal cells to ventral tecta. The selectivity of binding of dorsal retinal cells was abolished by treatment with B-*N*-acetylhexosaminidase and could be mimicked by lecithin vesicles containing G_{M2} ganglioside[12]. A study using high performance liquid chromatography on lipid extracts of chick retina has recently demonstrated slightly higher endogeneous levels of G_{M2} in ventral retinal quadrants than in dorsal retinal quadrants[13]. The JONES antibody does not react with chick tissue. However, the initial biochemical characterization of the JONES antigen presented in this paper and studies using enzymatic treatments of extracts[14] suggest that it too may be a ganglioside. Monoclonal antibodies to ganglioside antigens (for example, 18B8[15,16], AbR24[17,18] and D1.1[19–21]) have been shown to vary in their cytoarchitectonic distribution with age in developing nervous system but no differences in binding based solely on topographic position have been described. To date, only one other molecule, TOP, has been found with a pronounced topographically varied distribution across the retina[22]. In binding assays the TOP molecule was nearly 12 times more concentrated in dorsal than ventral E14 chick retina[23]. However, it has not been possible to demonstrate a gradient of anti-TOP binding with immunocytochemistry. The JONES antigen is unlikely to be related to TOP since the TOP molecule appears to be glycoprotein[23].

JONES binding was observed in regions of the retinal epithelium shortly after the genesis of the first post-mitotic cells. In the early fetus this region is in the centre of the eye. In the chick[24] and frog eye[25,26] the first regions of the retina to have post-mitotic cells become situated in dorsal retinal quadrants because of the later addition of cells to ventral retina. Several observations suggest that similar displacements occur in the fetal rodent eye[27,28]. Thus the change from a symmetrical to a graded distribution of the JONES antigen between E13 and E17 could reflect a bulk tissue movement, continued expression by the earliest differentiating regions and a gradual spread of expression to ventral retina as the component cells reach the critical developmental stage. But this is unlikely to account for the continued expression of the gradient as, during the eight day period E17–P3 when the gradient of JONES binding is pronounced, even the youngest post-mitotic cells in the ventral regions of E17 retina attain the post-mitotic age and differentiate beyond the stage of dorsal retinal cells at E17 when the dorso-ventral gradient is first apparent. Therefore the differential expression of the JONES antigen is related to retinal position rather than to the post-mitotic age of individual retinal cells or to the differentiated state of a retinal region.

Molecules involved in establishing visual system topography are thought to be expressed in a graded pattern across the population of retinal ganglion cells so that they bias the selectivity of optic tract axons for different subregions of their central terminal fields[29]. However there is relatively little information on these molecules. The expression of JONES antigen in retina

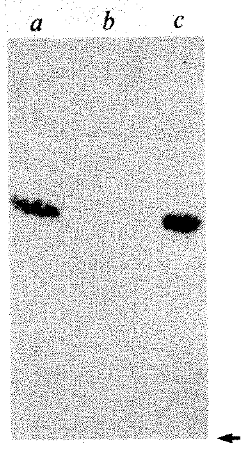

Fig. 4 Biochemical characterization of the JONES antigen using TLC/immunoblot analysis. *a*, The JONES antigen partitions into the aqueous phase of a Folch extract and is detected as a single band on immunoblots of lipids resolved by TLC. This band migrates to a position between that of G_{M2} and G_{M1} ganglioside standards run at the same time. (1) whole lipid extract. (2) organic phase; (3) aqueous phase; (4) G_{D1a}; (5) G_{M1}; (6) G_{M2}. 1-3, immunostaining of the nitrocellulose blot of a TLC plate; 4-6, resorcinol staining of purified standards run at the same time. *b*, The epitope recognized by JONES antibody contains sialic acid as it is removed by treatment with neuraminidase (+) but not buffer (−).

Methods. P4 rat retinas were homogenized in chloroform/methanol (2:1) to give a crude lipid extract[36]. This was partitioned into organic and aqueous phases by 0.1 M KCl[9]. Gangliosides and other highly polar lipids (including some phospholipids) partition into the aqueous phase, whereas most neutral glycolipids and some less polar gangliosides partition into the organic phase. The sialic acid content of the fractions was determined by the resorcinol method[37]. Samples containing 0.3-0.4 μg sialic acid were applied to a precoated HPTLC plate (Merck, silica gel 60, 0.2 mm thick) and developed with chloroform/methanol/0.25% aqueous $CaCl_2$ (60:40:10). Chromatograms were dried, wetted with isopropanol/water (2:1) and blotted onto nitrocellulose[38]. The nitrocellulose blot was blocked in 5% normal goat serum and incubated with JONES antibody for 4 h. After washing, the blot was incubated in peroxidase-conjugated goat anti-mouse IgG (H+L) for 2-4 h and washed. Bound antibody was visualized by incubation with 3.3′ diaminobenzidine. Ganglioside standards were run on parallel lanes as controls and were visualized by resorcinol staining[37]. For neuraminidase digestion the aqueous phase retinal lipids were dried under N_2 and resuspended in 0.1 M sodium acetate, *p*H 5.5, with or without neuraminidase (Sigma type X from *Clostridium perfringens*) at 8 mU per μg sialic acid. Incubations were carried out for 15 h at 37 °C. Digested lipids were extracted into chloroform:methanol, 2:1, dried under N_2 and resuspended in a small volume of chloroform:methanol, 2:1. Samples were run and analysed by TLC/immunoblot as described above.

coincides with the formation of central retinal connections. The first appearance of the JONES antigen in the retina on E12-13 is at the start of the period when the retinal ganglion cell axons first leave the eye[30]. These axons begin to terminate in the superior colliculus on E17 when the JONES gradient first becomes apparent in the retina. Throughout the period when the retinotectal map is laid down, the JONES antigen maintains its graded distribution in the cellular layers of retina and can also be localized to the retinal regions of optic fibre growth. Moreover, recent evidence indicates that the JONES antigen is also present in all the diencephalic and midbrain regions invaded by the retinal axons[31,32].

We thank Dr Burkhard Schlosshauer for help in the maintenance of the JONES hybridoma cell line, the production of the purified IgM antibody used for immunogold staining and immunofluorescent staining of freshly dissociated retinal cells. The neural cell adhesion molecule (N-CAM) has been implicated in morphogenetic events during formation of the nervous system[1,2]. Three forms of N-CAM exist, all glycoprotein chains, of relative molecular masses 180,000 (180K), 140K and 120K (N-CAM$_{180}$, N-CAM$_{140}$ and N-CAM$_{120}$) which are differentially expressed on neural cell types and during development[3–5]. The three chains are thought to carry similar if not identical amino-acid sequences on their extracellular amino-terminal domains, but differ in the length of their carboxy-terminal cytoplasmic region[6–8]. They occur in highly sialylated embryonic and less sialylated adult forms[9,10]. N-CAM$_{180}$ is selectively expressed in more differentiated neural cells and may play a role in the stabilization of cell contacts[5]. To investigate this, we have studied in the surface membrane of a mouse neuroblastoma cell line N2A the lateral mobility of the two predominant forms of N-CAM, N-CAM$_{180}$ and N-CAM$_{140}$, as a function of differentiation. Here we report that as judged by fringe pattern photobleaching, the surface mobility of N-CAM$_{140}$ is higher than that of N-CAM$_{180}$, suggesting an association of N-CAM$_{180}$ with the cytoskeleton or other stabilizing factors. We also show that brain spectrin, a membrane-cytoskeleton linker

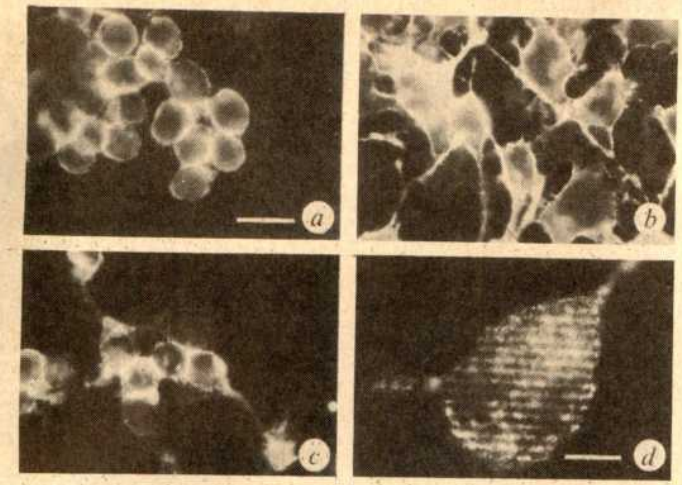

Fig. 1 Immunofluorescence localization of N-CAM in monolayer cultures of the mouse C1300 neuroblastoma clone N2A (ref. 35). Cells were stained with Fab fragments[36] of monoclonal antibody to mouse N-CAM (clone H28.123)[37,38] coupled to rhodamine (lissamine rhodamine B sulphonylchloride, Kodak)[39]. *a*, N2A cells maintained on coverslips coated with poly-L-lysine for 1 day in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal calf serum (FCS). *b*, N2A cells maintained for 1 day *in vitro* on coverslip coated with laminin (5 μg per ml DMEM for 12 h at 4 °C) in DMEM supplemented with 0.2% FCS. *c*, N2A cells cultured on coverslip coated with laminin for 7 day *in vitro* in DMEM supplemented with 0.2% FCS. *d*, Cells maintained as in *c* and illuminated with a fringe pattern. Scale bars, 30 μm (*a*, *b*, *c*) and 10 μm (*d*).

Methods. Cells were maintained under exponential growth conditions in plastic tissue culture flasks and subconfluent cells were trypsinized in the presence of EDTA as described[24], before being seeded at a density of 1×10^5 cells per ml on round 18 mm diameter glass coverslips under the culture conditions stated above. Live cells were incubated for 20 min at 0 °C with rhodamine-labelled Fab fragments of monoclonal N-CAM antibody (30 μg ml^{-1}) in Dulbecco's phosphate buffered saline (*p*H 7.3). They were rinsed 4 times with ice cold Hank's balanced salt solution, *p*H 7.3, supplemented with 0.1% bovine serum albumin. The coverslips were then subjected to fluorescence microscopy (*a*–*c*) after fixation with paraformaldehyde[40] or to photobleaching (*d*). For photobleaching, they were placed in a circular Plexiglass chamber containing 400 μl of the same medium. The chamber was quickly sealed on both faces with molten paraffin and transferred to the cold stage of the photobleaching microscope[13,14]. The cultures were maintained at 4 °C and a field diameter of 28 μm was illuminated by two coherent laser beams that create a fringe pattern with an interfringe spacing of 1.85 μm.

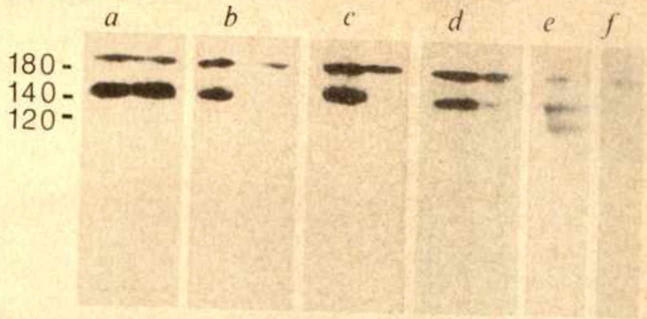

Fig. 2 Western blot analysis of: *a*–*d*, N-CAM expression by N2A cells maintained *in vitro* for 1 and 4 days (left and right lanes, respectively); *e*, immunoaffinity purified N-CAM; and *f*, radiolabelled brain spectrin bound to N-CAM. *a*, Cells seeded on poly-L-lysine-coated plastic flasks in DMEM supplemented with 10% FCS. *b*, Cells seeded on laminin-coated plastic flasks (see Fig. 1) in DMEM supplemented with 0.2% FCS. *c*, Cells plated on poly-L-lysine-coated plastic flasks in DMEM supplemented with 0.2% FCS and 2% dimethyl sulphoxide. *d*, Cells seeded on poly-L-lysine-coated plastic flasks in DMEM supplemented with 0.2% FCS. N2A cells were homogenized and further dissociated by ultrasonification (5 × 3 s). NP40 was then added to a final concentration of 0.5%. The homogenate was stirred for 30 min on ice, clarified by centrifugation for 3 min at 200*g* (Biofuge) and immediately boiled in sample buffer, separated by SDS-PAGE (7% slab gels), transferred to nitrocellulose filters, incubated with polyclonal antibodies to mouse N-CAM followed by incubation with ^{125}I-labelled protein A (2.5 μg ml^{-1}, 30 mCi mg^{-1}; Amersham) and autoradiographed[25]. *e*, Affinity-purified N-CAM from adult mouse brain[5] separated by SDS-PAGE was transferred to nitrocellulose filters, incubated with polyclonal rabbit antibodies to mouse N-CAM then horseradish peroxidase-coupled anti-rabbit Ig-antibody (Cappel) and developed with chloronaphtol as described[25]. *f*, Incubation of affinity-purified N-CAM (as in *e*) with ^{125}I-labelled brain spectrin[41] following the instructions of the supplier (Amersham) in a solid phase radioligand assay[42]. ^{125}I-labelled brain spectrin (specific activity 340,000 c.p.m. per μg) was used at a concentration of 1 μg ml^{-1} in 10 mM phosphate buffer, *p*H 7.4, containing 4% bovine serum albumin. Apparent relative molecular masses ($\times 10^{-3}$) are indicated on the left.

protein[11], binds only to N-CAM$_{180}$. The immobilization of N-CAM in differentiated N2A cells is achieved by a shift in expression from N-CAM$_{140}$ to N-CAM$_{180}$.

The mouse neuroblastoma cell line N2A can be maintained, depending on the culture conditions, in proliferating, morphologically undifferentiated and stationary (morphologically differentiated) states[12]. Under these conditions N2A cells only express the adult form of N-CAM. When cultured in low serum conditions or on laminin-coated coverslips, the cells stop proliferating and within one day of plating change from round cells with no processes to become more flattened, with numerous, sometimes branched neurites with growth cones, lamellipodia and filopodia (Fig. 1*b*). During the next 6–8 days, neurites become longer and less numerous (Fig. 1*c*). In low serum and with dimethyl sulphoxide, cell bodies assume a less flattened shape, but stop proliferating and extend neurites as on laminin. Because proliferation ceases under both conditions, differentiation does not alter the extent of cell contact except for the relatively small addition of the contacts made by outgrowing neurites. When laminin is used as substrate, N2A cells show a morphologically differentiated phenotype within a day (Fig. 1*b*), but express the two N-CAM components as in undifferentiated cells. It takes four more days for the gradual loss of N-CAM$_{140}$ (Fig. 2). When N2A cells are cultured on poly-L-lysine in dimethyl sulphoxide, the disappearance of N-CAM$_{140}$ correlates with morphological differentiation[5] (Fig. 2). We define undifferentiated cells as those that express both N-CAM$_{180}$ and N-CAM$_{140}$ and differentiated ones as those that only express N-CAM$_{180}$.

Lateral mobilities of cell surface constituents can be studied by determining the rate of diffusion of the fluorescence-labelled molecules from unphotobleached into photobleached areas. We created a series of stripes alternatively bleached and not bleached by using fringe pattern illumination (Fig. 1*d*). The decay in contrast of the periodic fluorescence concentration profile was measured as a function of time after pattern photobleaching[13,14]. To study the lateral mobility of N-CAM components, they were labelled using Fab fragments of a monoclonal antibody against N-CAM, directly conjugated with rhodamine. This antibody recognizes both forms of N-CAM[15,16], does not interfere with adhesion[16] and did not dissociate cell–cell or cell–substrate contacts in our experiments. As a control, we used rhodamine-labelled Fab fragments from polyclonal antibodies directed against mouse liver membranes. The antibodies react with an unrelated 130K antigen in undifferentiated and differentiated neuroblastoma cells (not shown). Single measurements were limited to a spot of 28 μm diameter, so that one cell and parts of neighbouring cells are photobleached. Data therefore represent the average N-CAM mobility in the surface membranes with and without cellular contact. This contact does not

Table 1 Lateral mobility of N-CAM and 130K antigen on surfaces of cultured neuroblastoma cells

Conditions of cell culture	*a*	*b*	*c*	*d*

* Criteria for morphological differentiation are the following: undifferentiated, cells with round cell bodies and without processes; differentiated, cells with flattened cell bodies and several processes, sometimes branched, with growth cones and filopodia. DMSO, dimethyl sulphoxide.

† The fraction of mobile fluorochrome-coupled Fab fragments bound to live N2A cells was estimated from the modulated emission of fluorescence (MEF) curves (see Fig. 3) by fitting the data to a sum of two exponential components plus a constant baseline using a program developed by Vogel[34]. The decaying traces of lateral diffusion were found to contain essentially two terms: a rapid diffusion component in the range of 10^{-10} cm^2 s^{-1}, referred to here as the mobile fraction and a second component, either resulting from a very small diffusion coefficient, ($D < 4 \times 10^{-12}$ cm^2 s^{-1}) or due to subtle changes in the shape of the cell or even to a partial dissociation of Fab fragments. The diffusion coefficient reported here is given by $D = l^2/(4\pi^2 T)$, where l is the interfringe spacing (1.85 μm) and T the exponential decay time constant of the mobile fraction. The data are expressed as the mean ± s.d.

appear to be significant in determining the membrane mobility of N-CAM. Photobleaching measurements were performed at 4 °C to avoid internalization of antigen-antibody complexes, which was considerable with the 130K antigen and least significant with N-CAM$_{140}$.

After pattern photobleaching, the randomization of the immunolabelled N-CAMs occurred with two distinct diffusion kinetics (Fig. 3). In undifferentiated cells, the decay of the periodic fluorescence concentration profile is rapid (Table 1) and goes virtually to completion (Fig. 3*a*, curves *A*, *B*). Here, most of the N-CAM is of the N-CAM$_{140}$ form (see Fig. 2*a*, *b*) that has a high lateral mobility. In differentiated cells, there is a slow and incomplete randomization of N-CAM, characterized by a persistent periodic contrast (Fig. 3*a*, curve *C*). This immobile fraction of N-CAM is primarily N-CAM$_{180}$ which is exclusively present in differentiated cells (Fig. 2*c*). In contrast, the randomization of the 130K surface antigen is nearly complete during the time course of the experiment (Fig. 3*b*, curves *A*, *B*, *C*). The mobile fraction and respective mean diffusion coefficients were calculated (Table 1). N-CAM shows a highly mobile fraction which amounts to ~87% of all immunolabelled N-CAM molecules in the undifferentiated state and ~24% in the differentiated state of N2A cells. The diffusion coefficient is 1.1×10^{-10} cm^2 s^{-1} at 4 °C for undifferentiated cells, and approximately the same for differentiated cells. The 130K component has a mobile fraction amounting to approximately 91% of all immunolabelled 130K molecules in the undifferentiated state, 83% for cells induced to differentiate on laminin, and 25% on cells induced to differentiate in low serum and dimethyl sulphoxide for 7-9 days. Thus, the 130K component has a similar mobile fraction in undifferentiated and differentiated cells provided that differentiation is induced under the more physiological conditions of laminin as substrate. We cannot explain why cells allowed to differentiate in the presence of dimethyl sulphoxide contain a smaller fraction of mobile components. More importantly, however, the mean diffusion coefficient of the 130K component is nearly the same ($8.9\text{-}13.1 \times 10^{-11}$ cm^2 s^{-1}) in both the undifferentiated and differentiated states and does not depend on whether cells are induced to differentiate by dimethyl sulphoxide or by laminin. These experiments show a close correlation between the ratio of expression of N-CAM$_{140}$ to N-CAM$_{180}$ and the ratio of mobile to immobile N-CAM fractions in undifferentiated and differentiated states.

To test whether N-CAM$_{180}$ is linked to cytoskoletal components, immunoaffinity-purified N-CAM from adult mouse brain was separated by SDS polyacrylamide gel electrophoresis (SDS-PAGE), transferred to nitrocellulose and either stained with antibodies to N-CAM (Fig. 2*e*) or incubated with radiolabelled brain spectrin (Fig. 2*f*). Brain spectrin[11] binds exclusively to N-CAM$_{180}$.

We have shown that differentiation of neuroblastoma cells is accompanied by increased expression of N-CAM$_{180}$ which is less mobile in the surface membrane than N-CAM$_{140}$, the form expressed in undifferentiated cells. The rate of diffusion of N-CAM$_{140}$ is relatively high and similar to that of highly mobile cell surface glycoproteins (see, for instance, refs 17, 18). The immobilization of N-CAM is manifested by a decrease in the mobile N-CAM fraction (the N-CAM$_{140}$ component). This reduction in mobility is not due to a general differentiation-induced immobilization because another, unrelated membrane component of 130K has the same mobility in undifferentiated and differentiated cells. Morphological differentiation *per se* does not correlate with restriction in surface mobility or disappearance of N-CAM$_{140}$: when plated on the extracellular matrix component laminin, a physiological substrate for neurones[19-21], morphological differentiation of neuroblastoma cells is induced within one day. At this stage, both N-CAM$_{140}$ and N-CAM$_{180}$ are expressed and have a surface mobility characteristic of morphologically undifferentiated neuroblastoma cells. Morphological differentiation thus precedes N-CAM$_{180}$ immobilization. Failure to detect differences in surface mobilities between N-CAM and other cell surface molecules on neural cells[22] may have been due to an inability to distinguish between the individual N-CAM components.

The immobilization of N-CAM$_{180}$ in differentiated N2A cells could be related to an interaction with other cell surface components or with the cytoskeleton. We have previously shown that N-CAM$_{180}$ first appears in the central nervous system on post-mitotic neurones, whereas N-CAM$_{140}$ and N-CAM$_{120}$ appear at earlier developmental stages[5,23]. The appearance of N-CAM$_{180}$ is accompanied by the expression of another cell adhesion molecule, the L1 antigen[24-26], before the first migration of granule cell neurones in the cerebellar cortex[27]. N-CAM and L1 act synergistically in reaggregating cerebellar cells taken at the time of early postnatal granule cell migration[25]. L1 is associated with N-CAM$_{180}$, but not with N-CAM$_{140}$, as shown by

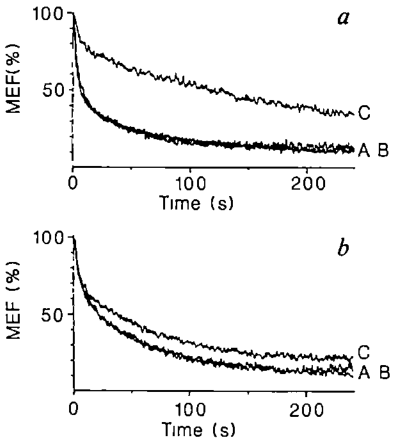

Fig 3 Modulated recovery of fluorescence after fringe pattern photobleaching of N2A cells *a*, Rhodamine-labelled Fab fragments of monoclonal N-CAM antibodies, *b*, rhodamine-labelled Fab fragments of polyclonal antibodies to a 130K antigen, *A*, N2A cells plated on poly-L-lysine in DMEM supplemented with 10% FCS and maintained in culture for 1-3 days *B*, N2A cells plated on laminin and maintained in DMEM supplemented with 0 2% FCS for 1 day in culture *C*, N2A cells plated on laminin and maintained in DMEM supplemented with 0 2% FCS for 7-9 days *in vitro*

Methods Polyclonal antibodies (raised in rabbits) against mouse liver membranes[27] recognize a single band of 130K relative molecular mass in Western blots of NP40 extracts of N2A cells (unpublished results) N2A cells were maintained on glass coverslips, labelled with fluorescent antibody and illuminated with a fringe pattern as described in Fig 1 Measurements were done on individual cells with or without contact sites During the bleaching pulse of 200 ms (1,500 W cm^{-2}, $\lambda = 514$ nm), between 10-20% of the total rhodamine-labelled Fab fragments present on the illuminated fringes with an interfringe spacing of 1 85 μm (see Fig 1*d*) are irreversibly bleached at the origin of the time axis This low level of bleaching was used to minimize photodamage to the cells After pattern photobleaching, the decay of the periodic fluorescence concentration profile was monitored continuously by an interrogation fringe pattern (less than 1 W cm^{-2}) that scans back and forth (3 kHz)[13,14] The resulting modulated emission of fluorescence (MEF) was detected using a photomultiplier coupled to a lock-in amplifier, and stored after digitalization with a time resolution of 240 ms Only the periodic distribution of bleached versus non-bleached fluorophores contributes to the signal The amplitude of MEF which is a measure of the periodic contrast created by the fringe pattern photobleaching was normalized with respect to its peak value (100%) The MEF decayed as a function of time because of the randomization of fluorochrome-labelled antibodies Each trace represents the average value of several measurements (n) $n = 26$ (*a*, *A* and *B*), $n = 10$ (*a*, *C*), $n = 9$ (*b*, *A*) and $n = 11$ (*b*, *B* and *C*) (see Table 1) Per coverslip, 5-10 individual photobleaching measurements could be performed within 1 h of mounting The standard deviations of the population curves were smaller than the peak-to-peak level of the noise of the averaged curve

antibody-induced co-redistribution on the surface of neuroblastoma cells[28] Both L1 and N-CAM$_{180}$ are concentrated at contact points between neighbouring neuroblastoma cells, whereas N-CAM$_{140}$ shows a more uniform distribution in both normal and transformed neural cells[5,29] The membrane-cytoskeleton linker protein brain spectrin (for reviews, see refs 30, 31) is also more concentrated at these contact points and copurifies with N-CAM$_{180}$, but not with N-CAM$_{140}$ nor N-CAM$_{120}$ under the stringent conditions of immunoaffinity purification[32] Combining these observations with the fact that N-CAM$_{180}$ shows a restricted lateral mobility in differentiated neuroblastoma cells suggests a direct cytoskeletal involvement in the restriction of lateral mobility, as in other systems[17,30,31,33] The membrane-cytoskeleton linker protein brain spectrin does indeed bind exclusively to N-CAM$_{180}$ The association of N-CAM$_{180}$ with the cytoskeleton could be mediated by the longer cytoplasmic domain of N-CAM$_{180}$ Further stabilization of cell contacts could be achieved by conformational modifications in intracellular protein domains triggered by conformational changes on extracellularly domains and vice versa It will be interesting to determine whether the restriction of N-CAM$_{180}$ within the surface membrane is induced by the preceding accumulation of the cytoskeleton at contact sites between neighbouring cells Alternatively, N-CAM$_{180}$ could be induced to accumulate by L1 antigen or other components localized within the surface membrane of the same cell, or by an extracellular component(s) In any case, restriction of lateral mobility and accumulation at particular sites within the surface membrane would then lead to the stabilization of selective cell-cell contacts

The authors are grateful to K Burridge for a gift of brain spectrin, C Goridis for clone H28 123, R Vogel for help with computer analysis and J Gruenberg and K Simons for helpful comments on the manuscript Supported by Deutsche Forschungsgemeinschaft (SFB 317), Fonds der chemischen Industrie and Studienstiftung des Deutschen Volkes (G E P)

Note added in proof It has been recently reported[43,44] that phosphatidylinositol is involved in the membrane attachment of NCAM$_{120}$ Therefore we would expect the surface mobility of NCAM$_{120}$ to be identical or higher than the one reported here for NCAM$_{140}$

Endfeet of retinal glial cells have higher densities of ion channels that mediate K$^+$ buffering

Helen Brew, Peter T. A. Gray,* Peter Mobbs & David Attwell

A major function of glial cells in the central nervous system is to buffer the extracellular potassium concentration, $[K^+]_o$. A local rise in $[K^+]_o$ causes potassium ions to enter glial cells, which have membranes that are highly permeable to K$^+$; potassium then leaves the glial cells at other locations where $[K^+]_o$ has not risen. We report here the first study of the individual ion channels mediating potassium buffering by glial cells. The patch-clamp technique was employed to record single channel currents in Muller cells, the radial glia of the vertebrate retina. These cells have 94% of their potassium conductance in an endfoot apposed to the vitreous humour[1], causing K$^+$ released from active retinal neurones to be buffered preferentially to the vitreous[2,3] Recordings from patches of endfoot and cell body membrane show that a single type of inward-rectifying K$^+$ channel mediates potassium buffering at both cell locations. The non-uniform density of K$^+$ conductance is due to a non-uniform distribution of one type of K$^+$ channel, rather than to the cell expressing high conductance channels at the endfoot and low conductance channels elsewhere on the cell.

Cell-attached patch recordings[4] were made from the cell body or terminal endfoot membrane of Muller cells isolated from axolotl retinae (Fig 1*a*) As a rule, cell body recordings revealed no channels or only one channel, while recordings from the terminal endfoot membrane showed five or more (up to 50) channels Occasionally, however, cell body patches contained up to four channels and endfoot patches sometimes showed less than five channels

Over the voltage range where single channel transitions were seen, at potentials hyperpolarized from the channel reversal potential, the open channel current-voltage relations were linear with a conductance that was higher when the pipette $[K^+]_o$ was higher (Fig 1*b*) The current-voltage relations of membrane patches (Fig 2) suggest that the channels exhibit inward rectification, that is, the channel conductance is much smaller at potentials more positive than the reversal potential than at potentials below it This inward rectification may reflect the properties of the open channel I-V relation, or the presence of voltage-dependent gating, too fast to be detected as discrete channel jumps, decreasing the channel open probability at depolarized potentials[5,6] Extrapolated reversal potentials for the channels change by approximately 52 mV for a ten-fold change in $[K^+]_o$, indicating that the channels are largely potassium-selective (Fig 3*a*) The conductance is approximately proportional to the square root of $[K^+]_o$ (Fig 3*b*), as found for inward rectifier channels in other preparations[5,7,8] The potassium-selectivity and the $[K^+]_o$-dependence of the single channel conductance are indistinguishable for endfoot and cell body channels

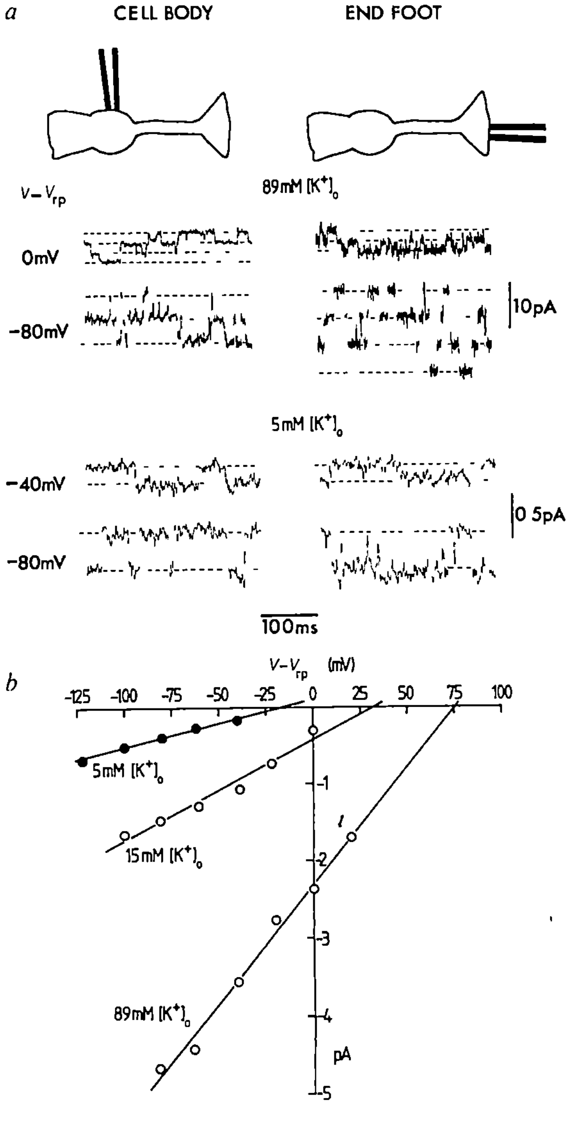

Fig. 1 *a*, Cell-attached recordings and *b*, single channel current-voltage plots for the cell body or terminal endfoot membrane of Muller cells isolated from enzymatically-dissociated[1] retinae of the axolotl (*Ambystoma mexicanum*) *a*, Records are shown from four different patches, two studied at each cell location, with 5 mM or 89 mM K$^+$ solution in the patch pipette (1 5 mM K$^+$ solution bathing the cell) Note the different current scales for the two $[K^+]_o$ values Inward current shown downwards For each patch, data are shown at the two potentials shown on the left relative to V_{rp}, the resting potential ($V-V_{rp}$ is minus the command potential applied to the pipette) Conventional micro-electrode recordings from 93 isolated Muller cells gave a mean resting potential of $V_{rp}=-88$ mV (±7 mV s d) Channel opening is downward (increased inward current) Dashed lines at constant current intervals show the single channel current levels A patch containing 3 channels has been chosen to display the 89 mM $[K^+]_o$ cell body data, typically there were one or no channels in cell body patches The K$^+$ channels characterized here were by far the most common channels observed They contributed the majority (typically 85% in 50 or 89 mM $[K^+]_o$) of the conductance in membrane patches studied at both the cell body and the endfoot the remaining conductance (not showing single channel transitions) was probably the conductance of the seal between the patch electrode and the cell, since its reversal potential was always around a pipette potential of zero rather than at the potassium reversal potential

Cells were maintained at 20-25 °C in perfusate containing (mM) NaCl 90 5, KCl 1 5, $MgCl_2$ 0 5, $CaCl_2$ 3, glucose 15, hydroxyethyl piperazine ethane sulphonic acid (HEPES) 20, adjusted to pH 7 3 with NaOH, bubbled with O_2 Solutions in the patch pipette were as above but with KCl replacing NaCl to give any desired $[K^+]_o$ value (5, 15, 30, 50 or 89 mM) *b*, Current-voltage plots obtained from records like those in *a*, for three patches studied with different concentrations of K$^+$ in the patch pipette Data for 5 mM $[K^+]_o$ are from an endfoot, 15 and 89 mM $[K^+]_o$ data are from cell body patches Each point plotted is the average of 10-20 single channel transitions Abscissa gives membrane potential relative to the resting potential in 1 5 mM K$^+$ solution (−88 mV)

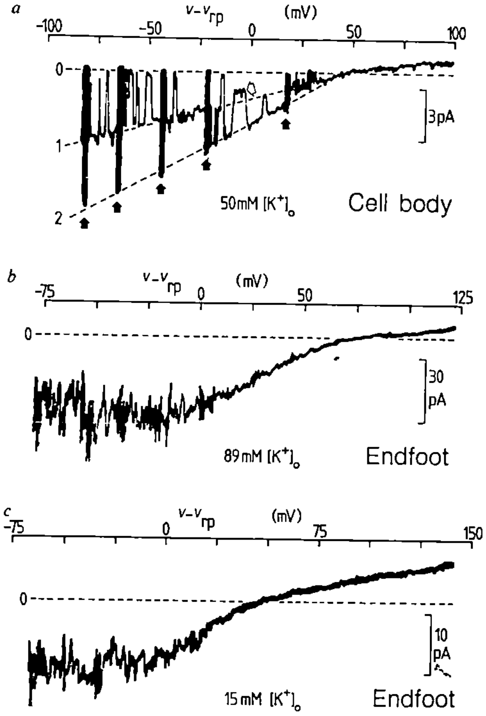

Fig. 2 Inward rectification of the Muller cell potassium channels. *a*, Current-voltage relation of a cell body membrane patch containing 2 channels, with 50 mM K$^+$ in the patch pipette. *b*,*c*, Current-voltage relations of endfoot patches showing inward rectification with 89 mM (*b*) or 15 mM (*c*) K$^+$ in the pipette. *a*, Current through the seal conductance (approximately 30% of the conductance of one open channel at negative potentials, with a reversal potential of 0 mV) was subtracted electronically from this record. The membrane potential (abscissa, given with respect to the resting potential of −88 mV) was ramped at roughly 70 mV s^{-1} from $V-V_{rp}=+100$ to −100 mV. Dashed lines connect values when no channels are open (0), when only one is open (1) and when both are open (2). At the voltages labelled with filled arrows, the voltage ramp was stopped to allow time for transitions to occur between all three states (0, 1 and 2). For $V-V_{rp}<-25$ mV, only 1 or 0 channels are open most of the time because of the low channel open probability, while for $V-V_{rp}>-25$ mV both channels are often open because the open probability is higher (see Fig. 4). For $V-V_{rp}>+50$ mV, above the channel reversal potential where the probability of channel opening is high (Fig. 4), the outward current carried by the channels is much less than would be predicted by extrapolating the channel I-V relation from more negative potentials. At one point, just negative to 0 mV, one channel enters a conductance substate (open arrow). Such substates were seen both at the endfoot and the cell body. At the cell body they were seen for 20% of channels and for these channels the probability of being in a substate was about 0.1 at −90 mV. *b*,*c*, Endfoot patches containing 24 and 30 channels respectively (calculated by dividing the inward current at $V-V_{rp}=0$ mV by the open probability at that potential (0.64, see Fig. 4) and by the single channel current). Flattening of the current for hyperpolarization below $V-V_{rp}=0$ mV reflects the voltage-dependence of the channel open probability (Fig. 4). For example, multiplying the curve describing the voltage-dependence of P_{open} in Fig. 4 by an ohmic I-V relation with a reversal potential of $V-V_{rp}=70$ mV predicts that the maximum inward current through the channels should be near $V-V_{rp}=-30$ mV and that the current at $V-V_{rp}=-80$ mV will be 84% of this maximum value, in reasonable agreement with the data in *b*. Above the reversal potential the outward current is much smaller than predicted by extrapolating from more negative potentials. No subtraction of the seal conductance was applied to records *b* and *c*.

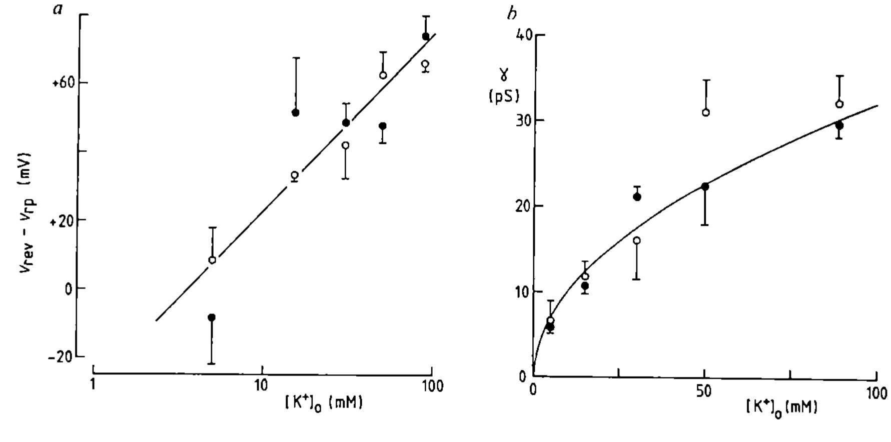

Fig. 3 *a*, Reversal potentials (measured relative to the resting potential of −88 mV) extrapolated from I-V plots like those in Fig. 1*b* for ○, cell body and ●, endfoot patches studied with 5 different pipette $[K^+]_o$ solutions. Each point is the average of 1-7 values, bars show standard errors. The line through the points is a least squares fit, with a slope of 52 mV per 10-fold change of $[K^+]_o$. *b*, Single channel conductance measured from I-V plots like those in Fig. 1*b*, for ○, cell body and ●, endfoot patches studied with 5 different $[K^+]_o$ values. Curve has the form $\gamma=(A[K^+]_o)^{\frac{1}{2}}$ with $A=10.24\ (\mathrm{pS})^2(\mathrm{mM})^{-1}$.

To investigate whether the probability of channels being open is higher at the endfoot than at the cell body, we constructed current amplitude histograms (Fig. 4*a*,*b*). Figure 4*c* and *d* shows the voltage-dependence of the steady-state open probability, calculated from such histograms, for endfoot and cell body channels. The open probability increases with depolarization, has similar values in endfoot and cell body channels and is independent of $[K^+]_o$ and $[Na^+]_o$.

We believe that the potassium channels characterized here are those responsible for mediating the spatial buffering of potassium by Muller cells for the following reasons. First, the channels have the necessary potassium specificity for carrying out potassium buffering. Second, the dependence of single channel conductance on potassium concentration in Fig. 3 is similar to that found for the conductance of whole Muller cells (measured at −90 mV by whole-cell clamping, for $[K^+]_o$ up to 20 mM, data not shown). Lastly, although Muller cell bodies contain I_A-type and calcium-activated potassium currents, in addition to inward-rectifying potassium currents, the former currents are only activated by depolarization beyond

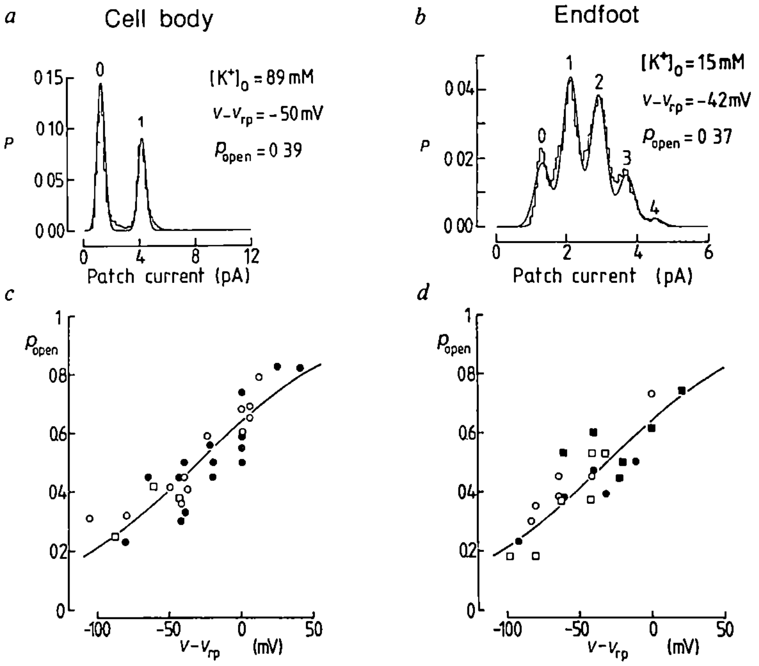

Fig. 4 *a,b*, Current amplitude histograms for determining the channel open probability, constructed from 10–40 second stretches of current at different potentials *c,d*, The open probability of cell body (*c*) and endfoot (*d*) channels, obtained at different voltages from data like those in *a* and *b*, with different values of $[K^+]_o$ ○, 89 mM K^+, ●, 50 mM K^+, ■, 30 mM K^+, □, 15 mM K^+ *a*, Cell body patch containing only one channel, held at a potential 50 mV hyperpolarized from the resting potential (at about −138 mV), 89 mM K^+ in the patch pipette P is the probability per 165 fA bin The two current levels (0 = no channels open, 1 = one channel open) are sufficiently separated on the amplitude histogram (by 2 95 pA) that the areas of their distribution peaks could be calculated directly The smooth curve through each peak shows a gaussian distribution with a standard deviation of 0 28 pA The open probability (area of 'open' peak/sum of areas of 2 peaks) was $P_{open} = 0\ 39$ *b*, An endfoot patch containing 4 channels, held 42 mV hyperpolarized from the resting potential (at about −130 mV), with 15 mM K^+ in the patch pipette P is the probability per 66 fA bin Curve through the points is a fit of the binomial prediction for the probability, $P(I)$, of a current amplitude, I, being seen $P(I) = \sum_{j=0}^{N} B(N,j)\, S(I - jI_1)$ where there are N channels present (4 in this case) each carrying an open channel current I_1, the current flowing when there are j channels open is jI_1, S is a gaussian function describing the noise present in the current (assumed, for simplicity to be independent of the number of channels open), $S(I) = \exp(-I^2/\sigma^2)$, and $B(N,j)$ is the probability of j of the N channels being open, obtained from the binomial prediction $B(N,j) = N!/[(N-j)!j!]P_{open}^{j}(1 - P_{open})^{N-j}$ where P_{open} is the open probability For these data $P_{open} = 0\ 37$, $I_1 = 0\ 81$ pA and $\sigma = 0\ 22$ pA *c,d*, Smooth curves through the points are best fits of the form $P_{open} = 1/\{1 + \exp(-(V - V_{rp} - V_{\frac{1}{2}})/k)\}$ The parameters $V_{\frac{1}{2}}$ and k were essentially identical at the cell body and endfoot $V_{\frac{1}{2}} = -30\ 5$ mV, $k = 53\ 2$ mV at the cell body, and $V_{\frac{1}{2}} = -31\ 4$ mV, $k = 54\ 9$ mV at the endfoot. This voltage-dependence of the open probability appears to be due to true voltage-dependent gating, rather than a voltage-dependent block by external Na^+ ions as occurs for the inward rectifier in tunicate eggs[8] and frog skeletal muscle[9], since (1) the dependence of P_{open} on voltage is independent of the extracellular sodium concentration (the variations of $[K^+]_o$ were obtained by substituting NaCl for KCl in the patch pipette) and (2) replacing extracellular NaCl by choline chloride did not change the open probability

−40 mV, which is probably more positive than physiological voltages[10]

This is the first study of the individual ion channels responsible for potassium buffering by glial cells It is also the first investigation attempting to account for the non-uniform distribution of K^+ conductance in glial cells in terms of the properties of individual ion channels Newman[10] suggested that potassium buffering might be mediated by different types of channels at the cell body and the endfoot We have shown that there is just one type of channel present, with more channels being expressed at the endfoot than elsewhere Recently, Newman[11] has shown that the non-uniform potassium conductance causing directed spatial buffering of potassium is not unique to Muller cells, but also occurs in optic nerve astrocytes The mechanisms we have characterized in Muller cells may therefore be common to all glial cells carrying out potassium buffering

Cyclic GMP is involved in the excitation of invertebrate photoreceptors

Edwin C. Johnson, Phyllis R. Robinson & John E. Lisman

Department of Biology, Brandeis University, Waltham, Massachusetts 02254, USA

The hyperpolarizing receptor potential in vertebrate rod photoreceptors appears to be mediated by the second messenger, cyclic GMP. Injection of cGMP into rods[1,2] or application of cGMP to inside-out membrane patches[3] activates a conductance resembling that produced by light. Light produces a rapid reduction of cGMP in living rods[4], leading to closure of sodium channels and membrane hyperpolarization. In most invertebrate photoreceptors the response to light is depolarizing. We have investigated whether cGMP is involved in controlling the increase in sodium conductance that underlies this depolarization[5]. We show here that injection of cGMP into *Limulus* photoreceptors produces a depolarization that mimics the receptor potential. We also show that the cGMP concentration of the squid retina increases rapidly during exposure to light. These results support the hypothesis that cGMP mediates the light-induced depolarization in invertebrate photoreceptors and suggests that vertebrate and invertebrate phototransduction may be more similar than previously thought.

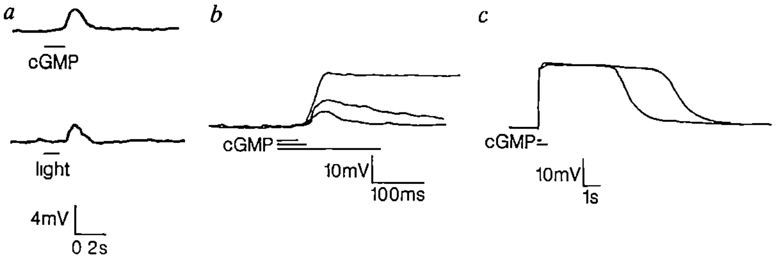

Fig. 1 Responses to injection of cGMP Individual photoreceptor cells were mechanically isolated from a desheathed *Limulus* ventral nerve with a large suction pipette in order to distinguish the light-sensitive lobe A microelectrode containing cGMP was placed in the R-lobe under the control of a motor-driven micromanipulator Injections were monitored optically with an infrared television[17] The microelectrode had 10 mM or 1 mM cGMP in stock solution of 300 mM K aspartate, 10 mM HEPES, *p*H 7 0 *a*, The response to a single photon (lower trace) compared with the response to a very small injection of cGMP (upper trace) *b*,*c*, Superimposed responses to pressure injection of increasing amounts of cGMP Duration of injections is marked by bars below the voltage traces The applied pressure was <1 p s i

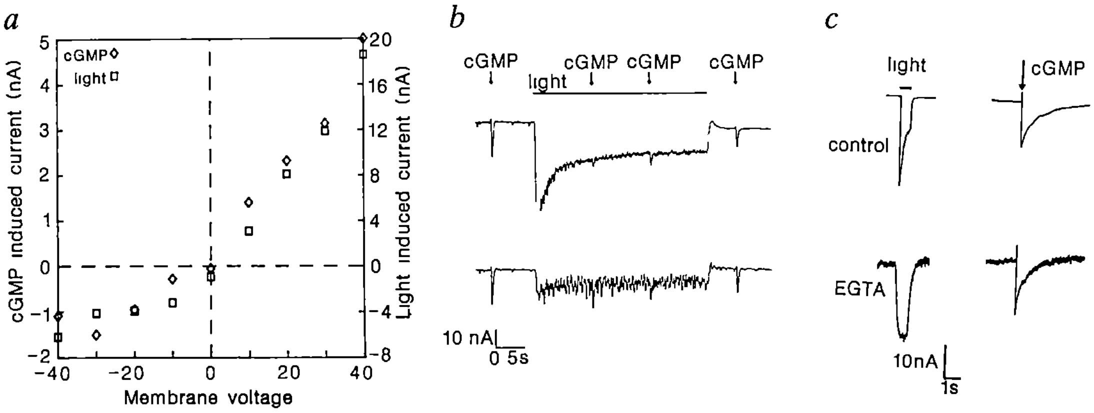

Fig 2 Effect of voltage, background light, and intracellular Ca^{2+} buffer on cGMP-induced currents measured using two-electrode voltage-clamp *a*, Current-voltage characteristics of light-induced and cGMP-induced currents Light intensity 0 08 μW cm^{-2}, currents are given in nA *b*, Effect of adapting lights on the response to cGMP A brief pulse of cGMP was injected at each arrow Upper trace light intensity 0 05 μW cm^{-2}, lower trace 0 005 μW cm^{-2} Note that the light-adapted cGMP response at the end of the upper trace recovered in the 30-s dark period between the upper and lower traces *c*, Response to cGMP was not blocked by injection of EGTA from a second electrode Note that this is a different cell and slower time base than in *b* The responses on the left demonstrate that the light response after EGTA injection (lower left) did not display the decline from the initial transient phase to the plateau phase normally observed in the light response (upper left) This is evidence that EGTA buffered the change in intracellular calcium level that regulates light adaptation[18] On the right are responses to cGMP injection in the dark (top right, before EGTA injection, bottom right, after EGTA injection) The reason for the increase in baseline noise after EGTA injection is unclear

We pressure-injected cGMP into the cytoplasm of *Limulus* ventral photoreceptors If the injection electrode was in a cGMP-sensitive region of the cell (see below), injections evoked a transient depolarization For small injections, the response kinetics were similar to the kinetics of the light response (Fig 1*a*) The size of the depolarization was smoothly graded with the strength of the injection (Fig 1*b*), there was no indication that cGMP can evoke discrete waves[6], as is characteristic of other agents that depolarize ventral photoreceptors[7-9] With larger injections the response saturated, the only effect of further increases was to lengthen the response duration (Fig 1*c*) Once the response began to fall, it fell with kinetics that were independent of the duration of the response The saturation of the cGMP response was only 20–30 mV, much lower than the saturation of the light response (50–60 mV) This is as expected if the injected cGMP saturates a local subpopulation of channels The cGMP would then be rapidly hydrolysed, but the voltage would not fall until the local cGMP concentration fell below saturation The larger the injection, the longer cGMP levels would remain at saturation Voltage-clamp measurements allowed further comparison of the responses to light and cGMP cGMP induced a current with a reversal potential and voltage-dependence nearly identical to that of the light-induced current (Fig 2*a*) The response to cGMP was reduced by an adapting light the same way as the response to a flash would be (Fig 2*b*) Thus, in several respects the conductance activated by cGMP is similar to that activated by light

Recently inositol trisphosphate ($InsP_3$) has been suggested as a messenger of excitation in invertebrate photoreceptors[7,8] One difficulty with this hypothesis is that injection of calcium buffers blocks the excitation produced by $InsP_3$ (ref 10) but enhances the maintained excitation produced by light[18] Injection of calcium buffer (EGTA) did not block the response of a dark-adapted cell to cGMP (Fig 2*c*) Thus both the response to light and cGMP can occur without a change in cytoplasmic calcium

Not all regions of the *Limulus* ventral photoreceptor were sensitive to cGMP The ventral photoreceptor is divided into lobes[11,12], the light-sensitive R-lobe (40 μm in diameter) contains rhodopsin in microvillar specializations of the plasma membrane The A-lobe contains no microvilli Microvilli are restricted to small subregions of the R-lobe The sensitivity of the cell to cGMP was highly dependent on the position of the pipette Injection of cGMP into the A-lobe was without effect Injection of cGMP into the R-lobe often produced only small depolarizations (0–5 mV) By moving the injection electrode through the R-lobe, it was sometimes (<10%) possible to find a region in which injections produced large responses The position dependence of the cGMP response was confirmed by making reversible movements in and out of the cGMP-sensitive region (Fig 3*a*) Because of this position dependence, it was difficult to study the cGMP response This probably explains the failure of previous efforts[9,13] to detect a cGMP response

Because of the low probability of obtaining responses to cGMP it was possible that these responses were artefacts It was therefore important to see if other substances produced responses when injected into regions known to be responsive to cGMP We used double-barrel θ micropipettes with one barrel containing cGMP, the other a test solution Once a cGMP-

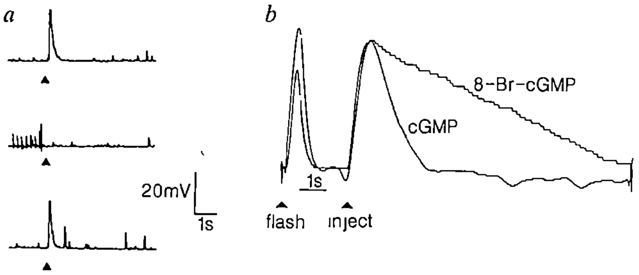

Fig. 3 Dependence of the response to cGMP on electrode placement and cGMP hydrolysis rate. *a*, Dependence of response to cGMP on electrode position. Upper trace, response to brief injection of cGMP (▲); middle trace, after ~10 μm movement of electrode (stepping motor caused series of artefacts) there was no response to cGMP injection; bottom trace, movement of micropipette back to original position restored the response. *b*, Response to the slowly hydrolysable analogue 8-Br-cGMP. A double-barrel pipette with 10 mM cGMP in one barrel and 10 mM 8-Br-cGMP in the other barrel was used. Injections given at arrows. Average responses from 7 injections of each are shown superimposed. Peak responses to 8-Br-cGMP and cGMP differed by <20%, but are shown here normalized. Depolarizations at left are responses to test flashes.

sensitive region was found, larger amounts of the test solution were injected through the other barrel. We found that cGMP-sensitive regions showed no significant response to the injection stock, cAMP or 5′-GMP, but were sensitive to 8-Br-cGMP. The response to 8-Br-cGMP fell more slowly than the response to cGMP (Fig. 3*b*) as would be expected of this slowly hydrolysable analogue[14,15].

The very rapid hydrolysis of cGMP must limit its spread and may explain why the response to cGMP is more localized than the response to Ca^{2+} (ref. 21) or $InsP_3$ (refs 7, 8). We suspect that localization may also be due to restricted access to the microvillar membrane, possibly caused by the subhadromeric reticulum, a fenestrated internal membrane system that abuts the microvillar membrane[10]. Indeed, a quasi-independent compartment between the reticular and microvillar membranes might enhance transduction, since a change in the number of cGMP molecules leads to a concentration change inversely proportional to the volume over which cGMP is spread; a restricted diffusion therefore enhances the signal.

If cGMP is a messenger for excitation in invertebrate photoreceptors, cGMP levels must rise rapidly in light. We examined cGMP levels in squid (*Loligo paeili*) because its retina is large and primarily contains photoreceptors. Punches ($\frac{1}{4}$ inch diameter) of living retina and associated scleral material were obtained from dark-adapted animals under deep-red illumination and were frozen with a liquid nitrogen cooled hammer. The punch from one eye was frozen in the dark, that from the other eye was frozen 100–200 ms after the onset of illumination. cGMP was extracted by homogenizing the frozen retinas in cold HCl-ethanol (1:99), and measured by radioimmunoassay[19]. Dark levels of cGMP were 2.0 ± 0.3 (s.e.m., $n=23$) pmol per mg protein. Light levels were 1.7 ± 0.27 (s.e.m., $n=23$) times greater than dark levels, a significant increase ($t=1.87$, d.f. $=22$, $P<0.05$, one tail). As this is the sum of cGMP changes over the whole punch of retina, the fractional change of cGMP in the transducing region is likely to be much larger than 1.7.

The finding of a light-induced increase in cGMP in the intact squid retina is consistent with the *in vitro* work of Saibil[16] showing a light-induced rise of cGMP in homogenates of squid outer segments. Our general conclusion regarding the importance of cGMP is consistent with the early suggestion[20] that cyclic nucleotides are involved in invertebrate phototransduction. Previous work on vertebrate rods[1–3] and the work reported here on invertebrate photoreceptors suggest that cGMP increases the sodium conductance in both types of cells. The difference in sign of the receptor potentials appears to be due to a difference in sign of the light-induced change in cGMP. The decrease in cGMP concentration in vertebrates is due to activation of phosphodiesterase. Whether the rise in cGMP concentration in invertebrates is due to activation of guanylate cyclase and/or inactivation of phosphodiesterase remains to be determined.

We thank Larry Pinto for advice on the use of double-barrel electrodes, Jim Nathanson for advice on preparation of frozen tissue for cGMP analysis, and Joel Brown, Gordon Fain and Irwin Levitan for critical readings of this manuscript. This work was supported by NIH grants EY01496 and EY05807.

Characterization of single pacemaker channels in cardiac sino-atrial node cells

Dario DiFrancesco

Università di Milano, Dipartimento di Fisiologia e Biochimica Generali, Elettrofisiologia, via Celoria 26, 20133 Milano, Italy

Normal pacemaking in the mammalian heart is driven by spontaneously active cells located in the sino-atrial (SA) node. The rate of firing of these cells and the modulation of this rate by catecholamines are controlled by i_f, an inward Na- and K-current that turns on at voltages more negative than −40 mV[1–9]. The 'pacemaker' current i_f is also present in other types of cell where its ability to produce and modulate a depolarizing process may be useful[10]. For example, in vertebrate photoreceptors i_f drives the depolarization that terminates the light-induced hyperpolarization[11]. Currents similar to i_f are also found in hippocampal neurones and DRG neurones[12,13]. The present report shows for the first time that the opening of single i_f-channels of low conductance (1 pS) can be resolved using a modification of the patch-clamp technique[14] on isolated SA-node cells. Modulation of i_f by adrenaline is shown to be mediated by an increase in the probability of channel opening, whereas the single-channel amplitude remains unchanged.

Although the 'pacemaker' current was one of the first currents to be discovered in cardiac tissues and has a mixed ionic nature which suggests a relatively large single-channel conductance such as that found for other non-specific cation currents[15–17], attempts at recording the activity of single i_f channels have previously been unsuccessful. This has led to the suggestion that either the elementary current steps are too small, or the current is carried by a transport mechanism that is not a channel[18].

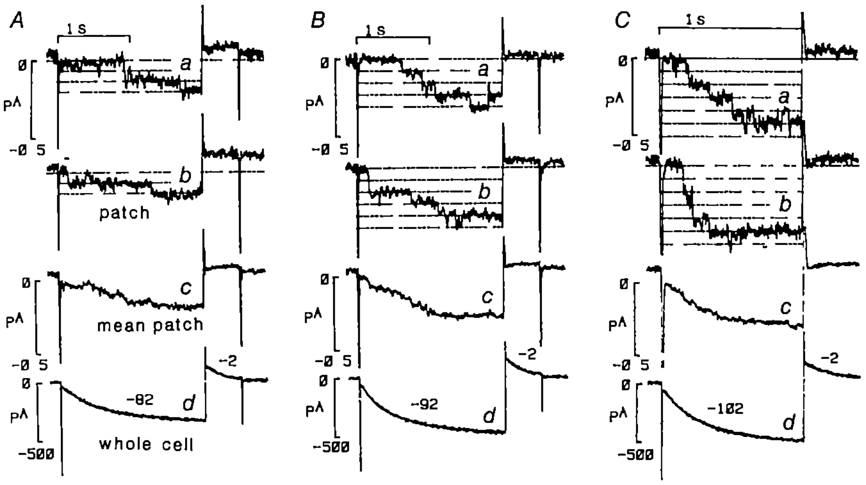

Fig. 1 Simultaneous measurements of whole-cell i_f and single i_f channels in a sino-atrial node cell. The bottom traces (labelled *d*) represent i_f recorded with a pipette in the whole-cell configuration during voltage-clamp steps from a holding potential of −32 mV. Voltages are labelled near corresponding traces. Activity from a membrane patch of the same cell was simultaneously recorded using an independent pipette in the cell-attached configuration. The top traces (*a* and *b*) are examples of patch recordings during i_f activation showing multiple step-like transitions. These transitions represent consecutive openings of single channels during hyperpolarization. Grids with fixed intervals were used to fit patch records by eye and to determine the elementary current step at each potential. These were −0.067, −0.077 and −0.085 pA at −82, −92 and −102 mV, respectively. The traces labelled *c* are averages of patch records ($n = 7$, 7 and 9 in *A*, *B* and *C*, respectively). Their time courses follow those of the corresponding whole-cell currents, indicating that patch activity reflects opening of single i_f channels. The maximum number of elementary openings was 3 at −82 mV, 5 at −92 mV and 6 at −102 mV. Notice that the time courses of mean-patch and whole-cell traces differ at −2 mV. This can be attributed to the different Na and K concentrations used for the patch-pipette and extracellular solutions (below) which determine different reversal potentials for the two traces. A similar observation applies to the data in Fig. 3.

Methods Cells were dissociated from the sino-atrial region of rabbit hearts as described[19]. Their mean resistance and capacity were 1213 ± 417 MΩ (number of recordings (n) = 17) and 29.3 ± 9.5 pF ($n = 20$), respectively. The cells were superfused with warm (35–36 °C) Tyrode solution containing (in mM): NaCl 140, KCl 5.4, $MgCl_2$ 1, $CaCl_2$ 1.8, glucose 10, hydroxyethyl piperazine ethane sulphonic acid (HEPES) 10 (pH 7.4). Single myocytes were whole-cell voltage-clamped using a pipette filled with intracellular-like solution containing (mM): NaCl 10, K-aspartate 130, $MgCl_2$ 1, EGTA 1, Na_2-ATP 2, HEPES 10 (pH 7.2). In experiments where adrenaline was used the pipette also contained 0.1 mM GTP, and ascorbic acid (0.5 mM) was added to the external solution. Pipettes for patch recording contained (mM): NaCl 70, KCl 70, $MgCl_2$ 1, $CaCl_2$ 1.8, $BaCl_2$ 1, $MnCl_2$ 2, HEPES 5 (pH 7.4). After a successful whole-cell recording of i_f was obtained in one cell, a second independent pipette was sealed onto the same cell for simultaneous cell-attached recording. Currents were recorded on tape and displayed on an 8-bit digital oscilloscope interfaced to a table computer. Single-channel currents were digitized at 500/1000 Hz and low-pass filtered before digital conversion using a 4-pole Bessel filter with a corner frequency of 80/160 Hz.

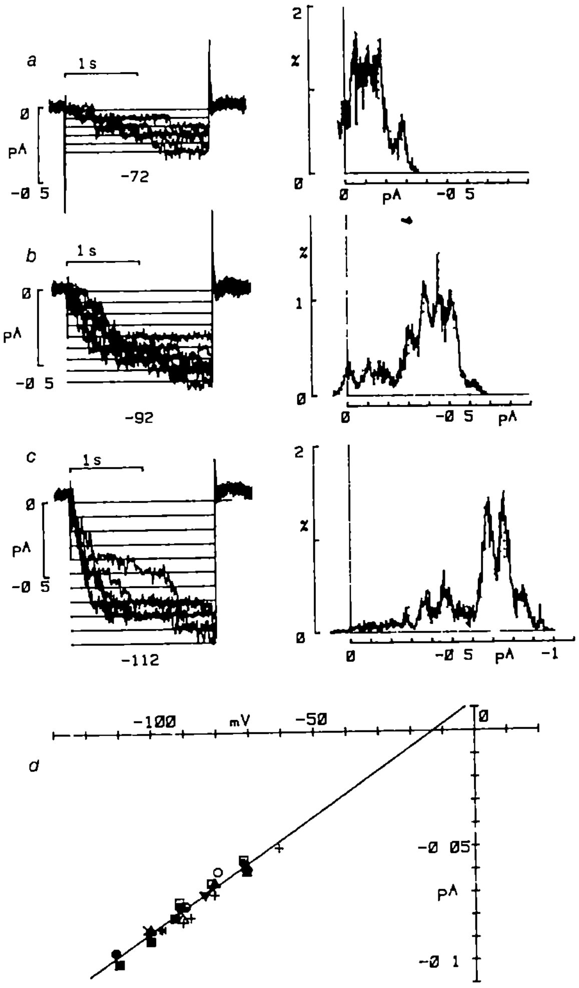

Fig. 2 *a–c*, transient distribution of patch currents during activation at different voltage levels; *d*, current-voltage relation for the single i_f channel. Whole-cell activation of i_f was obtained by applying 2 s hyperpolarizations to −72 (*a*), −92 (*b*) and −112 mV (*c*) from a holding potential of −32 mV through the pipette in whole-cell configuration. The left-hand panels show the superimposition of 4, 8 and 5 consecutive traces recorded from a membrane patch with a pipette in the cell-attached configuration sealed onto the same cell, during whole-cell hyperpolarizations. The right-hand panels show histograms of the current distribution for the same sets of patch records shown on the left. For each set of traces, the current axis was divided into intervals of 3 fA and the fraction of digitized points in each interval was plotted against current. Current levels corresponding to multiple channel openings can be clearly identified from the peaks in the histogram plots and correspond to single-channel levels evident in the current plots. Grids fitted by eye to histogram peaks (dotted lines) and current levels in the patch records (full lines) have interdistances of −0.056 pA (*a*), −0.075 pA (*b*) and −0.095 pA (*c*), representing the estimated single-i_f channel amplitudes at the absolute membrane voltages of −72, −92 and −112 mV, respectively. The maximum number of channels opening increased with larger hyperpolarizations, varying from 6 at −72 mV to 9 at −92 mV and 10 at −112 mV. This reflects the increase in the degree of i_f activation observed in whole-cell conditions[7,8]. *d*, Single-channel levels were measured in 10 cells by fitting either patch records or histograms as illustrated above in the voltage range −61 to −112 mV. Linear least-squares fitting of experimental points yields a single channel conductance of 0.98 pS and an extrapolated reversal at −13 mV.

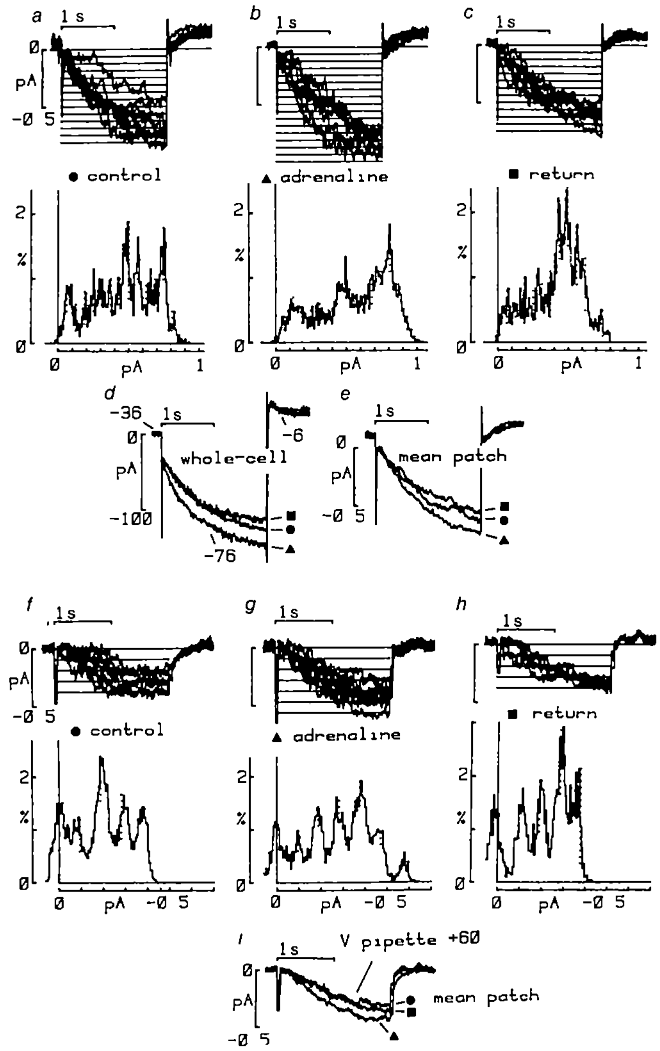

Fig 3 Modulation of i_f channels by adrenaline *a–e*, two-pipette experiment *f–i*, single-pipette experiment *a–e*, Whole-cell and patch currents were recorded during pulses to −76 mV from a holding potential of −36 mV in a control solution (*a*, ●), in a solution containing 5 μM adrenaline (*b*, ▲) and on return to the control solution after 2 5 min perfusion with the drug (*c*, ■) The single channel amplitude obtained from the fitting, done by eye, of patch current levels and histogram peaks did not vary in adrenaline (−0 062 pA) Adrenaline increased the maximal number of channels opened by hyperpolarizations (13 in *a*, 16 in *b* and 12 in *c*) and accelerated the rate of current development by decreasing the mean latency to first opening For example, the mean time required for 8 channels to be open was 452 ($n=7$), 326 ($n=12$) and 481 ms ($n=6$) in panels *a*, *b* and *c*, respectively This resulted in a faster activation rate of the mean patch current (*e*), which was comparable to that of the whole-cell current (*d*) Notice that the higher probability of channel opening favours the appearance of records with many open channels, and thus histogram peak levels corresponding to few open channels are depressed Histograms were constructed from 7 (*a*), 12 (*b*) and 6 (*c*) records *f–i*, Whole-cell pipettes were not used Patch currents were recorded during 2 s, +60 mV pulses applied to the cell-attached pipette Traces were electronically corrected for leakage and capacitative components and were stored after digital addition of the mean of 3 records during 2 s, −60 mV pulses Previous control runs showed that adrenaline at the concentration used did not alter significantly either the resting level or the holding current in the cell (see for example panel *d*) As in the two-pipette experiments, addition of 5 μM adrenaline increased the maximal number of channels opening (from 4 to 6) and caused i_f channels to open more readily (for example, the mean time required for the sequential opening of 3 channels was 670 ($n=6$), 521 ($n=9$) and 791 ms ($n=5$) in *f*, *g* and *h*, respectively) However, as apparent from the superimposition of patch traces and histograms, the elementary current step was unchanged in adrenaline (−0 094 pA) Histograms were constructed from 7 (*f*), 9 (*g*) and 5 (*h*) records

Recording of single-channel events of small amplitude during voltage pulses is complicated by the presence of capacitative transients and current drifts that cannot always be properly corrected To overcome this problem two pipettes have been used on the same cell, one for whole-cell and one for cell-attached patch recording Activation of i_f was obtained by applying intracellular hyperpolarizations via the whole-cell pipette as previously reported[19] Although technically more complicated, the use of two pipettes on one cell has several advantages over the single pipette patch-clamp method (1) voltage pulses delivered to the intracellular patch side do not involve charging of the cell-attached pipette, which eliminates the need for leakage and capacitative corrections and improves the resolution of single-channel current measurements, (2) single-channel activity and whole-cell currents are recorded simultaneously and can therefore be correlated, (3) the absolute membrane potential is known

A recent investigation[19] has shown that the current i_f in SA node cells has properties similar to those in the intact tissue The bottom traces in Fig 1 (labelled *d*) show whole-cell records of i_f activating during hyperpolarization to −82, −92 and −102 mV in one cell Simultaneous recording from a membrane patch of the same cell was performed using a second pipette in the cell-attached configuration, yielding records like those shown in traces *a* and *b* At all voltages the patch records show step-like transitions consistent with sequential openings of single inward channels that occur simultaneously with the whole-cell-driven activation of i_f

The elementary transitions that can be resolved in the cell-attached current records are of small amplitude −0 067 pA at −82 mV, −0 077 pA at −92 mV and −0 085 pA at −102 mV The activity recorded in the membrane patch reflects opening of single i_f channels, as shown by the similar time courses of averaged patch records (traces labelled *c*) and corresponding whole-cell i_f records (*d*) at the three voltages investigated

We studied the distribution of single open-channel current levels and determined the i_f elementary current step amplitudes during activation more accurately using the method shown in Fig 2 The current histogram for several cell-attached traces (left-hand panels) recorded during repetitive whole-cell-driven membrane hyperpolarizations was constructed at each voltage The histograms on the right give the fractional distributions of current levels for each set of traces At all voltages the histograms peak at the denser regions in the current panels, which represent the overlapping single-channel current levels Histogram peaks can be satisfactorily fitted by vertical grids with intervals of −0 056 pA at −72 mV, −0 075 pA at −92 mV and −0 095 pA at −112 mV In the lowest panel (*d*) the single-channel curve of current against voltage was reconstructed in the limited voltage range where measurements can be made using the experiments shown in Figs 1 and 2 and 8 further experiments The relationship is linear and the single channel conductance is found to be 0 98 pS The extrapolation crosses the voltage axis at −13 mV, a value close to that expected at the same external Na and K concentrations for i_f in Purkinje fibres[8]

Binding of catecholamines to cardiac β-receptors modulates pacemaker activity through the current i_f[3,10] Pacemaking acceleration is caused by a shift of the current activation curve to more positive voltages and is therefore attributable to an action of catecholamines on the i_f current kinetics[1,2,19,20] The effect of adrenaline on single i_f channels was investigated (Fig 3) The upper panels (a–e) show an experiment where adrenaline 5 μM was added to the cell superfusing solution In agreement with previous results[19], adrenaline caused the whole-cell i_f to increase during pulses to the current half-activation voltage range (panel d) A similar increase was also observed for the average of several patch records (e) Inspection of the patch records and corresponding histograms reveals that these changes are brought about by an increase of the maximal number of open channels (from 13 in a to 16 in b) and a decrease of the mean latency to first openings The single-channel amplitude was, on the other hand, unaltered (−0 062 pA throughout) These changes are in agreement with the shift in the current activation curve mentioned above

As shown in a recent study on i_f in SA node cells[19], part of the effectiveness of adrenaline on i_f may be lost due to buffering of cell content by the whole-cell pipette solution To avoid this, experiments were performed using cell-attached single-pipette patch-recording, thus excluding internal cell dialysis Cell-attached patch records obtained with the single-pipette arrangement needed to be corrected for leakage and capacitative components, and single i_f channels could be clearly resolved only in a few cases The lower panels in Fig 3 (f–i) illustrate one such case where in control conditions (f) four channels of −0 094 pA were seen to open during +60 mV pulses applied to the cell-attached pipette Perfusion with adrenaline (5 μM, g) caused more channels (6) to open more quickly compared with control conditions, without any alteration in the elementary current step size This resulted in a larger mean-patch current developing faster during a pulse (panel i), in agreement with the results of the two-pipette experiment above

The data presented here show that under favourable experimental conditions the opening of low-conductance single pacemaker channels during whole-cell driven activation of i_f can be resolved in isolated SA node cells In 70 mM KCl, 70 mM NaCl external solution the single i_f channel conductance is about 1 pS, a value much lower than that of other cation channels of low selectivity[21]

The recording of single i_f channels will be useful in detailed investigations of the properties of the pacemaker current, and in particular of the way the current is regulated by the adrenergic neurotransmitter Stimulation of cardiac β-adrenoceptors triggers a cascade of intracellular reactions leading to modifications of, among others, the slow Ca current and the pacemaker current[1,3,22–25], which are responsible for the chronotropic and inotropic responses of cardiac cells There is now ample evidence that modulation of cardiac Ca channels involves phosphorylation by the cAMP-dependent protein kinase[26–30] On the other hand, detailed information on the mechanisms involved in the catecholamine-controlled regulation of the current i_f has been limited so far by the absence of single i_f channel measurements The data presented here indicate that the pacemaker current modulation by adrenaline is mediated by an increased probability that i_f channels open upon hyperpolarization, while the channel conductance is unaltered These data confirm that adrenaline acts on the current kinetics rather than on its amplitude[1,2,20]

I thank Drs C Tromba and C Foglieni for assistance, Dr H F Brown for taking part in preliminary experiments and comments on the manuscript and Professor A Ferroni for encouragement This work was performed under a joint C N R and B C grant to D D and Professor D Noble (Oxford University) (CT85 00455 04 115 12810)

Atrial natriuretic peptide causes pre-glomerular vasodilatation and post-glomerular vasoconstriction in rat kidney

M. Marin-Grez, J. T. Fleming & M. Steinhausen

Physiologisches Institut der Ludwigs-Maximilian Universitat,
Munchen and I Physiologisches Institut der Universitat,
Heidelberg, FRG

Atrial natriuretic peptide (ANP) can be extracted from rat hearts, and is found to increase fluid excretion by the kidneys when injected into test animals[1]. The mechanism of ANP action is still unclear. ANP may reduce sodium reabsorption in the renal tubules, but it is also known that it increases the rate of glomerular filtration in the kidney, and relaxes preparations of smooth muscle, including one made from arteries that supply the kidney[2,3]. To clarify its mode of action, we have studied directly the effects of semi-purified and synthetic ANP on blood vessels in the kidney of anaesthetized rats. We found that ANP causes a vasodilatation of the blood vessels which supply the glomeruli and a vasoconstriction of the arterioles which drain them. This substantiates the finding that increased filtration pressure participates in the natriuretic response[4].

The lack of effect of ANP on sodium transport *in vitro* suggests that reduction of sodium reabsorption *in vivo* may be secondary to another process, perhaps to renal vasodilatation Renal vasodilators cause natriuresis[5] ANP both lowers the vascular resistance of the pre-constricted isolated perfused kidney and increases renal blood flow (RBF) in intact animals[6,7] Suprarenal aortic clamping prevents the rise of GFR on ANP administration and blunts the natriuretic response, suggesting that vascular events are involved in this response[8]

However, RBF has also been found to be unaffected or even reduced after ANP administration[9,10] Since these conflicting effects could be due to different actions of ANP on distinct segments of the renal vascular tree, we investigated the effect of the peptide on pre- and post-glomerular resistance vessels

For this purpose semipurified ANP (see legend to Fig 2) or synthetic peptide (α-hANP) was infused intravenously into rats with unilateral hydronephrosis (Fig 1, refs 11 & 12) Experiments were also performed in which synthetic ANP (rANP, 26 aminoacids) was introduced into the lucite chamber holding the

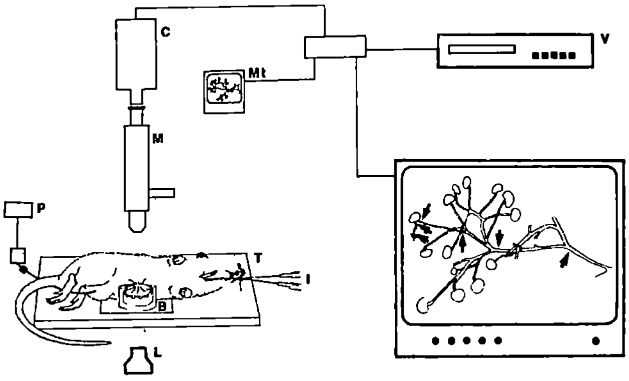

Fig. 1 Schematic representation of the experimental set-up L, light source, T, automatic controlled temperature table, B, temperature-controlled kidney bath, P, blood pressure transducer linked to amplifier and recorder, M, microscope, C, videocamera, V, video recorder, Mt, monitors The arrows on the monitor show the measuring points

Methods. For intravital microscopy a unilateral hydronephrosis was induced by occluding the renal artery (60 min) and ligating the ureter of female Wistar-Furth rats Seven to twelve weeks later the animals, which had been deprived of food but not of water for 15 h, were anesthetized with 5-ethyl-5-(1-methylpropyl)-2-thiobarbituric acid (Inactin, Byk Gulden, Konstanz, FRG, 100 mg kg^{-1}, i p). Body temperature was kept at 37 °C by a feed-back-controlled heated operating table The trachea was cannulated Blood pressure was recorded by means of a strain gauge connected to a catheter in the left carotid artery Infused solutions were delivered through two catheters into the left jugular vein The hydronephrotic kidney was exposed through a flank incision and split at its greater curvature using a cautery knife The dorsal sheet was retracted and the ventral one sutured to a semicircular wire holder This was fixed to a lucite chamber filled with warmed (37 °C) isotonic and isocolloidal solution (Haemaccel, Behringwerke, Marburg, FRG) The place at which the renal vessels entered the chamber was sealed with high vacuum grease (Dow Corning, Seneffe, Belgium) A vascular pathway that could be followed from the arcuate artery to the efferent arteriole was selected for study Measurements were made on the arcuate arteries (vessels which do not give rise to afferent arterioles) and on the interlobular arteries (vessels which do give rise to afferent arterioles), as well as on the afferent arteriole close to and distant from the glomerulus and on the efferent arteriole close to the glomerulus and at the welling point, by two independent observers Total magnification was 1389× and 2083×, respectively Isotonic NaCl was infused throughout the experiment at 3 75 ml h^{-1} An equilibration period of 2 h was allowed before starting the experiment

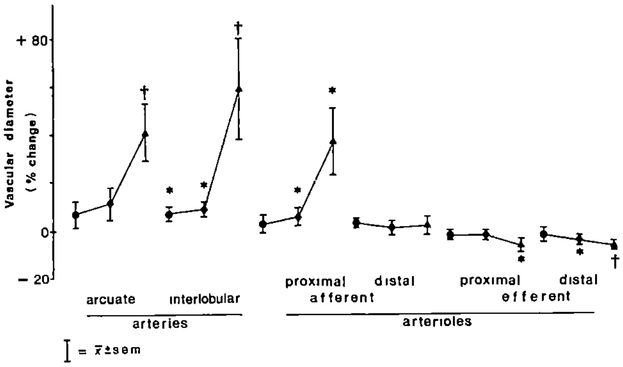

Fig 2 Percentage change of the vascular diameter at different levels of the renal vasculature Control measurements were made at the end of a 20 min i v infusion of potassium phosphate buffer (0 1 M, *p*H 7 4) at 10 or 100 μl/min^{-1} Semipurified ANP (see below) was infused for 20 min at the rate of ●, 1, ◆, 10 and ▲, 100 μl min^{-1} (Statistical significance is indicated thus *, $P<0\ 05$, †, $P<0\ 02$)

Methods. ANP was prepared from right and left atria dissected out of 44 rat hearts obtained under pentobarbital anesthesia (60 mg kg^{-1}, i p) The tissue was blotted, frozen in liquid nitrogen and pulverized Boiling water (32 ml) was added to the 3 2 g powder obtained After 15 min in a boiling water bath, the precipitate (11,000 g, 60 min, 4 °C) was discarded while the supernatant was removed and lyophilized The residue was dissolved in 20 ml phosphate buffer (0 67 M, *p*H 7 4), cold acetone was added (90%) and the precipitate was separated by centrifugation (11,000g, 30 min, 4 °C) The remaining acetone in the precipitate was evaporated at room temperature under vacuum. The residue was dissolved in 10 ml 150 mM NaCl and stored frozen (−20 °C) After thawing, the atrial extract was separated by chromatography in 2 separate runs through a BioGel P60 column (50 × 2 cm) Elution was carried out with potassium phosphate buffer (0 1 M, *p*H 7 4, 2 °C) at 10 ml h^{-1} The low molecular weight fractions containing natriuretic material were pooled An aliquot (0 1ml) of this pool increased sodium excretion by 69% in the rat bioassay[21] Considering that atrial ANP content is 10–20 μg[22] and that about 50% natriuretic activity is recovered in the low molecular weight fractions, our preparation should have contained about 100–200 ng ANP ml^{-1} so that bolus injection of 0 1 ml should increase sodium excretion by 50–100%[23] The observed value was within this range (see above)

kidney Images of intrarenal vessels were formed in a television camera, through a microscope immersion objective, and displayed on monitors for on-line measurements of the lumen diameter Each experiment was recorded on video tape for off-line analysis The diameter of a given vessel, measured during an infusion of ANP or after application of the peptide to the lucite chamber holding the kidney, was expressed as a percentage of the diameter measured during the control period The data was assessed by analysis of variance and the statistical significance evaluated by Wilcoxon's test for paired differences Results are given as mean ± s e m

A dose-dependent vasodilatation of the arcuate and interlobular arteries was observed during the infusion of semipurified ANP (Fig 2, Table 1) The vascular diameter was 141% and 159% of control with the highest dose respectively, indicating a decrease in vascular resistance to less than 30% and 20% of control respectively The proximal end of the afferent arteriole was also vasodilated by ANP (Fig 2) The effect (137% of control with the highest dose infused) was, though significant, somewhat lower than that seen in the interlobular artery Semipurified low molecular weight ANP had no effect on the afferent arteriole in the vicinity of the glomerulus The efferent arteriole was constricted by the high dose near the glomerulus and by the middle and high dose away from it The estimated increases in vascular resistance with the high dose of semipurified ANP was 35% near the glomerulus and 64% distant from it (Fig 2) Blood pressure decreased from 112 1 ± 3 0 mm Hg during the control period to 102 1 ± 3 2 mm Hg ($P<0\ 01$) during the 100 μl min^{-1} ANP infusion It remained unchanged (113 ± 5 and 109 ± 4 mm Hg) at 1 and 10 μl min^{-1} ANP

Infusion of synthetic α-hANP dilated all preglomerular vessels and constricted the efferent arteriole (Fig 3) The beginning of the afferent arteriole was the segment most strongly vasodilated, its diameter increasing by 12 ± 8%, 38 ± 13% and 42 ± 6% at infusion rates of 0 05, 0 1 and 0 2 μg α-hANP min^{-1} respectively ($n=3$) The distal portion of the efferent arteriole was vasoconstricted by 5 ± 0 3% and 5 9 ± 1% with 0 1 and 0 2 μg α-hANP min^{-1} respectively The blood pressure fell from 95 mm Hg during the control phase to 90 ± 4 mm Hg during the infusion of 0 2 μg min^{-1} ANP Addition of synthetic rANP to the lucite bath also induced a pre-glomerular vasodilatation and a post-glomerular vasoconstriction (Table 2) without affecting the arterial blood pressure

Our results clearly show that ANP, of either natural or synthetic origin, has the capacity to induce vasodilatation in the preglomerular renal vessels Our findings are in agreement with

Table 1 Diameter of intrarenal vessels (μm) during infusion of semipurified ANP

	Control phase	Treatment rate of infusion of ANP (μl ANP pool min^{-1}) 1	10	100
Arcuate artery	25.0±1.6	26.6±1.6	27.6±1.9	32.4±2.1
Interlobular artery	11.7±1.2	12.5±1.3	12.7±1.3	18.1±1.3
Afferent arteriole, proximal end	6.6±0.9	6.6±0.8	6.9±0.8	9.5±1.0
Afferent arteriole, distal end	6.0±0.6	6.2±0.6	6.1±0.6	6.2±0.7
Efferent arteriole, proximal end	12.4±1.0	12.1±0.9	12.4±1.1	11.7±1.0
Efferent arteriole, distal end	16.9±1.7	16.3±1.4	16.1±1.5	15.2±1.4

Semipurified ANP was prepared as described for Fig. 2. Each value is based on 7 measurements.

Table 2 Percentage change in vascular diameter in the hydronephrotic kidney after treatment with synthetic ANP

Location of measurement	Concentration of rANP in chamber (mol l^{-1}) 10^{-9}	10^{-8}	10^{-7}	3×10^{-7}
Interlobular artery, near arcuate artery	+9.7±2.9* (6)	±17.0±7.4 (6)	+25.5±7.3* (6)	+39.0±11.9* (6)
Interlobular artery, near afferent arteriole	+3.6±3.6 (6)	+12.5±3.4* (6)	+27.6±6.8* (6)	+31.6±7.5* (6)
Afferent arteriole, near interlobular artery	+12.0±3.6* (6)	+18.0±3.8† (6)	+32.8±7.7* (6)	+30.0±4.6† (6)
Afferent arteriole, near glomerulus	+10.5±2.6* (6)	+14.2±2.9† (6)	+20.0±3.9† (6)	+28.1±7.9* (6)
Efferent arteriole, near glomerulus	2.9±2.0 (12)	−5.5±3.0 (12)	−10.0±3.0* (18)	
Efferent arteriole, near welling point	−2.0±3.0 (12)	−6.0±5.0 (12)	−12.0±3.0* (18)	

Statistical significance as follows: * $P < 0.05$, † $P < 0.01$. Measurements were made 15 min after adding rANP (R-R-S-S-C-F-G-G-R-I-D-R-I-G-A-Q-S-G-L-G-C-N-S-F-R-Y) to the lucite chamber holding the kidney. Figures in parenthesis indicate the number of measurements used to obtain each value.

the observation that ANP reduces the induced tone of isolated renal arcuate arteries from rat (2). We cannot exclude the possibility that in the hydronephrotic kidney the preglomerular vessels are partly vasoconstricted and thus more sensitive to vasodilatory stimuli. However, angiotensin (0.2 μg per kg per min) still constricts preglomerular vessels by 30–40% in this system[13]. It has been suggested that the natriuretic effect of ANP depends mainly on enhanced GFR[14]. We have found in addition that this peptide increases proximal tubule stop-flow pressure (an index of filtration pressure, ref. 4). It appears therefore reasonable to conclude that in intact animals ANP also causes pre-glomerular vasodilatation. ANP may, in addition, induce post-glomerular vasoconstriction, and even the slight reduction in diameter seen with the lowest dose of ANP tested can cause a substantial rise in resistance. It has been shown that in the absence of vasoconstrictors ANP increases the renal vascular resistance and the glomerular filtration rate of the isolated perfused rat kidney, suggesting a preferential effect on the efferent arterioles[15]. Increased filtration fraction has been a repeated finding in studies of the renal effects of atrial peptides[16].

The vasodilating effect of ANP might be due to activation of the particulate guanylate cyclase[17]. Involvement of dopamine cannot yet be excluded. Although dopamine antagonists like haloperidol block the natriuretic effect of ANP, they do not prevent the vasodilating effect of the peptide[18,19].

It seems likely that the primary role of ANP is to regulate renal haemodynamics, and that ANP-induced natriuresis depends on increased filtration pressure and dissipation of the medullary osmotic gradient[10].

This work was supported by the Deutsche Forschungsgemeinschaft Forschergruppe Niere. Dr Fleming was a fellow of the Boehringer Ingelheim Fonds. Synthetic rANP was a gift of Merck-Sharp & Dohme. We acknowledge the excellent technical assistance of R. Dussel and E. Mack-Kühn.

In mammalian tissues the C-terminal amide structure has been found to occur only in neuroactive or hormonally-active peptides[1]. About half known neuropeptide and peptide hormones have this unique chemical feature. Using a chemical detection method[2], a search for previously unknown peptides that possess the C-terminal amide structure in extracts of brain and intestine was carried out[3] and a number of novel neuropeptides and hormonal peptides[4], designated neuropeptide Y[5,6], PHI[7], peptide YY[8], galanin[9] and neuropeptide K[10] were isolated. We recently performed a similar search in porcine pancreas and found a high concentration of a peptide having a glycine amide at its C-terminus. Here we report the isolation, primary structure and biological activity of this novel peptide. The 49-residue peptide strongly inhibits glucose-induced insulin release from the isolated perfused pancreas and was therefore named pancreastatin. It may be important in the regulation of insulin secretion and in the pathogenesis and treatment of diabetes mellitus.

The pancreastatin-containing fractions were located by the amounts of glycine amide released from tryptic digests of the samples using the chemical method described previously[2]. The peptide was extracted from porcine pancreas (20 kg) as described[11], and purified by ethanol fractionation, gel filtration (Sephadex G-25) and ion exchange chromatography (CM cellulose) (Fig. 1, legend). The final HPLC purification steps (Fig. 1*a*-*c*) yielded a homogeneous peptide preparation (0.2 mg) which was subjected to structural analysis.

Terminal analyses indicated that the peptide has an N-terminal glycine and a C-terminal glycine amide. From amino acid analysis, it consists of 49 residues: Ala (8), Arg (3), Asp (1), Glu (13), Gly (9), His (1), Leu (1), Lys (2), Met (1), Phe (1), Pro (5), Ser (1), Thr (2), Trp (1). Edman degradation of the intact molecule (2 nmoles) using a gas-phase sequencer (Applied Biosystems) revealed the sequence of the first 25 residues of the N-terminal region. Because there are only two lysine residues in the molecule, the intact peptide (1.8 nmoles) was treated with a lysine-specific protease (Endoproteinase Lys-C, Boehringer, Mannheim) and the resulting digest was separated on HPLC (Fig. 1*d*). Peak I was found to contain a peptide with an N-terminal threonine. Sequence analysis indicated that this peptide corresponded to the middle fragment (residues 14-25) of the parent molecule. Peak II was found to contain two peptides, one with an N-terminal glycine and the other with an N-terminal glycine and a C-terminal glycine amide, indicating that this peak contained both the N- and C-terminal fragments of the parent molecule. Edman degradation of the peptides in peak II therefore yielded two residues for each cycle. Because the structure of the N-terminal fragment (residues 1-13) was already known, the structure of residues 26-49 was deduced from the sequence data by subtraction of the N-terminal sequence. The complete amino-acid sequence of porcine pancreastatin was deduced in this way (Fig. 2). In agreement with the proposed structure, pancreastatin was found to have a chemical molecular weight of 5103.1 daltons (calculated 5103.46) as measured by FAB mass-spectrometry (VG-ZAB-SE, R700, 10 μg pancreastatin in thioglycerol, mass range 5120-4780 u, scan rate 200 s/d, 15 scans accumulated).

Table 1 Effect of pancreastatin and its fragments (10 mM) on glucose-induced insulin response of the isolated rat pancreas

Conditions of perfusion	*n*	Insulin release (μU min^{-1} ml^{-1})

* $P < 0.05$.

The primary structure of pancreastatin is different from all other known peptides although the peptide has partial structural similarities to several known peptides. For example, pancreastatin shares the -Glu-Glu-Glu-Glu-Glu-structure (residues 34-38) with gastrin[12], and the C-terminal -Arg-Gly-NH_2 structure with vasopressin[13]. However, no other structural homology with these peptides is evident. These results suggest that pancreastatin may belong to a hitherto unknown peptide family.

Chemical synthesis of pancreastatin and its fragments was carried out using a solid-phase synthesizer. Fully protected pancreastatin (1-49) and the (14-49) and (33-49) fragments were synthesized by a published method[14]. After complete deprotection and cleavage by hydrofluoric acid, the crude synthetic preparations were purified by semipreparative HPLC. The synthetic pancreastatin (1-49) obtained was found to elute from the HPLC at the same position as the native peptide (Fig. 1). The results of amino-acid sequence analysis and molecular weight (found 5103.4) determination by FAB mass-spectrometry indicated that the synthetic peptide had an identical structure to native pancreastatin.

The effects of natural and synthetic pancreastatin and the synthetic fragments, pancreastatin (14-49) and pancreastatin (33-49) on glucose-stimulated insulin release, have been studied using isolated rat pancreas[15]. As expected, perfusion with glucose (16.7 mM) induced a biphasic insulin release from the isolated pancreas. Pancreastatin and the two fragments (10 nM) markedly decreased the early phase of insulin release (Fig. 3 and Table 1). The effect on late-phase insulin secretion was less

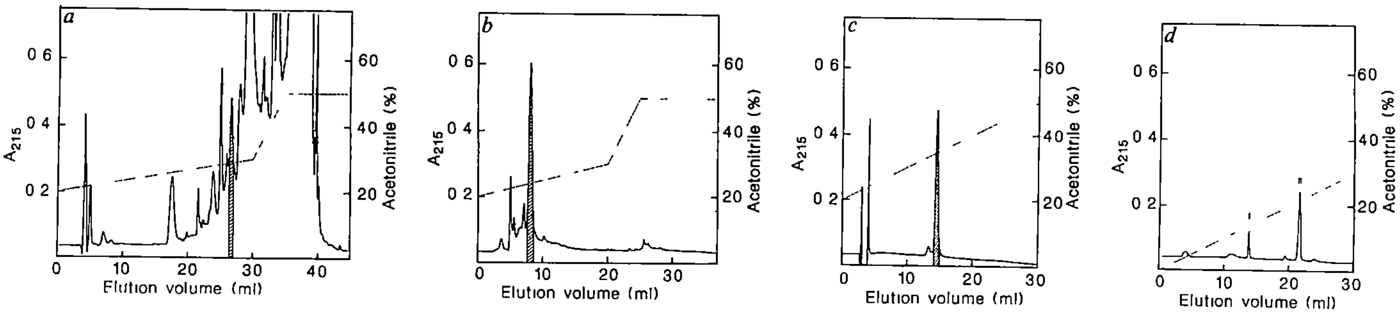

Fig. 1 Reverse-phase HPLC purification of pancreastatin (*a–c*) and its fragments (*d*). *a*, Reverse-phase HPLC of the partially-purified pancreastatin preparation (5 mg, see below) on a Ultrapac TSK ODS 120-T column (4.6×250 mm, LKB AB, Sweden) using a gradient of acetonitrile in 0.1% aqueous trifluoroacetic acid at a flow rate of 1.0 ml min^{-1}. Absorbance at 215 mm (A_{215}) is shown. The pancreastatin-containing fraction (hatched area) was evaporated to dryness using a vacuum centrifuge. A total of 20 mg of the preparation was purified by repeating the HPLC separation and the combined pancreastatin fractions were subjected to the next HPLC purification. *b*, Reverse-phase HPLC of the pancreastatin fractions from *a* on a Ultrapac TSK ODS 120-T column with a gradient of acetonitrile in 10 mM phosphate buffer *p*H 6.5 (flow rate 1.0 ml min^{-1}). *c*, Reverse-phase HPLC of the pancreastatin fraction from *b* on a Ultrasphere ODS column (4.6×250 mm, Altex) under the conditions described in *a*. *d*, HPLC separation of the peptide fragments obtained by treatment of pancreastatin with a lysine-specific protease. Pancreastatin (1.8 nmoles) was dissolved in 10 μl of 1% ammonium bicarbonate, 2 μl of Endoproteinase Lys-C (Boehringer Mannheim) solution (2 mg ml^{-1}) was added and the reaction mixture was incubated at room temperature overnight, then at 100 °C for 10 min and lyophilized. The enzyme digest was applied to a reverse-phase HPLC column (Ultrapac TSK-ODS 120-T, 4.6×250 mm) and eluted at a flow rate of 1 ml min^{-1} with the solvent systems described in *a*. The partially-purified pancreastatin preparation was prepared by boiling porcine pancreas (20 kg) in water for 10 min. The pancreas was then frozen, minced and extracted with 0.5 M acetic acid for 24 h. Peptides in the extract were adsorbed onto alginic acid (1 kg wet weight (wt)), eluted with 0.2 M HCl and precipitated with NaCl at saturation. The peptide precipitate (18 g wet wt) was redissolved in water (360 ml) and two volumes of ethanol were added to the solution. The *p*H of the solution was adjusted to 7.2 and the resulting precipitate was removed by filtration. After addition of three volumes of water to the filtrate, peptides in the filtrate were again adsorbed onto alginic acid (250 g wet wt), eluted with 0.2 M HCl and reprecipitated with NaCl at saturation. This second peptide precipitate (4 g wet wt) was applied to a Sephadex G-25 column and eluted with 0.2 M acetic acid. Fractions containing pancreastatin were pooled and lyophilized. The lyophilized material (0.8 g) was further purified by ion-exchange chromatography on CM cellulose with a step-wise elution (0.01–0.2 M) of ammonium bicarbonate. The fraction eluted by 0.01 M ammonium bicarbonate was found to contain pancreastatin and this partially-purified preparation (90 mg) was used as the starting material for further purification by the HPLC steps.

Fig. 2 Complete amino-acid sequence of pancreastatin from porcine pancreas. The cleavage sites for Endoproteinase Lys-C are indicated by the arrows.

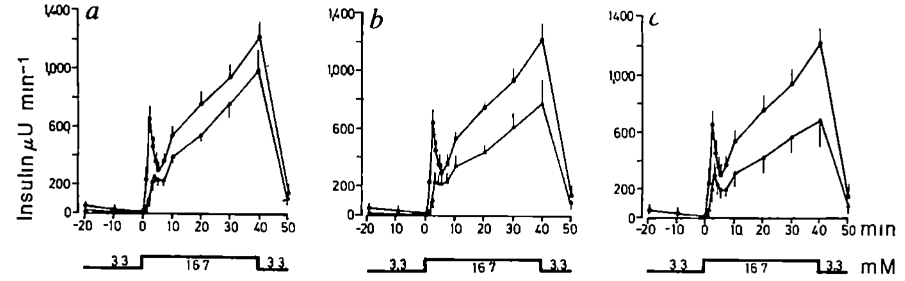

Fig. 3 The effect of 10 nM of *a*, pancreastatin (1–49), *b*, pancreastatin (14–49) and *c*, pancreastatin (33–49) on the glucose-induced insulin release from the isolated perfused rat pancreas. ●, control values, ▲, test values. The insulin release in the presence of pancreastatin or fragment is lower in each case than the control. The perfused rat pancreas was prepared as follows. Sprague-Dawley rats, weighing 200–250 g, were fed *ad lib*. They were anaesthetized by intraperitoneal injection of 50 mg kg^{-1} pentobarbital and the pancreas was isolated[15]. In control experiments the pancreas was first perfused with Krebs-Ringer buffer containing 20 g l^{-1} of bovine serum albumin and 3.3 mM glucose for 20 min and then perfused for 50 min with the buffer and 16.7 mM glucose. The peptide (10 mM) was added 10 min before and during glucose (16.7 mM) administration. The solution was perfused by the use of a perfusion pump through the abdominal aorta. The flow rate of perfusion was 3 ml min^{-1}. The perfusate was collected in tubes containing 0.1 ml of Trasylol. Insulin was measured by radioimmunoassay using a rat insulin standard. The sensitivity of the assay was about 300 ng l^{-1} and coefficient of variation 10%. Points are the mean ± s.e.m. for 5 determinations, except for the test valves in *a*, which are the mean of 6 determinations.

pronounced, but statistically significant for the fragments Thus pancreastatin may have an important role in the regulation of insulin secretion The potent effects of the C-terminal fragments of pancreastatin on insulin release suggest that this portion of the molecule is important for the biological activity and that C-terminal active fragments of pancreastatin may occur *in vivo* It has been suggested[16] that suppression of insulin release upon glucose stimulation, especially in the early phase, is a characteristic feature of manifest type-2 diabetes Because pancreastatin strongly suppresses insulin release, particularly in the early phase, it may be important to examine whether abnormalities in the regulation or action of pancreastatin and its receptors are involved in the pathogenesis of type-2 diabetes If so, the discovery of pancreastatin would have therapeutic implications, particularly in the treatment of diabetes mellitus

Preliminary results indicate that pancreastatin also inhibits the release of somatostatin upon glucose stimulation from the perfused pancreas Pancreastatin may thus also be important in the control of carbohydrate metabolism and hyperglycaemia in diabetes

We thank Drs S R Levin and K Faull for discussions and Mrs P Angwin, A Nylen, L Melin and Mr W Kammerer for technical assistance This study was supported by grants from NIMH (MH 23861), the Office of Naval Research, the Swedish Medical Research Council (Projects 00034 and 13X-1010) and Nordisk Insulinfond

Glucocorticoid receptors lacking hormone-binding activity are bound in nuclei of ATP-depleted cells

Dirk B. Mendel, Jack E. Bodwell & Allan Munck

Department of Physiology, Dartmouth Medical School,
Hanover, New Hampshire 03756, USA

The glucocorticoid receptor binding capacity of rat thymus cells disappears when the cells are depleted of ATP by anaerobiosis, and rapidly reappears when ATP levels are restored[1–3]. Loss and recovery of binding capacity occurs even when protein synthesis is suppressed with cycloheximide[3,4]. In view of this and similar work in other cell systems[5,6], we proposed that in cells deprived of ATP the receptor is present in a form—the 'null receptor' form, as we shall call it—that cannot bind hormone[4]. Although many subsequent observations support this idea, no direct evidence has appeared for the existence of the null receptor. We have attempted to detect the null receptor in WEHI-7 mouse thymoma cells with a monoclonal antibody to the glucocorticoid receptor. Here we report that the null receptor is bound in the nuclei of ATP-depleted cells, and is present in amounts comparable to those of receptors in normal cells

WEHI-7 cells incubated without hormone at 37 °C with 1 mM dinitrophenol (DNP) rapidly lose ATP and receptor binding capacity (Fig 1) ATP levels drop to ~10% of control values within 10 min, whereas glucocorticoid receptor binding capacity in the cell cytosol decreases more slowly No significant decreases occur in control cells incubated without DNP These results are consistent with those obtained with other cells and other methods for lowering ATP[1-6] Receptor binding measured with whole cells falls similarly[1-6], and, as we show below, no binding is detectable in nuclei from the DNP-treated cells

Although there is controversy over the intracellular location of glucocorticoid receptors in the absence of steroid[7-9], by most cell fractionation procedures (including ours) the receptors without bound ligand are recovered in the cytosolic fraction Because our experiments were conducted without hormone, we first looked for the null receptor in that fraction Our attempts to immunoprecipitate receptors from cytosolic fractions from cells incubated with DNP for 90 min were unsuccessful, leading us to suspect that the null receptor, if it existed at all, was located in the nuclear fraction DNP-treated WEHI-7 cells were lysed using a freeze-thaw procedure by which receptors from cytosolic and nuclear fractions can be purified separately The relative amounts of receptor in the two fractions were determined from the relative amounts of immunoreactive protein detected by Western blot analysis[10]

Lanes 1 and 2 of Fig 2 represent cytosolic and nuclear fractions from cells lysed immediately after the addition of DNP Almost all the receptors (arrow) are located in the cytosolic fraction The small amount of receptor in the nuclear fraction (1,800 c p m ^{125}I in lane 2 compared with 15,000 c p m in lane 1) may represent trace contamination with cytosolic receptor This result is similar to that obtained with WEHI-7 cells in the absence of steroid and DNP However, after 90 min of DNP treatment (Fig 2, lanes 3 and 4), the receptors are located predominantly in the nuclear fraction (lane 4), even without hormone present The cytosolic fraction (lane 3), which contained ~20% of the original binding capacity (Fig 1*b*), contained a similar proportion of the immunoreactive receptor protein (5,000 c p m in lane 3 compared with 21,000 c p m in lane 4) The total amounts of receptor present in the cells before and after DNP treatment were comparable (17,000 c p m in lanes 1 and 2 and 26,000 c p m in lanes 3 and 4, the greater amount of receptor after DNP treatment probably indicates more efficient recovery of receptor from the nuclei than the cytosol) The receptors in the DNP-treated cells do not appear to be bound to the outer nuclear membranes as they were still present in nuclei treated with 0 05% Triton X-100 for 5 min at 3 °C to strip off the outer nuclear membranes[11] (23,000 c p m in lane 5, 21,000 c p m in lane 4) Preliminary studies, in fact, suggest that the null receptor is less easily extracted from nuclei than most nuclear-bound complexes formed by glucocorticoids

In separate experiments (not shown), nuclei of DNP-treated cells were incubated for 2 h at 3 °C with 50 nM ^{3}H-triamcinolone acetonide, in the presence and absence of 2 μM of the unlabelled compound, to test the ability of these receptors to bind hormone No saturable binding was detected, indicating that the null receptor cannot bind steroid.

Nuclear binding of steroid hormone receptors in whole cells has until now been induced only with hormone, which forms receptor complexes that become activated and bind to the nucleus New light may be shed on these processes by our observation that nuclear binding can be induced without hormone Initially we proposed that the null receptor represents a stage of a cycle, possibly driven by cyclic phosphorylation-dephosphorylation[4], in which the receptor, after binding in the

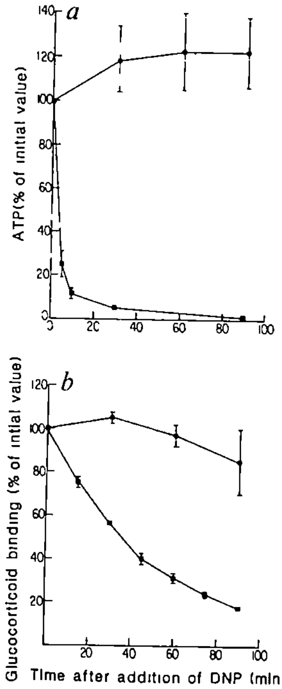

Fig 1 Time course of drop in cellular ATP and glucocorticoid-binding capacity in WEHI-7 cells WEHI-7 cells ($\sim 2\times10^8$), maintained in culture as described[10], were washed by suspending in 80 ml of modified Krebs-Ringer buffer containing 25 mM hydroxyethyl piperazine ethane sulphonic acid (HEPES), *p*H 7 4, 3 6 mM sodium bicarbonate, 2 mg ml^{-1} bovine serum albumin, at 37 °C for 5 min, the suspension centrifuged at 400*g* for 3 min, and the cells resuspended in 3 6 ml of the same buffer containing 1 mM DNP (■) or no DNP (●) Cells were incubated at 37 °C in an orbital water bath At various times, aliquots of the cell suspension were assayed for ATP (*a*) and saturable glucocorticoid-binding capacity (*b*) Results are presented as % of initial value determined at 0 min, just after the addition of DNP, and represent the main value ± s e m of duplicate measurements from two separate experiments Cell viability, as determined by Trypan blue exclusion, was unaffected by the 90 min DNP treatment

Methods. *a*, Cellular ATP was assayed by a modification of the luciferase procedure[16] 25 μl of the cell suspension was added to 500 μl of 5% perchloric acid at 0 °C After 30 min, the sample was centrifuged at 11,000 *g* for 4 min Aliquots (450 μl) of the supernatant were added to 500 μl of a 1 1 mixture of trichlorotrifluoroethane and tri-*n*-octylamine[17] The mixture was vortexed and centriguged at 1,500*g* for 2 min in a clinical centrifuge at room temperature The amount of ATP in 20 μl aliquots of the top phase, which contained the nucleotides in acid-free solution, was determined in a Packard liquid scintillation spectrophotometer from the light emitted upon addition of 100 μl of a solution of desiccated firefly tails (Sigma) prepared in sodium arsenate according to the manufacturer's instructions Absolute values of ATP were determined from a standard curve of events per 0 1 min versus known quantities of ATP prepared from a 2 mM stock solution *b*, Glucocorticoid receptor binding capacity was assayed in cytosolic fractions obtained by a modification of the freeze-thaw procedure[10] in which 100 μl of the cell suspension was added to 250 μl of lysis buffer containing 10 mM trimethylamino-ethanesulphonic acid (TES), *p*H 7 6 at 0 °C, 50 mM NaCl, 1 mM EDTA, 20 mM sodium molybdate and 10% glycerol (v/v) After the broken cell suspension had been centrifuged at 11,000g, aliquots of the cytosolic fraction were incubated with ~50 nM ^{3}H-triamcinolone acetonide (specific activity = 43 8 Ci per mmole) in the presence or absence of 2 μM triamcinolone acetonide to determine glucocorticoid receptor binding capacity[18]

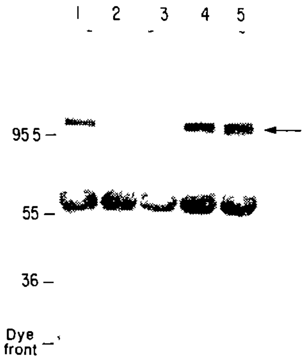

Fig 2 Cellular localization of the glucocorticoid null receptor Samples shown are cytosolic (lane 1) and nuclear (lane 2) fractions of WEHI-7 cells removed at time = 0 min, immediately after addition of DNP, cytosolic (lane 3) and nuclear (lane 4) fractions of WEHI-7 cells exposed to 1 mM DNP for 90 min, and Triton X-100-washed nuclear fraction of WEHI-7 cells exposed to 1 mM DNP for 90 min (lane 5) At various times after the addition of DNP, 1 ml of the WEHI-7 cell suspension was centrifuged at 400*g* for 1 5 min The cell pellet was lysed by a freeze-thaw procedure[10] in 1 ml of a lysis buffer containing 10 mM TES, *p*H 7 6 at 0 °C, 50 mM NaCl, 2 mM $MgCl_2$, 20 mM sodium molybdate and 10% (v/v) glycerol After lysis, the broken cell suspension was centrifuged at 400*g* at 3 °C for 3 min The supernatant was used without modification as the cytosolic fraction The nuclei were suspended in 5 ml of the lysis buffer, centrifuged at 400*g* for 5 min, and the supernatant discarded The nuclei were then resuspended in 600 μl of lysis buffer Nuclei to be treated with Triton X-100 were suspended in 5 ml of 0 05% Triton X-100 in 6 mM $MgCl_2$ for 5 min at 3 °C, centrifuged at 400*g* for 5 min, the supernatant discarded and the pellets resuspended in 600 μl of lysis buffer Glucocorticoid receptors were denatured in both fractions by addition of 200 μl of a detergent solution containing 10 mM TES, *p*H 7 6 at 0 °C, 10% (w/v) SDS, 10 mM sodium molybdate and 10% (v/v) glycerol, and heating the samples in a boiling water bath for 5 min (cytosolic fraction) or 10 min (nuclear fraction) After cooling to room temperature, 2 ml of a 5% solution of Triton X-100 (w/v) in 10 mM TES, *p*H 7 6 at 0 °C, 10 mM sodium molybdate, 10% (v/v) glycerol was added to bring the total volume of each sample to 5 ml Ascites fluid (10 μl) of BuGR2 antibody (directed against the glucocorticoid receptor[19]) was added to each sample, and the receptors purified on protein A-Sepharose CL-4B columns[10] Antibody-purified receptors were run on 7 5% polyacrylamide gels under denaturing and reducing conditions, transferred to nitrocellulose and identified by reaction with BuGR2 antibody and subsequent labelling with ^{125}I-sheep anti-mouse IgG (ref 10) After autoradiography the amount of receptor in each sample was determined by counting the ^{125}I in the receptor-containing region (arrow) The sizes (daltons × 10^3) and migration positions of prestained relative molecular mass standards (Diversified Biotech) are shown The immunoreactive protein which migrates just above the 55,000 standard is BuGR2 antibody

nucleus as the activated hormone/receptor complex and transducing hormonal activity, is released in the null form and the hormone binding form is subsequently regenerated It has been shown that the receptors for glucocorticoid and other steroids are phosphorylated and lose hormone-binding activity under cell-free conditions when treated with phosphatase (see refs 12 and 13 for reviews) Because the null receptor can also be generated in cells in the absence of steroid[3,6], it can directly interconvert with the normal unoccupied receptor Our demonstration that the null receptor is located in the nuclei of ATP-depleted cells, rather than in the cytosolic fraction, however, raises some interesting questions Among these is the possibility that the null receptor may be present as the predominant form in some of the mutant cells which have been considered receptor-deficient based on the lack of binding capacity or receptor protein in their cytosolic fractions[14,15]

We do not know where the null receptor is bound in the nucleus, nor whether it can initiate biological activity Many other questions also remain, such as how the null receptor is formed from the normal receptor, whether it interconverts with the normal receptor in metabolically intact cells, and whether its accumulation in nuclei of ATP-depleted cells means that release of receptors from nuclei is an energy-requiring step. Our identification and localization of the null receptor should allow definitive experimental answers to these and other questions.

We thank Dr Robert Harrison for the generous gift of the BuGR2 antibody used in these studies, and Sue Bagas for technical assistance. This research was supported by NIH grants AM 03535 and CA 17323, and by the Norris Cotton Cancer Center Core grant CA23108 from the US Public Health Service.

A new subunit of the human T-cell antigen receptor complex

Allan M. Weissman, Lawrence E. Samelson & Richard D. Klausner

Cell Biology and Metabolism Branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland 20892, USA

The T-cell antigen receptor binds antigen in association with a cell surface molecule encoded by the major histocompatibility complex (MHC)[1]. MHC restricted recognition of antigen by this receptor leads to the complex pattern of programmed gene expression that characterizes T-cell activation. The eventual understanding of human T-cell function will require the complete elucidation of the structure of the human T-cell antigen receptor. On human T cells, clonally determined, disulphide-linked α and β chains of the receptor are non-covalently and stoichiometrically associated with three additional polypeptides known as the T3 complex[2,3]. These receptor subunits are glycoproteins of relative molecular mass (M_r) 25,000 (25K) and 20K (γ and δ) and a non-glycosylated 20K protein (ε). Our studies of murine T cells show that the mouse T-cell antigen receptor consists of at least seven distinct polypeptide chains[4-6]. In addition to clonotypic α and β chains, the murine complex consists of glycoproteins of 26K and 21K and endoglycosaminidase F (endo F)-insensitive polypeptides of 25K, 21K and 16K. The latter, which we have termed ζ (zeta), exists as a homodimer within the complex. The 26K component (gp26) has been shown to be the murine analogue of the human δ chain[6,7]. Other cross species homologies remain to be established, however none of the described human receptor components appear similar to the murine ζ polypeptide. We report here the use of an antiserum raised against the murine ζ subunit to identify a previously unrecognized component of the human T-cell antigen receptor. This human protein is T-cell specific and biochemically similar to the murine ζ polypeptide.

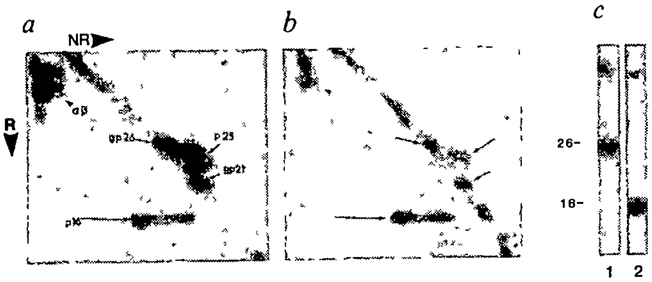

Fig. 1 Immunoprecipitation of radio-iodinated murine T-cell antigen receptor complex from the antigen specific hybridoma 2B4. Specific immunoprecipitates with *a*, the anti-clonotypic monoclonal antibody A2B4-2, or *b*, anti-ζ antiserum were subjected to two-dimensional diagonal non-reducing (NR)/reducing (R) electrophoresis. Arrows delineate subunits of interest. α–β are 40-45K glycoproteins, gp26 is a 26K glycoprotein (δ), p25 migrates at 22K under non-reducing and 25K under reducing conditions and gp21 is a 21K glycoprotein, p16 is the ζ chain. The 21K endo F insensitive protein, p21 (ref. 5) is not seen in this study. *c*, Solubilized cell membranes radio-iodinated using Iodobeads (Pierce) were immunoprecipitated and incubated with ionic detergents SDS and DOC before elution, reduction and SDS-PAGE. Lane 1, anti-δ rabbit serum, lane 2, anti-ζ rabbit serum.

Methods. 2B4 cells were maintained in exponential phase of growth as previously described[12]. Lactoperoxidase catalysed radio-iodination with ^{125}I at 4 °C, lysis of cells in 0.5% Triton X-100 and immunoprecipitation using antibodies precoupled to protein A Sepharose (Pharmacia) were performed as described[4]. 2B4 cell membranes were prepared and solubilized as described[5]. Incubation of immunoprecipitates in ionic detergents SDS and DOC was carried out by the addition of 0.2-0.4% SDS and 0.2% DOC to protein A Sepharose immunoprecipitates after an initial wash in 0.1% Triton X-100 wash buffer. After 15 min at 22 °C the immunoprecipitates were again washed in 0.1% Triton X-100 containing wash buffer and analysed after reduction on 12.5-13% polyacrylamide gels using the buffer system of Laemmli[16]. Two-dimensional diagonal electrophoresis was carried out using 12.5% SDS-PAGE tube gels in the first dimension on non-reduced material. After reduction and equilibration in 0.5% dithiothreitol, 0.1% SDS and 0.125 M Tris, *p*H 6.8 for 2 h at room temperature, SDS-PAGE in the second dimension was carried out on 12.5% polyacrylamide slab gels (Hoeffer) according to the manufacturer's recommendations. Fixing of gels, glycerol treatment, drying and autoradiography were all performed as previously described[4]. Solubilised 2B4 cell membranes were used for the preparation of antisera. Insoluble material was removed at 15,000g and the supernatant was immunoprecipitated with A2B4-2 covalently linked to cyanogen bromide-activated Sepharose (Pharmacia). After extensive washing of immunoprecipitates using buffers described previously[7], the receptor complex was eluted from the beads at 37 °C in a buffer consisting of 0.1% SDS, 50 mM Tris, *p*H 6.8, 0.5 M NaCl, 1 mM Phenylmethylsulphonylfluoride (Sigma), 10-100 µg ml^{-1} leupeptin (Boehringer Mannheim), 10 µg ml^{-1} Aprotinin (Boehringer Mannheim), 10 mM EDTA and 10 mM iodoacetamide. After elution the material was concentrated at 22 °C using Centricon 10 Microconcentrators (Amicon). Radio-iodinated, solubilized A2B4-2 membrane immunoprecipitates were added to the concentrated material, boiled in 3% 2-mercaptoethanol/10% glycerol and electrophoresed on 17.5% polyacrylamide gels cross-linked with Acrylaide (FMC Corporation). After autoradiography of the undried gel, the 16K band was cut from the gel, eluted in 0.1% SDS 10 mM Tris, *p*H 7.6 at 95 °C and concentrated as above. Material from approximately 1.5×10^{10} cell equivalents was emulsified in complete Freund's adjuvant (CFA) in a final volume of 2 ml and injected into an adult female New Zealand White rabbit by multiple subcutaneous injections. The animal was boosted after 5 weeks with antigen emulsified in CFA and bled two weeks thereafter.

Rabbit antisera were raised against the ζ chain after separation of receptor components by sodium dodecylsulphate polyacrylamide gel electrophoresis (SDS-PAGE). The antiserum was evaluated by immunoprecipitation of lysates from the murine T-cell hybrid 2B4. The proteins specifically immunoprecipitated from surface-iodinated cells by the anti-clonotypic monoclonal antibody A2B4-2 were compared to those precipitated by the

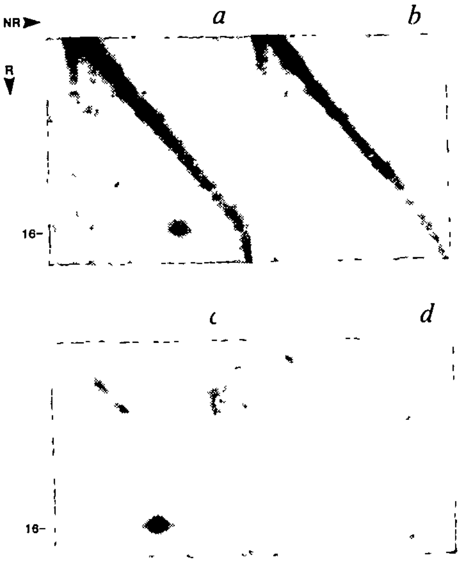

Fig 2 Identification of the human ζ chain Radio-iodinated solubilized membranes from Jurkat cells (*a*, *b*), human tonsillar T cells (*c*), and human tonsillar B cells (*d*) were immunoprecipitated with the anti-ζ serum (*a*, *c*, *d*) or non-immune rabbit serum (*b*) and subjected to electrophoresis on diagonal gels
Methods Jurkat human tumour cells were maintained as described previously[4] Purified tonsillar T and B cells (provided by Dr John Kehrl) were prepared as previously described[17] Tonsillar T cells were judged to be 90% pure by indirect immunofluorescence with the T-cell specific monoclonal antibodies OKT4 and OKT8 B cells were 94% surface immunoglobulin positive In this study 6 5 × 10^7 T cells and 5 × 10^7 B cells were used

anti-ζ serum on two-dimensional non-reducing/reducing diagonal gels (diagonal gels) (Fig 1*a*,*b*) The serum specifically precipitated all of the components of the T-cell receptor complex seen with the monoclonal antibody The relative intensities of the receptor components are different between panels *a* and *b* This may be due to disruption of the complex by the anti-ζ serum or to the presence of some dimeric ζ not associated with the receptor complex A 16K band present on the diagonal in the material precipitated by the antiserum may represent monomeric ζ A small amount of streaking is seen at 16K and 14K in both panels, this finding is variable and probably due to proteolysis This antiserum also immunoprecipitates an identical pattern of subunits from murine thymocytes (data not shown) In contrast, the anti-ζ serum fails to immunoprecipitate specific proteins from lysates of a murine B-cell tumour line LK 35 2, or from murine fibroblasts

To identify the direct target antigen of this antiserum we subjected radio-iodinated immunoprecipitates to an incubation in a buffer containing the ionic detergents SDS and deoxycholate (DOC) This treatment results in dissociation of the receptor complex[7] Immunoprecipitation from radio-iodinated membranes with an antiserum raised against the carboxy terminus of the murine δ chain[7] revealed a single band at 26K when the SDS/DOC incubation was carried out (Fig 1*c*) When the anti-ζ serum was used, SDS/PAGE under reducing conditions revealed a single prominent band at 16K In this experiment a small amount of material is seen at 50K with both of the specific antisera and with control serum

We used this anti-ζ serum to look for a similar protein in human T cells The human T-cell tumour line Jurkat expresses both α-β and the T3 complex on its surface[8] Solubilized membranes from these cells were radio-iodinated using lactoperoxidase and immunoprecipitates were electrophoresed on diagonal gels Immunoprecipitation with the anti-ζ serum (Fig 2*a*) revealed a 32K protein with a M_r of 16K after reduction No other components of the T-cell antigen receptor complex were detected with varying exposures of the autoradiograph Non-immune serum (Fig 2*b*) revealed a pattern of non-specific material on the diagonal similar to that seen in Fig 2*a*, but the 16K dimer was clearly not present Surface iodination of intact Jurkat cells gave identical results (data not shown) We prepared radioiodinated solubilized membranes from human tonsillar T and B cells to examine whether this protein is found in normal human T cells The anti-ζ-antiserum immunoprecipitates a 16K protein with a non-reduced M_r of 32K from T cells but not from B cells (Fig 2*c*,*d*) It is clear that in these cells no other components of the T-cell antigen receptor are specifically

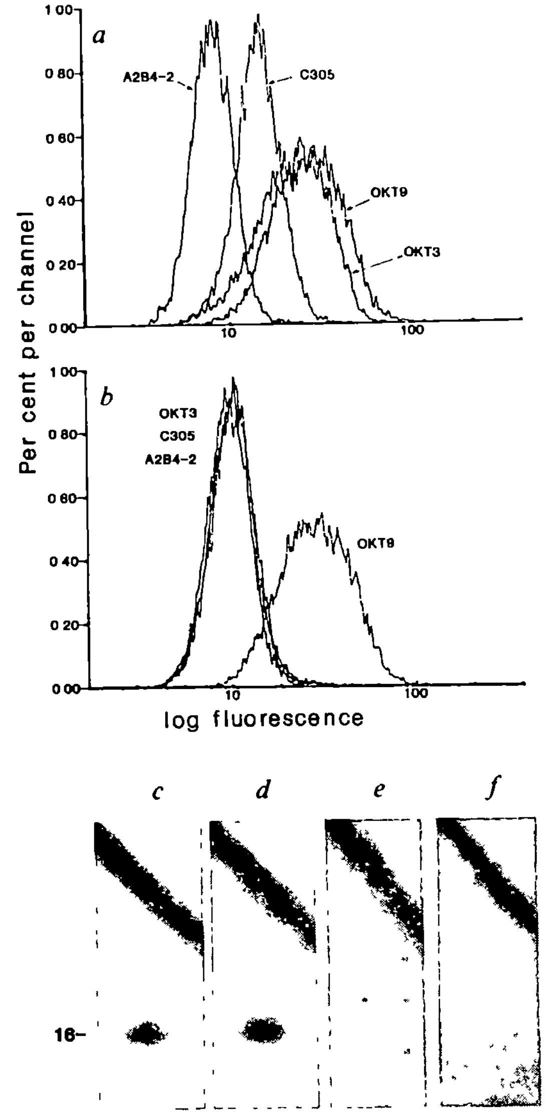

Fig 3 Jurkat cells incubated for 24 h with *a*, A2B4-2, or *b*, OKT3 ascites at a dilution of 1 1000 The cells were washed 3 times and treated for 30 min at 4 °C with ascites or culture supernatants of monoclonal antibodies A2B4-2, OKT3, OKT9 or C305 The cells were washed and incubated with fluorescein-conjugated Fab fragments from affinity-purified goat anti-mouse serum, then subjected to FACS analysis as described[18] Incubation with OKT9 for 24 h resulted in persistence of surface antibody as measured by FACS, interfering with analysis of antibody binding In parallel, Jurkat cells were surface iodinated after 24 h treatment with A2B4-2 (*c*), OKT9 (*d*) or OKT3 (*e*,*f*) Equivalent numbers of trichloroacetic acid precipitable counts were immunoprecipitated with anti-ζ serum (*c*, *d*, *e*) or non-immune serum (*f*) and subjected to electrophoresis on diagonal gels The position of ζ is shown The non-immune immunoprecipitate shown (*f*) is representative of similar control immunoprecipitations carried out after 24 h treatment with A2B4-2 or OKT9

precipitated with this antiserum Additional studies revealed that the 16 K human homodimer has the same apparent *p*I as the murine ζ chain and is likewise insensitive to endo F (data not shown)

Thus ζ, which is clearly a component of the murine T-cell antigen receptor complex, has a human analogue which (1) is immunologically related to the murine chain, (2) has identical size and charge characteristics to the murine protein and (3) is found in T cells but not B cells Based on these findings we analysed radio-iodinated immunoprecipitates of Jurkat cells obtained by using the anti-T3 monoclonal antibody OKT3 (ref 9) and the anticlonotypic antibody C305 (ref 8) With both antibodies, material that migrated identically to ζ was consistently seen on long exposures of autoradiographs of diagonal gels (data not shown) Although the level of ^{125}I associated with this material was significantly less than that found in the other subunits of the complexes, these results provided suggestive evidence that the human ζ polypeptide is part of the T-cell antigen receptor

One possible explanation for the apparently lower amount of ζ-like material in human receptor immunoprecipitates is that solubilization may lead to disruption of the complex We wished to determine whether the human ζ analogue was associated with the other receptor components on intact cells To test this, we used antibody-mediated co-modulation This approach has allowed the determination of specific non-covalent association of membrane proteins In particular it has been used to show the association of the T3δ chain with the clonotypic α-β heterodimer on the surface of human T cells[10] Modulation of surface T3 with anti-T3 reagents results in loss of both the clonotypic and T3 antigenic determinants without affecting other cell surface antigens Since the anti-ζ serum does not bind to the surface of cells as measured by fluorescence activated cell sorter (FACS) analysis, we modified the standard co-modulation technique by carrying out surface iodination of cells at 4 °C after antibody incubation This labelling allowed us to quantify surface ζ by immunoprecipitation

Jurkat cells were used for these studies because specific reagents for this cell line are available Jurkat cells were treated for 24 hours with ascites from hybridomas producing the OKT3, OKT9 or A2B4-2 monoclonal antibodies to modulate antigen receptors OKT9 is a monoclonal antibody which binds the human transferrin receptor[11] A2B4-2 does not bind to human cells[12] and served as a control When T3 surface expression was measured by FACS, the A2B4-2 pretreated cells bound considerably more OKT3 than did the OKT3 pretreated cells (compare Fig 3*a* with 3*b*) As expected, the α-β chains of the antigen receptor were co-modulated with the T3 antigen after OKT3 treatment as shown by the reduced binding of the anti-clonotypic C305 antibody Immunoprecipitation of the surface iodinated cells with C305 confirms the FACS data, essentially no residual heterodimer is seen after T3 modulation, but OKT9 and A2B4-2 treated cells have approximately the same amount of heterodimer (data not shown) The association of ζ with the T-cell antigen receptor complex on the intact cell is shown by the loss of ζ chain expression from the cell surface on OKT3-treated cells (Fig 3*c*-*f*) Thus ζ co-modulates with the α-β heterodimer and T3δ confirming the *in situ* association of these polypeptides The specificity of this co-modulation was demonstrated by FACS analysis OKT3-treated cells showed no loss of surface transferrin receptor binding compared to A2B4-2 treated cells, nor was there loss of binding of an anti-LFA-1 antibody MHM-23 (ref 13) (data not shown) In addition, when radio-iodinated OKT3-treated cells were compared to OKT9 or A2B4-2 treated cells on SDS-PAGE, few if any differences in the pattern of total cell surface proteins were seen

Solubilization of multicomponent membrane complexes invariably results in a certain degree of denaturation of native protein-protein interactions, as shown in studies of the T-cell antigen receptor and the IgE receptor[4,14] Optimizing ratios of lipid to detergent and the use of non-ionic detergents can minimize this denaturation[15] In the T-cell antigen receptor system however, ζ, which can be co-immunoprecipitated in a consistent stoichiometric relationship with other subunits from mouse cells, is not similarly co-immunoprecipitated from human T cells This disparity is probably due to minor structural differences that are manifest as varying degrees of disruption of subunit interactions upon solubilization

Aside from the identification of a new human T-cell antigen receptor component, we have shown that (1) when studying membrane protein complexes, comparison of the same receptor system in different species may allow for the identification of interactions that might not otherwise be detected, (2) because of the receptor denaturation that occurs on solubilization, methods other than co-immunoprecipitation, such as co-modulation and chemical cross-linking, may prove useful to help determine specific associations between cell surface structures

We thank Dr B J Fowlkes and Miss L Edison for assistance with fluorometry studies, Dr A Weiss for his gift of the antibody C305, Dr John Kehrl for providing tonsillar cells, Drs J Harford, Y Minami and J O'Shea for their help and advice, Miss H Luong for technical assistance, and Mrs K Perry for secretarial expertise in preparation of this manuscript

Athymic mice express a high level of functional γ-chain but greatly reduced levels of α- and β-chain T-cell receptor messages

Yasunobu Yoshikai, Marciano D. Reis & Tak W. Mak

The Ontario Cancer Institute, and Departments of Medical
Biophysics and Immunology, University of Toronto,
500 Sherbourne Street, Toronto, Ontario, Canada M4X 1K9

T lymphocytes differentiate and mature in the thymus. It is here that thymocytes with reactivities to self antigens are eliminated and those with specificities to 'altered' self-major histocompatibility complex (MHC) gene products are positively selected[1]. The selections are presumably carried out on the basis of their T-cell antigen receptors (TcR). The genes of the α- and β-chain T-cell antigen receptors have been cloned[2–7]. A third T-cell specific gene capable of undergoing somatic rearrangement has also been identified[8]; the role of this third gene is not known. An order of expression of γ, β, then α is found during T-cell ontogeny[9,10]. But although α- and β-chain messages are often functional[11–15],

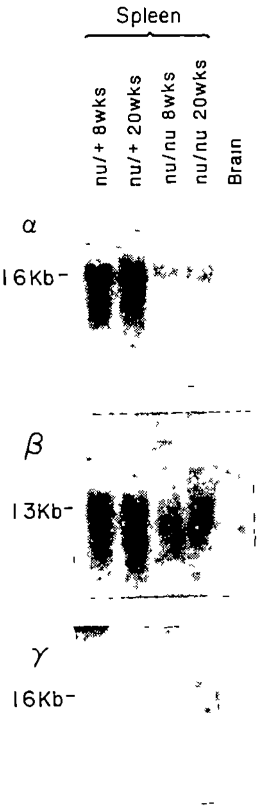

Fig. 1 Northern blot analysis of spleens in young and old nude mice Congenitally athymic nude (*nu*/*nu*) mice on a BALB/c (10th backcross) background and their littermate (*nu*/+) controls were used under pathogen-protected conditions in the animal facility maintained by the Ontario Cancer Institute, Toronto Original breeding pairs were obtained from Taconic Farms, N Y The life span of nude mice was 1 to 2 years under the maintenance conditions used All nude mice used in these studies appeared in good health RNA was extracted from spleens by the guanidine isothiocyanate and $CsCl_2$ gradient centrifugation procedures[29] and treated with glyoxal Total RNA (30 μg per spleen) was electrophoresed through 1% agarose in 10 mM sodium phosphate buffer *p*H 7 0 and transferred to Gene Screen Plus (NEN) Hybridization was to ^{32}P-labelled nick-translated α (5/10-20 Dα, *Hin*dIII-*Eco*RI fragment), β (5/10-20Dβ, *Taq*I-*Eco*RI fragment) and γ (8/10-2γ1 1, *Ava*I-*Eco*RI fragment) constant probe[11] Following hybridization in 5×SSC, 5×Denhardt's 10% dextran sulphate and 0 1% SDS at 65 °C, blots were washed three times in 2×SSC, 0 1% SDS at 65 °C and once in 0 2×SSC, 0 1% SDS at 65 °C

γ transcripts are rarely functional in thymocytes or mature T cells[16–18]. To define the sequential order of expression of these genes further and to continue the search for a possible role for the TcR γ gene products, we investigated the expression of 'functional' α-, β- and γ-chain transcripts in young athymic mice. These mice express an undetectable amount (less than one in 8×10⁵ spleen messages) of 'full-length' α- and β-chain T-cell receptor transcripts, but an increased level of expression of 'full-length' γ chain messages Nucleotide sequence analysis of four γ complementary DNAs show that all four γ transcripts sequenced are functional These findings suggest that γ gene products may be important in a prethymic or extrathymic pathway and may represent a second type of T-cell recognition, possibly in a lineage in which α and β genes are not used.

To investigate the expression of the α, β and γ T-cell receptor messages in athymic mice, we extracted RNA from total spleen cells from mice with genotype BALB/c (*nu*/*nu*) at 8 weeks and 20 weeks of age Control spleen RNA was also obtained from mice with genotype (*nu*/+) at 8 and 20 weeks of age The level of expression of these T-cell receptor genes was evaluated using Northern blots A typical result is shown in Fig 1 The experiments clearly show that a much lower level of the α- and β-chain T-cell receptor transcripts are found in both 8 and 20 weeks old athymic mice However the same level of expression of γ-chain messenger RNA is found in BALB/c (*nu*/*nu*) mice and in control mouse spleen Although the expression of these messages did not increase in old (20 weeks) control *nu*/+ mice, a higher level of these messages is found in old athymic mice The sizes of these γ-chain transcripts also suggest that they mainly consist of 'full length' 1 6 kilobase (kb) mRNA We have constructed cDNA libraries derived from spleen cells of 8 weeks old *nu*/+ mice and 8 weeks old athymic *nu*/*nu* mice The cDNA clones with sequences homologous to the constant region of either α-, β- or γ-chain genes were isolated and counted Results of one such experiment (Table 1) confirm that very low levels of α- and β-chain messages are found in the athymic mice whereas the level of γ chain messages is near normal

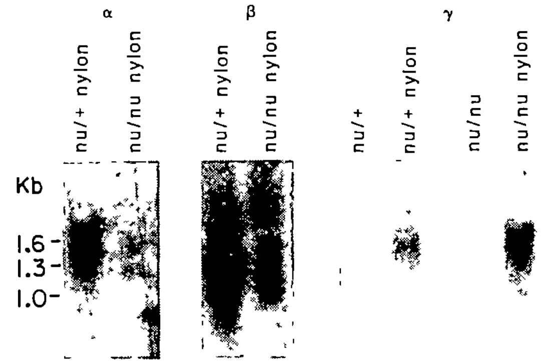

Fig 2 Northern blot analysis of nylon wool-passed spleen cells from nude mice Spleen cells were passed over nylon wool columns according to the method of Julius *et al*[20] Recovery of spleen cells after nylon wool passage varied (15–20%) Total RNA (15 μg each) and blots were prepared as described in Fig 1 Hybridization was carried out in 5×SSC, 5×Denhardt's, 10% dextran sulphate, 0 1% SDS at 65 °C Nick-translated constant probes of α, β and γ chain were used[33] After hybridization, blots were washed three times in 2×SSC, 0 1% SDS at 65 °C and once in 0 2×SSC, 0 1% SDS at 65 °C

The above data reflect the total amount of α-, β- or γ-chain T-cell receptor gene transcripts in total spleen RNAs However, it is known that spleens from athymic mice have a low number of T cells (reflected by the level of Thy-1⁺ cells[19]) We enriched for Thy-1⁺ spleen cells from 8-week-old *nu*/*nu* spleens using nylon wool[20] and compared them with the nylon-wool purified cells from spleens of mice with genotype *nu*/+ at the same age (Fig 2) The cells from athymic mice express a much lower level of both the α- and β-chain TcR transcripts Note also that, although control T cells express a high level of full-length transcripts of the α and β messages (1 6 and 1 3 kilobases (kb), respectively), cells from the athymic mice do not contain a high proportion of full length message This is particularly evident in the β- chain transcripts, where we find a prominent band of truncated message at 1 0 kb Examination of the sizes of eight inserts from the cDNA libraries described also confirms that all the α and β chain transcripts are less than the full length of 1.3 kb for α and 1 0 kb for β (Y Y, unpublished observations) These truncated transcripts are presumably composed of only *D-J-C* or *J-C* sequences[21-23] Thus the decrease in α- and β-chain transcripts in *nu*/*nu* mice is not solely due to the lower numbers of Thy-1⁺ cells

A different and interesting picture is seen for γ-chain messages Figure 2 clearly shows that after nylon-wool enrichment more γ-chain message can be found T cells from athymic mice express a several times higher level of γ-chain messages The majority of the γ cDNAs are 1 6 kb and are presumably 'full length'

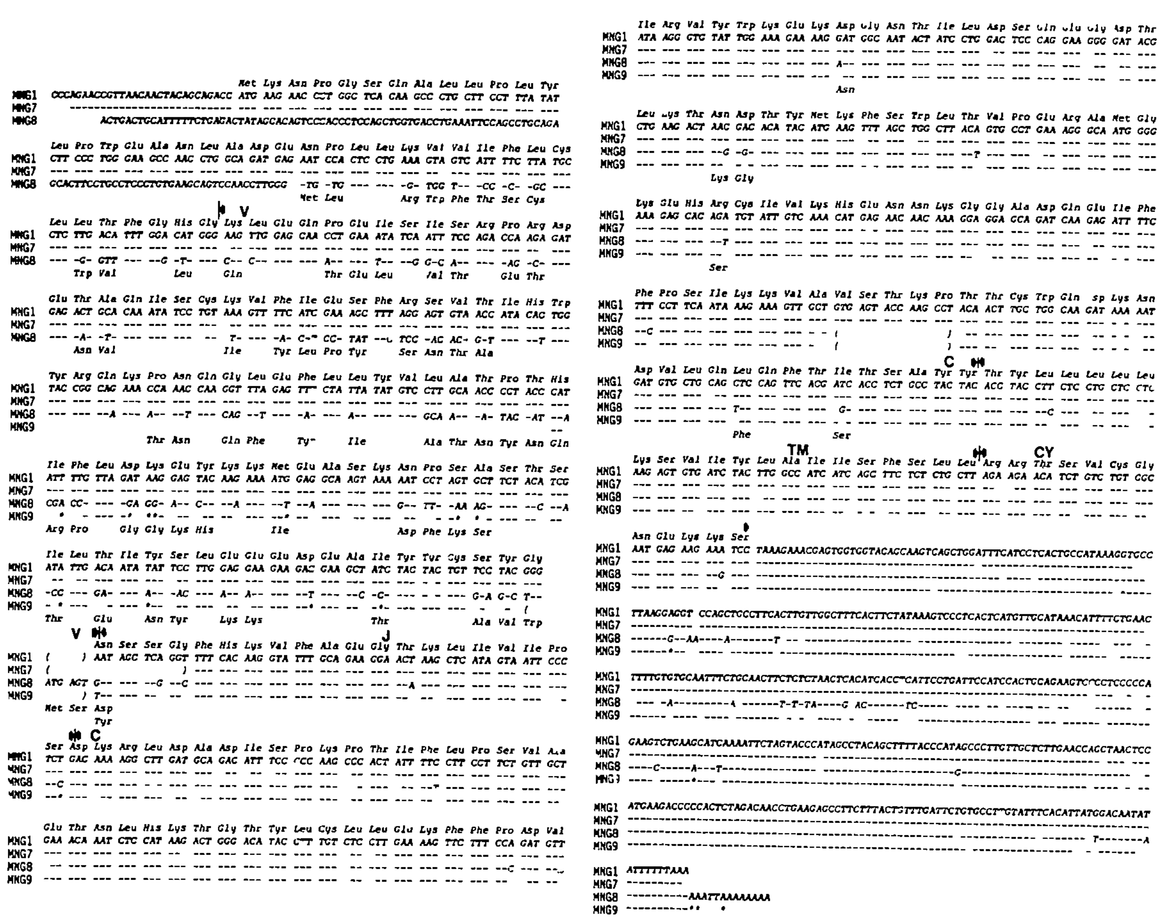

Fig. 3 The nucleotide and deduced amino acid sequences of four γ-gene cDNA clones isolated from *nu*/*nu* spleen. The cDNA inserts were subcloned into the M13mp9 bacteriophage, and their sequences were determined using both the universal M13 primer and the specific-primer-directed dideoxynucleotide sequencing technique[31,32]. The predicted amino acid sequence of cDNA clone MNG1 is shown above the nucleotide sequence. MNG8 and MNG9 amino-acid residue positions that differ from MNG1 are shown below the nucleotide sequence. The V, J, C transmembrane (TM) and cytoplasmic (CY) regions are indicated by the horizontal arrows. Dash, nucleotides in MNG7, MNG8 or MNG9 that are identical with those in MNG1; *, nucleotides in MNG9 that are identical with those in MNG8 ( ), missing nucleotides ( ).

To examine whether the γ-chain messages are functional, we sequenced four of these clones. The nucleotide sequences and deduced protein sequences are presented in Fig. 3. As can be seen, each of the four clones MNG1, MNG7, MNG8 and MNG9 contained sequences with open reading frames from the beginning of the variable region to the expected termination codons at the end of the constant regions. They also possess the entire *V*, *J* and *C* sequences presumably necessary for a functional receptor protein. The clones MNG1 and MNG7 use the *V*, *J* and *C* sequences of $V\gamma_4$ (3F9), $J\gamma_1$ (13.4), and $C\gamma_1$(13.4), while those of MNG8 and MNG9 correspond to $V\gamma_2$ (10.8A), $J\gamma_2$(10.5), and $C\gamma_2$(10.5) as defined in refs 24 and 34.

The above data clearly illustrate the difference between the expression of the α- and β-chain messages and the γ-chain transcripts in young athymic mice. The finding that there are full length, functional γ chain messages but no full length α and β transcripts in these athymic mice suggests that a complete thymic environment is not necessary for the rearrangement and expression of TcR γ gene.

Thy-1$^+$ T cells from athymic mice (purified using nylon wool) also contain a reduced level of both the α and β gene transcripts. This may be due to the presence of a different subpopulations of Thy-1$^+$ T cells in athymic spleens, possibly those of less mature T cells when compared to the normal mice. The finding that the α and β transcripts that do exist in young athymic mice are truncated is consistent with such a hypothesis. Another possibility is that the lower level of α and β TcR transcripts is due to a different environment in the athymic mice spleen or the predominance of a different subset(s) of splenic T cells in these *nu*/*nu* mice.

In either case it would be of interest to determine whether any *nu*/*nu* T cells use the α-β TcR heterodimer and whether a full wild-type germline repertoire of TcR α and β chain *V* and *J* gene segments are used in these athymic mice. This may require generation of 'functional' T cell clones from athymic mice. Some results have suggested that these cells may exist in *nu*/*nu* mice[25]. It would be of interest to examine whether older athymic mice use these α-β TcR genes.

It is interesting that although the levels of α- and β-chain TcR transcripts in athymic mice are dramatically reduced, the γ level in these mutant mice is elevated. The reason for this is not yet known. It is possible that the rearrangement and expression of γ-chain message occur before exposure to the thymus or is independent of the thymic environment, so that

Table 1 Expression of α, β and γ chain T cell receptor message in nude mouse spleen

	Frequency (%)	
	nu/+	*nu*/*nu*
α	0.006	0.0002
β	0.01	0.0004
γ	0.0006	0.0007

Double-stranded (ds) cDNA was synthesized from total RNA derived from spleens of *nu*/+ (8 weeks) and *nu*/*nu* (8 weeks) according to a modified procedure of Gubler and Hoffman[30]. After addition of the *Eco*RI linker, the cDNAs were cloned into λgt10. About 10^6 independent recombinant phages were plated on *E. coli* (C600 hfl) without amplification and screened using nick-translated constant probes of α, β and γ chain cDNA.

processing of these genes can occur outside the thymus Although the study of the ontogeny of the expression and rearrangement of the T-cell genes suggests an order of γ, β then α[9,10], these studies were done exclusively in the context of thymic environment Moreover, rearrangement of γ-chain genes before β-chain genes outside the thymus or in fetal thymus has not been documented It is possible that the rearrangement and expression of 'functional' γ-chain messages is more efficient than those of the α and β chain genes in the extrathymic pathways of T-cell differentiation in athymic mice

Perhaps the most exciting observation is that athymic mice contain a population(s) of T cells in which the γ-chain T-cell receptors are used It has been suggested that γ-chain gene products may be involved in the recognition of class I MHC gene products in a 'two receptor' model (one for antigen and one for MHC gene products)[9], but several recent findings suggest that the situation may be more complicated First, although it was thought that γ-chain genes are limited to cytotoxic T cells[26], helper T cells (especially autoreactive clones) have also been found to contain these messages[27] Secondly, Dembic *et al*[28] have reported the successful reconstitution of a new T cell specificity recognizing the antigen fluorescein in the context of murine class I D^d products by DNA transfer of only the α- and β-chain genes from a T cell with the same specificity This result suggests that the α-β heterodimer is sufficient for the recognition of both antigen and MHC gene products Finally, with only one exception, over thirty γ transcripts isolated from cytotoxic T lymphocytes[16,17,34], mature T lymphocytes and thymocytes[18] contain deletions, frameshift mutations, or unspliced messages Thus, it is likely that γ gene products may be important in a subpopulation or lineage of T cells responsible for a second type of immunorecognition that has yet to be identified Our observation that all four cDNAs obtained from athymic spleen cells are functional is in sharp contrast to the existing data on γ messages from functional T cells and thymocytes[16-18,34] The finding of no detectable full length α- and β-chain transcripts in young athymic mice suggests that the majority of these cells may not have the α-β heterodimer on their surfaces Athymic spleen cells should thus be the ideal cells for the study of the possible role of γ gene product They may contain populations of either pre-T cells or T cells in an extrathymic pathway, which may be involved in the establishment of tolerance or the recognition of self MHC gene products Other possibilities include γ gene products being receptors active in primitive defense mechanisms or receptors that recognize antigens and MHC gene products

This work was supported by grants from the MRC, NCI, NESERC of Canada and a special research grant from the University of Toronto Y Y is recipient of a fellowship from the MRC of Canada and M D R is a Terry Fox Fellow of the NCI of Canada We thank Drs Barry Toyonaga, Aikichi Iwamoto and Pam Ohashi for fruitful comments

Note added in proof A decrease of α-chain and β-chain messages in athymic mice[35] and the detection of γ-chain protein on the surface of human T cells have been reported[36-38]

Increased expression of P-glycoprotein, a plasma membrane glycoprotein of relative molecular mass (M_r) 170,000 (170K), occurs in a wide variety of cell lines that exhibit pleiotropic resistance to unrelated drugs[1-4]. The presence of P-glycoprotein in human cancers refractory to chemotherapy suggests that tumour cells with multidrug resistance can arise during malignant progression[5]. We have discovered striking homology between P-glycoprotein and the HlyB protein, a 66K *Eschericia coli* membrane protein required for the export of haemolysin (protein of M_r 107K). P-glycoprotein can be viewed as a tandem duplication of the HlyB protein. The hydropathy profiles of the two proteins are similar and reveal an extensive transmembrane region resembling those found in pore-forming plasma membrane proteins The C-terminal region of P-glycoprotein and the HlyB protein contain sequences homologous to the nucleotide-binding domains of a group of closely related bacterial ATP-binding proteins We propose a model for multidrug resistance in which P-glycoprotein functions as an energy-dependent export pump to reduce intracellular levels of anticancer drugs

A search of the GenBank DNA Sequence Database (using the FASTN program from the National Biomedical Research Foundation (NBRF) Protein Identification Resource) detected extensive homology between the 3′ end of a P-glycoprotein complementary DNA clone (pL20, see Fig 1 legend) and the *hlyB* gene of *E coli* This gene is one of four involved in the production and transport of haemolysin *hlyA* encodes the α haemolysin molecule (107K), *hlyC* encodes a small (20K) cytoplasmic protein that may be involved in activating haemolysin, whereas *hlyB* and *hlyD* encode membrane proteins required for the export of α haemolysin from the bacterium[6] (for reviews see refs 7-10)

When the deduced amino-acid sequences of the *hlyB* gene[6] and pL20 are compared graphically, extensive C-terminal homology is evident (Fig 1*a*) Whereas there is little direct

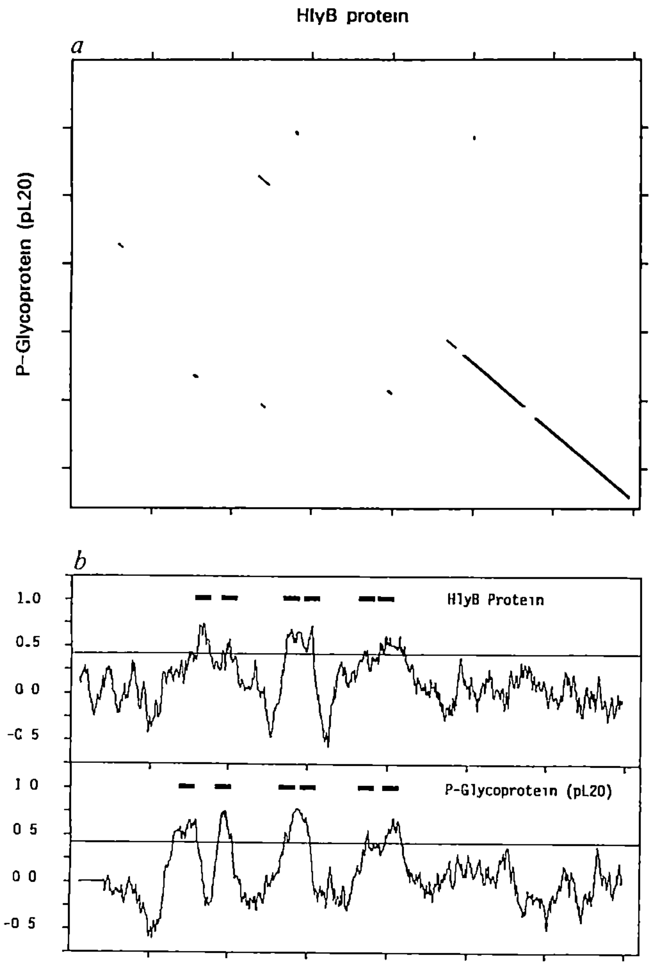

Fig. 1 Comparison of P-glycoprotein (C-terminal 655 amino acids) and the HlyB protein (707 amino acids). *a*, Segment comparison plot generated by the DOTMATRIX program from the National Biomedical Research Foundation (NBRF) Protein Identification Resource using the mutation probability data matrix for amino-acid replacements for scoring[35]. The window size was 21 amino acids and the minimum score required to generate a point was 30. Each division on the axes corresponds to 100 amino acids. *b*, Hydropathy profiles of the HlyB protein (top) and P-glycoprotein (bottom) generated using the normalized hydrophobicity values of Eisenberg *et al.*[11] and a window size of 21 amino acids. Regions above the line at 0.42 are candidates for membrane-spanning segments. The six predicted transmembrane segments in each sequence, as identified using the criteria of Eisenberg *et al.*[11], are indicated by solid bars. The mean hydrophobicity for 21 amino acid segments is indicated on the vertical axis. Divisions on the horizontal axis correspond to 100 amino acids.

Methods. The pCHP1 cDNA probe[31] was used to select a 2,321-base pair (bp) cDNA clone (pL20) from an Okayama and Berg pcD vector-library prepared from a drug-sensitive Chinese hamster ovary cell line as described[36]. For DNA sequencing, pL20 DNA was digested with *Pst*I or *Bam*HI and cloned into M13mp9. Both strands were sequenced using synthetic oligonucleotide primers and the dideoxy method[37]. The pL20 clone contains a 1,965-bp open reading frame followed by a 355-bp untranslated region and a poly(A) tail (sequence available on request). The 640-bp sequence from positions 1,167 to 1,806 is homologous to pCHP1.

homology in the remainder of the amino-acid sequence, hydropathy profiles of the two sequences are remarkably similar (Fig. 1*b*). Both proteins have a large hydrophobic region containing six potential transmembrane segments arranged in pairs. The hydrophobicities and the hydrophobic moments[11,12] of these putative transmembrane segments are consistent with channel-forming functions. The C-terminal region of P-glycoprotein has been localized to the cytoplasmic side of the plasma membrane with monoclonal antibodies[3]. Consequently, the hydropathy plots indicate that only the short stretches of amino acids joining paired transmembrane segments are exposed on the cell surface.

Sequence data from overlapping cDNA clones[13] indicate that the P-glycoprotein gene consists of a tandem duplication (unpublished observations), a structure confirmed in a functional, full-length mouse cDNA clone (P. Gros, personal communication). This, coupled with the protein structural analysis (Fig. 1), implies that P-glycoprotein is a near-perfect tandem duplication of the HlyB protein.

Only three breaks in the P-glycoprotein C-terminal domain are required to produce an excellent alignment with the 230 C-terminal amino acids of the HlyB protein (Fig. 2). Of the 228 possible amino acid matches, 107 (46.9%) are identical and a further 63 (27.6%) are conserved substitutions. This suggests these two proteins share both a common function and a common history. A search of the NBRF Protein Sequence Database (using the FASTP program) identified two other bacterial transport proteins, the HisP protein of the histidine permease system of *Salmonella typhimurium*[14] and the MalK protein of the maltose and maltodextrin transport system of *E. coli*[15], with significant homology with this region. These two proteins have homology with each other[16] as well as with the PstB protein of the phosphate-specific transport system of *E. coli*[17] and the OppD protein of the oligopeptide permease of *S. typhimurium*[18]. These four proteins are membrane-associated components of high-affinity, substrate-binding dependent, active transport systems (for a review see ref. 19). Homology between P-glycoprotein and these proteins is greatest in two regions (indicated A–A and B–B in Fig. 2) that are involved in nucleotide (probably ATP) binding and are thought to energize transport directly[18].

The extent of the protein sequence homology between P-glycoprotein, the HlyB protein, the HisP/MalK/PstB/OppD proteins and five other nucleotide-binding proteins is shown by cluster analysis (Fig. 3). The highest homology occurred between P-glycoprotein and the HlyB protein. Furthermore, the HisP/MalK/OppD cluster is more similar to the P-glycoprotein/HlyB cluster than to the bacterial OppD protein. This suggests both P-glycoprotein and the HlyB protein couple energy production to transport in a manner analogous to the binding-protein dependent bacterial transport systems. Although the cluster analysis does not give direct evolutionary relationships, the high degree of amino-acid sequence homology suggests that these proteins arose from a common ancestor and homology has been maintained by selection pressure resulting from functional similarities in these transport systems. Such a degree of evolutionary conservation between a eukaryotic protein (excluding mitochondrial and chloroplast proteins) and a bacterial protein is unprecedented, and raises the question of ancestry. Based on codon usage, it has been suggested[6] that *E. coli* has only recently acquired the chromosomal haemolysin gene group from a distantly related organism. It is therefore possible that *E. coli* has acquired at least part of the *hlyB* gene from a mammalian P-glycoprotein gene.

Fig. 2 Aligned sequences of the C-terminal 232 amino acids of P-glycoprotein (upper sequence) and the C-terminal 230 amino acids of the HlyB protein (lower sequence) The alignment was generated by the ALIGN program from the NBRF Protein Identification Resource using the mutation probability data matrix for amino-acid replacements with a bias of two and a break penalty of six for scoring[35] Amino acids identical in both sequences are indicated by *** Conserved amino-acid substitutions (scores greater than zero in the mutation probability data matrix for amino-acid replacements[35]) are boxed The numbers at the ends of lines indicate the position in the sequence of the last amino acid in that line Three gaps introduced for alignment (single amino-acid breaks following positions 429 and 640 in the pL20 sequence and a two amino-acid break at position 572 in the HlyB sequence) are indicated (- - -) The underlined regions (A–A and B–B) contain the putative nucleotide-binding site and are highly conserved in other bacterial nucleotide-binding proteins (see Fig 3) Region A–A, characterized by the sequence hhG1/mSG(C/S)GKST ('h' indicates a hydrophobic amino acid conserved in P-glycoprotein, the HlyB protein and the HisP/MalK/PstB/OppD proteins), is glycine-rich and capable of forming a flexible loop that may undergo conformational change either on substrate binding or because of interaction with another protein domain[38] Region B–B contains four consecutive hydrophobic amino acids (which probably exclude water from the bound nucleotide to reduce hydrolysis[38]) followed by two acidic amino acids (hhhhDE) The high homology between P-glycoprotein and the bacterial transport proteins extends over 32 amino acids in this region suggesting an additional function(s) As this is the most conserved amino-acid sequence among the four binding-protein dependent transport proteins, it may couple energy production directly to transport

Based on homology and structural similarities between P-glycoprotein and the HlyB protein and on the homology with the four bacterial binding-protein dependent transport proteins, we propose that P-glycoprotein functions in the plasma membrane to export molecules from the cell It couples energy in the form of ATP directly to transport and effects transport through a channel formed by the transmembrane segments (Fig 4)

P-glycoprotein may export drugs directly (Fig 4*a*) This would require that the protein should not only be able to bind specifically many structurally diverse drugs but also that it should be able to release these drugs to the extracellular medium Support for such binding ability is provided by the vinblastine photoaffinity labelling of a 170K glycoprotein (P-glycoprotein?) in membrane vesicles from multidrug-resistant cells[20,21] The requirement for P-glycoprotein to recognize these compounds is eliminated if P-glycoprotein exports a protein rather than drugs (Fig 4*b*) Drugs bound by this protein (not necessarily reversibly) would be removed when the protein was exported Such binding might occur through hydrophobic domains such as those present in α haemolysin[6] We are examining culture medium from multidrug-resistant cells for such a protein

If P-glycoprotein functions in multidrug resistance in a manner analogous to that of the HlyB protein in haemolysin export, it is reasonable to expect these processes to have common aspects When inhibitors of energy production (for example potassium cyanide, 2,4-dinitrophenol, sodium azide) are added to mammalian cells in the absence of energy sources such as glucose, the net accumulation of drug is increased[22-26] This effect is greater in multidrug-resistant cells and, when glucose is restored, the intracellular concentrations of drug decrease more rapidly than in drug-sensitive cells An energy-dependent, efflux pump for drugs has been suggested as the mechanism of multidrug resistance[22,25,27] These compounds also inhibit the transport of haemolysin[28] Additionally, local anaesthetics (such as procaine), reduce the level of resistance of multidrug-resistant cells[29,30] and inhibit the export of haemolysin[28]

These findings have implications for cancer chemotherapy Although the homology reported here is for Chinese hamster P-glycoprotein, the conservation of P-glycoprotein, as judged by monoclonal antibodies[3] and DNA hybridization[31], makes it virtually certain that this homology will extend to other mammalian (including human) P-glycoprotein molecules It may be possible to screen for compounds to overcome multidrug

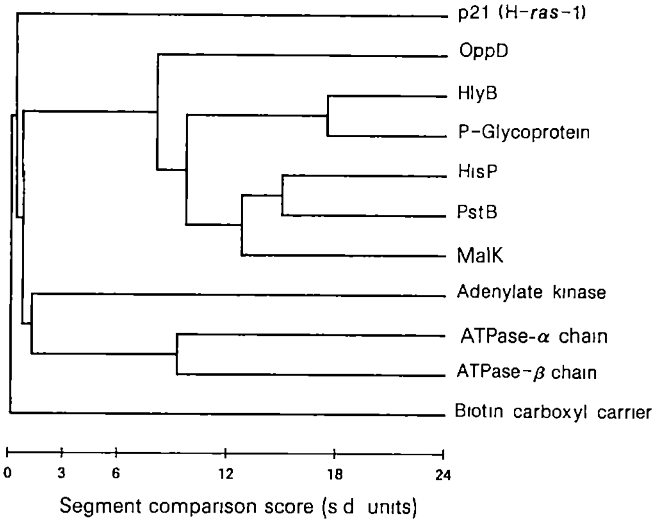

Fig. 3 Cluster analysis of the protein sequence homology of some nucleotide-binding proteins The RELATE program from the NBRF Protein Identification Resource[35] was used to determine objectively similarities between P-glycoprotein (pL20), the HlyB protein and nine proteins with nucleotide-binding regions homologous to regions A-A and B-B in Fig 2 Besides the HisP, MalK, PstB and OppD proteins, adenylate kinase (rabbit), the H-*ras*-1 p21 transforming protein (human), the biotin carboxyl carrier protein from *Propionibacterium shermanii* and the α and β chains of the *E coli* F_1-ATPase[38,39] were examined. These proteins were selected from known nucleotide-binding proteins because each has both of the nucleotide-binding regions present in the bacterial transport proteins and because they represent a functionally diverse group[38] The amino-acid sequences were from the NBRF Protein Sequence Database For each pair of proteins, the homology scores between all possible 25 amino-acid segments of one protein with all possible 25 amino acid segments in the other protein were determined using the mutation probability data matrix for amino-acid replacements[35] A numerical value derived from the distribution of scores was then determined for the actual sequences of the two proteins and for 500 runs performed using computer-generated randomized sequences of both proteins The difference between the value for the actual sequences and the mean value for the randomized runs was then divided by the standard deviation of the values from the randomized runs to yield a segment comparison score with units of standard deviation (s d) The probability of obtaining such a score by chance can then be estimated from a cumulative standardized normal distribution table This analysis has the advantage of being relatively insensitive to differences in the lengths of the proteins being compared[35] Clusters were formed by merging proteins with the highest segment comparison scores As clusters were formed, the score used for merging was the weighted average of the scores of the members of a cluster Note that cluster analysis forces the eventual merging of all proteins Only statistically significant groups should be considered representative of structural homology Thus we consider only the group consisting of P-glycoprotein, the HlyB protein and the HisP/MalK/PstB/OppD proteins and the group containing the ATPase α and β chains to be significant (the probability of obtaining a score >6 s d is $<10^{-9}$ whereas the probability of a score >10 s d is $<10^{-23}$)

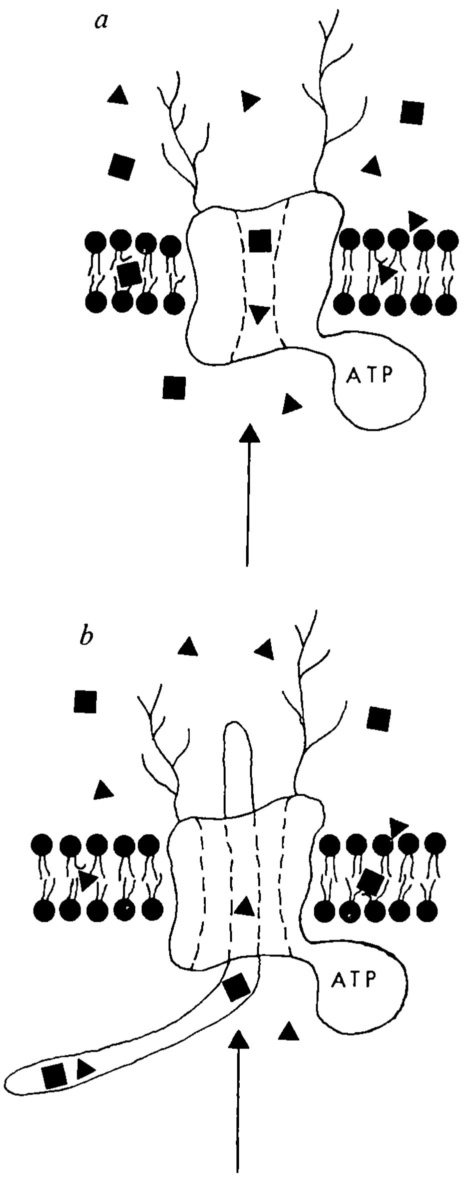

Fig 4 Models for the role of P-glycoprotein in multidrug resistance In *a* P-glycoprotein exports two structurally different drugs (■, ▲) directly through a channel In *b* the drugs are bound by an unidentified protein that is then exported from the cell by P-glycoprotein The presumptive ATP-binding site (ATP) is on the cytoplasmic side of the plasma membrane Drugs are shown entering the cell by diffusion through the lipid bilayer Arrows indicate the direction of movement through the membrane channel For clarity, only half the P-glycoprotein tandem duplication is shown In keeping with known channel-forming proteins[12], several P-glycoprotein molecules may be required to form this channel

resistance based on their ability to inhibit haemolysin export In a similar manner, it may be possible to screen existing and potential anticancer agents for their differential ability to kill haemolytic and non-haemolytic bacteria In this context, it is intriguing that there is a brief report that a nalidixic acid-resistant strain of *E coli* had also become haemolytic[32]

Although we have presented a model for the role of P-glycoprotein overexpression in multidrug resistance, the function of P-glycoprotein in drug-sensitive cells is not clear It may serve to protect cells from low levels of toxic lipophilic compounds and its role in multidrug resistance could simply be an extension of this function in response to increased concentrations of such compounds Alternatively, P-glycoprotein may have a transport function unrelated to multidrug resistance and only upon gross exaggeration of this function (for example by gene amplification) does resistance become apparent If this is the case, then the most likely candidates for transport by P-glycoprotein are, by analogy with haemolysin transport, large proteins One group of potentially haemolysin-like proteins is the pore-forming molecules released by cytotoxic cells such as eosinophils, cytotoxic T lymphocytes and NK-like cells[33,34] These molecules appear to be well conserved, in keeping with the conserved nature of P-glycoprotein

The potential existence of a previously unknown protein-translocation mechanism in eukaryotic cells is perhaps the most important aspect of the homology between P-glycoprotein and the HlyB protein The high degree of conservation of P-glycoprotein suggests this protein plays a fundamental role in mammalian cells As P-glycoprotein appears to be encoded by a multigene family[31], there may be a number of homologous systems, each translocating a different protein or proteins

Supported by the National Cancer Institute (NCI) of Canada and by NIH Grant CA37130 J A E is a recipient of a Medical Research Council (MRC) of Canada Studentship, P F J is an MRC Fellow and K L D is a recipient of an NCI Studentship We thank Dr G Bradley for helpful discussion and Drs D Trichler and S Minkin for advice on cluster analysis

Note added in proof The homology between the binding-protein dependent transport proteins and the HlyB protein has been independently reported[40] The nucleotide-binding region of these proteins also has homology with bacterial proteins involved in cell division[40], nodulation during nitrogen fixation[40] and DNA repair[41]

Clonal, antigen-specific, functionally responsive cell populations have proved critical for the analysis of the activation and regulation of lymphocytes. Such studies with B lymphocytes, the precursors of antibody-secreting cells, are hampered by the difficulty in generating phenotypically mature, antigen-reactive lines from defined cell populations. One method is to use acutely transforming retroviruses, which can transform B-lineage lymphocytes *in vitro*. However, Abelson murine leukaemia virus (A-MuLV) infection of murine bone marrow cells *in vitro* yields mostly immature B-cell lines[1–5], and infection of murine bone marrow cells with murine sarcoma viruses carrying *ras* related genes produces only immature lymphoid cell lines[6]. Retroviruses which contain *ras* can immortalize nonlymphoid cells without causing loss of mature phenotypic characteristics[7]. We used *ras*-containing Kirsten sarcoma virus (KiSV) pseudotyped with an amphotropic MuLV helper virus, to infect a purified population of mature, hapten-binding murine splenic B lymphocytes, aiming to generate mature B-cell lines to use as models for the study of B-cell growth and differentiation physiology. Immortalized B-cell lines which retain the same mature phenotype as the starting population, including hapten-specific binding, were produced. This is the first demonstration of a method for immortalizing selected antigen-binding B lymphocytes, and the first example of immortalization of mature B cells *in vitro* with an acutely transforming *ras*-containing retrovirus.

In most reported studies of retroviral transformation of B-lineage lymphocytes *in vitro*, the starting cell populations are heterogeneous, immature haematopoietic precursors With suitable manipulation of culture conditions, surface immunoglobulin positive lines are obtained[3] A-MuLV infection of clonal pre-B cells gives rise to B-cell lines which express surface immunoglobulin[4] These transformed lines are of unknown antigen specificity and are often autonomously growing and tumorigenic, or depend on nonphysiological stimuli such as high concentrations of lipopolysaccharide for continued growth[5] We infected mature B lymphocytes, selected on the basis of antigen-specific receptor expression, with an acutely transforming retrovirus To maximize the efficiency of infection of such phenotypically differentiated cells, we used viral pseudotypes composed of the transforming retrovirus and an amphotropic helper virus We isolated 2,4,6-trinitrophenol (TNP)-binding B cells (TNP-B cells) from the spleens of unimmunized (C3H × DBA/2)F$_1$ (C3D2F$_1$) mice by binding to and elution from TNP-gelatin plates This method normally enriches TNP-specific plaque-forming cells 50-100-fold and 50-90% of the cells form rosettes with TNP-modified sheep red blood cells[8] KiSV pseudotyped with amphotropic (virus 4070) or ecotropic (Moloney MuLV) helper virus was propagated in BALB/c 3T3 cells (BALB/3T3), as previously described[7] We used an amphotropic helper virus because acute transforming viruses tend to infect and immortalize only immature stem cells because of a limitation of target cell host range and this may be overcome using a helper virus with a broad range of cell/tissue infectivity[7,9,10] TNP-B cells were cocultivated with lethally irradiated BALB/3T3 cells producing amphotropic pseudotyped KiSV (KiSV-ampho) in microwell culture plates Growing colonies of lymphoblastoid cells were found in 6-25% of wells in 1-3 weeks (Table 1) Between 12-26% of wells gave rise to colonies in different experiments, consistent with each colony being clonal in origin by Poisson statistical analysis Assuming that the colonies of proliferating cells in each well were clonal, the efficiency of outgrowth of colonies was from 3×10^{-6} to $1\ 2 \times 10^{-5}$ Long-term cell lines were established from these colonies and have been growing continuously for 13 months The characteristics of two of these lines are described below No lymphoblastoid colonies were observed in cocultivations of TNP-B cells with BALB/3T3 cells producing ampho-MuLV

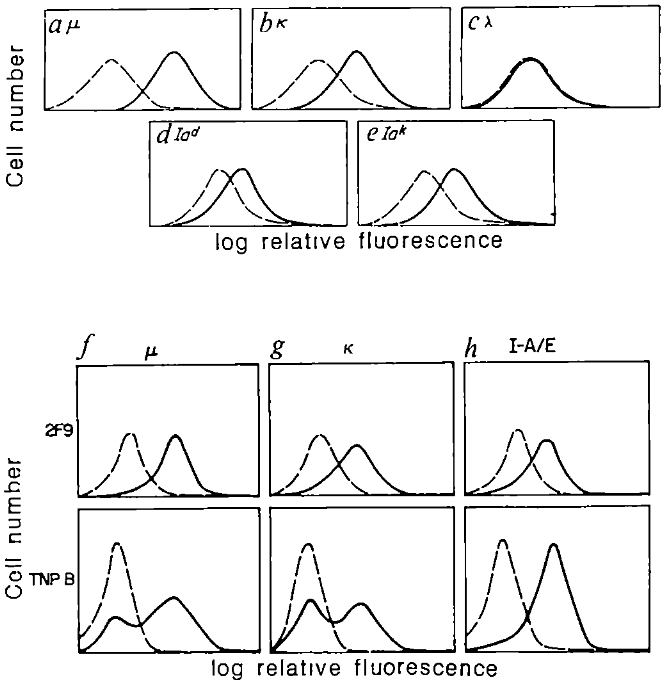

Fig 1 Surface immunoglobulin and Ia expression on a KiSV-immortalized B-cell line *a–e*, 2F9 cells were incubated with hybridoma supernatants specific for *a*, IgM (Bet 2) (ref 12), *b*, Ig κ light chain (187 1) (ref 13), *c*, Ig λ light chain (4/101) (from T Imanishi-Kari, MIT), *d*, I-A^d (MKD6) (ref 14), *e*, or I-A^k (10 2 16) (ref 15), for 30 min at 0 °C, followed by fluorescein-conjugated mouse anti-rat κ (FITC-MAR 18 5, Becton-Dickinson) (*a–c*), or fluorescein-conjugated goat anti-mouse IgG (*d*, *e*) for 30 min at 0 °C, *f–h*, 2F9 and freshly isolated C3D2F$_1$ TNP-binding B cells were incubated with Bet 2, 187 1 or M5/114 (rat anti-mouse I-A/E) hybridoma supernatants, followed by FICT MAR 18 5 Stained cells were fixed in 1% paraformaldehyde and examined by flow cytometry (solid traces) Dotted traces, nonspecific fluorescence (identical samples incubated with fluorescein-conjugated reagents alone) Note that 2F9 and TNP-B cells show comparable intensities of fluorescence, but the 2F9 cells are significantly larger (average diameter 12 5 μm compared to 6 4 μm for normal B cells) and, therefore, express IgM, κ and I-A/E at significantly lower densities Also, approximately 65% of the TNP-B cells are IgM, κ$^+$ (but 100% are Ia$^+$)—this may be due to immunoglobulin modulation during affinity purification or presence of Ia$^+$ non-B cells in this population

alone, or with uninfected BALB/3T3 cells TNP-B cells were also cocultivated with BALB/3T3 cells producing KiSV with Moloney-MuLV helper virus The titres of sarcoma virus produced by KiSV (ampho)- or KiSV (Moloney)-infected BALB/3T3 cells were similar, at approximately 5×10^7 focus forming units per ml In the cultures with KiSV (Moloney) 10% of wells showed colony growth, but no lines could be established from such colonies No viable cells could be recovered from cultures of TNP-B cells alone after 1 week

Two cell lines derived from KiSV infection of TNP-B cells (2F9 and 6H3) have been extensively characterized These lines have doubling times of 24 and 6–12 h, respectively, and grow as nonadherent cells in liquid culture medium with 10 or 20% fetal bovine serum and $2\ 5\times10^{-5}$ M 2-mercaptoethanol The phenotype of these cells was analysed by fluorescence-flow cytometry Both 2F9 and 6H3 express surface IgM with κ light chain (Fig 1*a*) In addition, they both express Ia determinants of the H-2^k and H-2^d haplotypes (Fig 1*a*) Compared to purified C3D2F$_1$ TNP-binding B cells, the KiSV-immortalized lines express lower densities of surface IgM and I-A/E determinants (Fig 1*b*)

The hapten specificity of 2F9 and 6H3 has been analysed by two methods First, up to 25% of these cells form rosettes with TNP-modified sheep erythrocytes (TNP-SRBC) Such rosette assays depend on the amount of hapten bound to the SRBC and the avidity of the surface receptors for the hapten (A K A , unpublished data) It is therefore not surprising that only a fraction of the cells formed rosettes No rosettes are seen in suspensions of these KiSV-immortalized B cells with unmodified sheep red blood cells, nor in suspensions of non-TNP-specific lines (such as the murine B-cell lymphoma A20) and TNP-SRBC (data not shown) The specificity of rosette formation was confirmed in inhibition assays using 2,4-dinitrophenyl (DNP)-lysine Inhibition of rosetting is 50% at a concentration of 6×10^{-6} M DNP-lysine with normal C3D2F$_1$ TNP-B cells and at $1\ 6\times10^{-5}$ M with the 2F9 line This suggests that 2F9 is an immortalized B cell whose receptors are of relatively low affinity, the population of normal hapten-binding B lymphocytes is heterogeneous Hapten binding was also analysed by flow cytometry Both 2F9 and 6H3 preferentially bind TNP-modified human serum albumin (TNP-HSA) over unmodified HSA, while a control BALB/c B lymphoma (A20 2J) that is not specific for TNP, shows no such preference (Fig 2) Thus the hapten specificity of the original uninfected B cells is retained in the immortalized lines

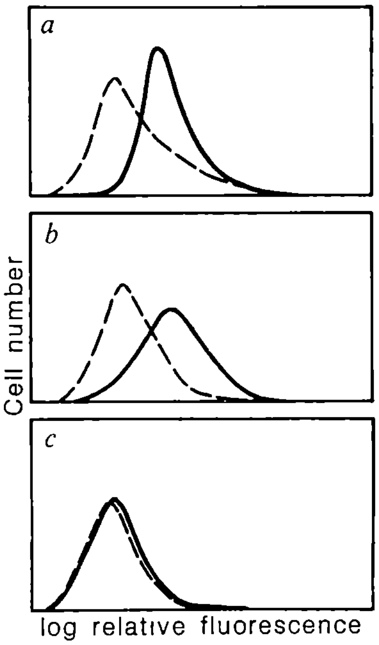

Fig 2 TNP-HSA binding to KiSV-immortalized B-cell lines Cells from the KiSV-immortalized B-cell lines 2F9 and 6H3 (*a*, *b*), and *c*, the murine B-cell lymphoma (ref 8) were incubated with dotted line, 20 μg ml^{-1} human serum albumin (HSA), solid line, TNP-conjugated HSA (TNP-HSA), for 30 min at 0 °C, followed by fluorescein-conjugated goat anti-HSA for 30 min, 0 °C Paraformaldehyde-fixed cells were then analysed by flow cytometry

Viral gene expression in the KiSV-immortalized B-cell lines was assayed by probing for viral transcripts Cytoplasmic RNA prepared from these cell lines was analysed for the presence of Ki-*ras* homologous RNA by dot blot hybridization using a v-*ras* probe derived from KiSV Significant levels were found in both 2F9 and 6H3 (Fig 3) Low or undetectable levels of v-*ras* RNA were present in other murine lymphoblastoid lines (for instance A20 2J) and in normal splenic TNP-B cells (Fig 3) Cytoplasmic RNA dot blot hybridizations using an amphotropic-MuLV *env* specific probe[7] also indicated a high level of MuLV-specific RNA in 2F9 and 6H3 (not shown) Thus, transcripts from both the helper virus and the sarcoma virus are present in the KiSV-immortalized lines Pelletable reverse transcriptase activity was measured in ultracentrifuged culture supernatants, by a standard technique in which [^{32}P]dTTP is incorporated into DNA using

Table 1 Generation of lymphoblastoid colonies by cocultivation of murine splenic B cells with virus-producing BALB/3T3 cells

Splenic B-cell target population	Virus (helper)	Positive wells	Estimated efficiency
TNP-binding (C3H×DBA/2)F_1	KiSV (ampho-MuLV)	43/250	0 86×10^{-5}
TNP-binding (C3H×DBA/2)F_1	KiSV (Moloney-MuLV)	5/50	0 5×10^{-5}
TNP-binding (C3H×DBA/2)F_1	Ampho-MuLV	0/50	0
TNP-binding (C3H×DBA/2)F_1	None	0/200	0

TNP-binding spleen cells were purified from (C3H×DBA/2)F_1 (C3D2F_1) mice by binding to and elution from TNP-gelatin plates These cells were mixed with γ-irradiated BALB/3T3 cells (10,000 rad) producing Kirsten sarcoma virus pseudotyped with either amphotropic or ecotropic (Moloney) murine leukaemia virus in RPMI 1640 supplemented with 20% fetal bovine serum, 2 0×10^{-5} M 2-mercaptoethanol and 5 μg ml^{-1} polybrene (Sigma) B cells (2×10^{-4}) were plated with 5×10^{-4} BALB/3T3 cells in 200 μl flat bottom microculture wells Cultures were fed with fresh medium every 2-4 days Wells were microscopically assayed for the presence of growing cells The number of microwells with growing lymphoblastoid clusters appearing within 1-6 weeks (positive wells) and the fraction of plated B cells induced to grow out into colonies, assuming a clonal origin of these colonies (estimated efficiency), are given Control cultures were plated with either no BALB/3T3 cells, or BALB/3T3 cells producing amphotropic MuLV alone The data are pooled from three separate experiments

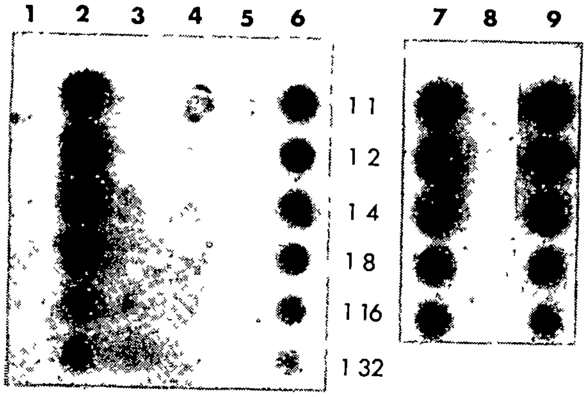

Fig. 3 RNA dot blot analysis of B-cell lines for Ki-*ras* specific RNA Ki-*ras* homologous cytoplasmic RNA was analysed in lanes 1 and 8, Abelson-MuLV-immortalized B-cell lines 1D12 and 12E11 (respectively), lanes 2 and 7, KiSV-immortalized B-cell lines 2F9 and 6H3 (respectively), lane 3, normal murine splenic B cells, lane 4, the murine B-cell lymphoma A20 2J, lane 5, Abelson-MuLV (amphotropic MuLV)-producing BALB/3T3 cells, lanes 6 and 9, KiSV (amphotropic-MuLV)-producing BALB/3T3 cells Cytoplasmic RNA was prepared from 4×10^6 cells of each type by NP-40 lysis and denatured in 5% formaldehyde at 55 °C for 15 min Samples were serially 2-fold diluted and blotted onto nitrocellulose with a vacuum manifold (Schleicher & Schuell) Blots were baked at 80 °C for 1 h under vacuum and hybridized to a ^{32}P-labelled Ki-*ras* specific probe (the 600 base-pair *SstII*/*HindII* fragment from KiSV) (ref 7) in 10% dextran, 5×SSC, at 42 °C, for 18 h The final washes of the blots were in 0 2×SSC at 50 °C Autoradiography was carried out at −80 °C for 18 h using intensifying screens[7,16]

a poly(A) template and trichloroacetic acid precipitable radioactivity is measured[17] Supernatant from cultures of 2F9 (10 ml) yielded 8,110 counts per minute (c p m) in this assay, compared to 677 c p m from an uninfected BALB/3T3 culture supernatant, and 128,761 c p m from the culture supernatant of a Mo-MuLV-producing BALB/3T3 line Thus 2F9 produces low levels of viral particles

We have shown here that introduction of the v-*ras* oncogene into mature B lymphocytes by retroviral infection can immortalize them This is the first demonstration of *ras*-induced immortalization of mature lymphocytes *in vitro* and it is likely that the use of an amphotropic helper virus was important to our success KiSV pseudotyped with an ecotropic helper (Moloney-MuLV) generated a few lymphoblastoid colonies none of which could be established as permanent lines (Table 1) The amphotropic envelope allows infection of cells that do not express membrane receptors for ecotropic viral envelope glycoproteins[9,10] The same approach has been used to immortalize differentiated human umbilical vein endothelial cells[7], and to infect mature helper T-cell lines *in vitro*[11] Mature B cells may have few or no functional receptors for ecotropic retroviruses, but do have amphotropic retroviral receptors

The cell lines described here retain their mature phenotype, and preliminary functional studies indicate that they can be further mitotically stimulated by reagents which stimulate normal B cells, particularly the helper T-cell-derived lymphokine, B-cell stimulatory factor 1 (data not shown) These cells do not secrete immunoglobulin constitutively, we are attempting to induce increases in immunoglobulin gene transcription, biosynthesis and/or secretion with activating stimuli, including lymphokines The technique of infecting purified, functionally well-defined lymphocyte populations with acute transforming retroviruses will be useful for the development of model systems to study lymphocyte physiology as well as the role of oncogene expression in lymphocyte growth deregulation

In this letter, the metal atoms in the Fig 1 legend were incorrectly defined They should read ●, Mo, ○, Ru, ⊜, Se

Stratigraphic record of earthquake incidence

CISNE[1] uses the Lofer cycles of the late Triassic Dachstein Formation (Northern Limestone Alps, Austria and Germany) as an illustration of how stratigraphy may record histories of stick-slip movement and thereby of earthquake incidence along fault zones As the discoverer of the emergence-submergence oscillations of the Lofer cycles, which I attributed to a sea-level oscillation[2], I am very interested in Cisne's alternative tectonic way of producing periodic emergence of a platform margin His model explains why the signs of emergence (microkarst, relict soils) should be restricted to the outer margin of the carbonate platform But it necessitates some revision of current sedimentological and/or tectonic concepts

It is necessary first of all to place these Triassic terranes into tectonic context They are now part of the giant Oberostalpin ('upper Austride') klippe that extends for 450 km, from the Swiss border to Vienna, in itself a patchwork of thrust sheets and klippen of various facies, complicated by high-angle faults, and developed in a complex and controversial history[3-7]

In Triassic time, the terrane was part of a tectonic trough, filled in the north with Triassic platform carbonates, while the southern part was open and accumulated the thin pelagic-hemipelagic Hallstatt beds[5]

In several places, the toe of the reef complexes interfingers with ammonite-bearing, pink or greenish calcilutites of Hallstatt type However, the bulk of the Hallstatt deep-water rocks are now found as discreet klippen masses emplaced on top of the platform facies and its deeper Jurassic/early Cretaceous cover

Cisne's stick-slip fault would have defined the southeastern margin of the platform, separating it from the Hallstatt facies It would have added to regional subsidence an additional component, either on the platform or on the Hallstatt side Throwing the Hallstatt side down, relative to the platform, accelerates the subsidence of the platform margin during the 'stick' phase, leading through intertidal into subtidal conditions The slip phase allows this margin to snap back into emergence, followed by truncation, and resubmergence in the next stick episode In the alternative case, throwing the platform down slows the platform margin's subsidence during the stick phase, and sedimentation leads to progressive shoaling, then the margin snaps down in the slip phase Thus, the Hallstatt-down model leads to upward deepening cycles, the platform-down model to upward shoaling cycles One of the most distinctive characteristics of the Lofer cycles is their generally upward-deepening character, which has seemed unusual to students of carbonate platforms If these cycles were caused by stick-slip faulting, then the motion was down on the Hallstatt side

It is here that difficulties develop If the Hallstatt basin underwent more subsidence than the platform, it must have subsided by more than the thickness of Norian platform sediments (some 1 5 km) during Norian time Since the Norian of the Hallstatt facies probably does not exceed a thickness of 150 m, the late Norian calls for a water depth of 1 5-2 km This depth is about the limit to which pelagic aragonite shells persist on the present sea floor (the aragonite compensation depth) It seems that modern compensation depths go back to the dramatic rise in plankton carbonate productivity in late Jurassic time[8] earlier carbonate compensation depths lay at far shoaler levels Thus, conventional wisdom assigns the Hallstatt carbonates with their ammonites to water depths of several hundred metres, not the required 2 km

I can think of three possible ways to escape this dilemma—all of which would require revision of current concepts One is that the oceans of the Triassic were saturated with calcium carbonate to much greater depths than those of the Jurassic, allowing preservation of aragonitic shells at depths of 1 5-2 km

A second possibility is that the Hallstatt basin was oceanic, a Triassic antecedent of the Jurassic (Pennine) ocean strip, and that most of the Hallstatt beds were seamount deposits, scraped off during southward subduction of that oceanic basin, and emplaced over the margin of the platform as it began to be subducted in mid-Cretaceous time

The third possibility is that the basin fronting the Loferite cycles was deep The Hallstatt beds were deposited in a shoaler part of the trough, to the west The Hallstatt facies was first brought to the longitude of the Lofer cycles by sinistral strike-slip displacements, probably in the mid-Jurassic when the Lammer-Torrenn zone underwent tens of kilometres of sinistral motion[5], and were then emplaced by Juvavian (mid-Cretaceous) thrusting

My preference is for the second of these models, which implies an 'accreted prism' origin for the entire stack of Alpine sediments

Primary structure of the histidine-rich protein of *Plasmodium lophurae*

SIR—We wish to address the literature concerning the sequence of the histidine-rich protein (HRP) and the corresponding gene from the avian malaria parasite *Plasmodium lophurae* Following publication of a DNA sequence derived from a *P lophurae* genomic clone[1], we were forced to reassess our own data, which differed extensively from the 3′ half of the published coding sequence Our results were derived from the complementary DNA clones[2] that were used to isolate the genomic clone A corrigendum to the genomic sequence was published[3], in the revised sequence, 120 base pairs (bp) were deleted and 90 bp were inserted Our analyses[4] independently suggested that the published genomic sequence contained an insertion and a deletion, each of about 120 bp, together with a region of about 100 bp containing multiple insertions of one or two bp in the genomic sequence The region of the genomic sequence between the insertion and deletion sites was not revised[3] There is a significant difference in the amino acid compositions predicted by the two sequences, the most extreme being a fourfold difference in phenylalanine content

What then are the most probable structures of the HRP and its gene? Making the assumptions that the published 5′ DNA sequence[1] and corrections[3] to the numbers of downstream repeats not covered by the cDNA sequence are correct and that the 3′ sequence from the cDNA[4] should take preference, a composite sequence can be constructed The mature HRP (289 amino acids) predicted by this sequence has a molecular weight of 37,109 and contains 71 3% histidine, 7 2% proline, 7 0% alanine, 6 2% glutamic acid and smaller amounts of eight other amino acids This composition is consistent with three independent determinations of the composition of purified HRP (cited in ref 4)

This new peer-reviewed, interdisciplinary journal from The Endocrine Society supplies a forum for the increasing number of scientists working on the molecular mechanisms of hormone action **MOLECULAR ENDOCRINOLOGY** publishes the best original articles on molecular mechanisms of cellular regulation, including studies involving the investigation of cloned genes and gene fragments relevant to hormone action, receptor and second messenger systems at the molecular level, and closely related areas such as lymphokines and oncogenes Other areas include

- autocrine controls
- genetic engineering
- structural organization of genes
- cell cycle
- regulation of gene expression
- excitable membrane channels
- control of cell motility
- chromatin & nuclear scaffold

JOURNALS FROM MACMILLAN

☐ ANTI-CANCER DRUG DESIGN *(Quarterly)*

Editors: S. Neidle S T Crooke S. Tsukagoshi

The development of new clinically-useful anti-cancer agents is increasingly dependent on rational scientific principles drawn from a wide range of disciplines This new journal aims to promote such approaches, providing a common meeting ground for medicinal chemists, pharmacologists, biochemists, biophysicists and oncologists involved in both fundamental and clinically orientated aspects

This journal is published with the support of The Cancer Research Campaign

Reader Service No 80

☐ BONE MARROW TRANSPLANTATION

(Quarterly)

Editor: J. M. Goldman
Co-Editor: R. P. Gale

A new journal which publishes clinical results in man and experimental results with animals, allografting and autografting, HLA and other methods of selecting donors, graft-versus-host disease and all types of methods to prevent and treat it, and much more

NEW JOURNAL FIRST ISSUE PUBLISHED MAY 1986

Reader Service No 81

☐ BRITISH JOURNAL OF CANCER *(Monthly)*

The Journal of the Cancer Research Campaign

Chairman: D. G Harnden Editor: M Moore

One of the leading cancer journals in the world publishing articles on all the major scientific disciplines

Publishes papers from researchers throughout the world and the proceedings of meetings of the British Association for Cancer Research and other symposia

Reader Service No 82

☐ HUMAN TOXICOLOGY

(Bi-monthly)

Secretary to the Editorial Board: P. Turner

Covers all aspects of human toxicology embracing both animal research with direct relevance to man and studies with humans

* Now in its fifth year, *Human Toxicology* publishes all the up-to-date information in this rapidly expanding field

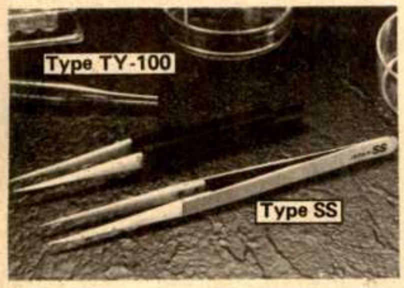
NEW CERAMICS PRECISION:
FUNA-TWEEZERS



"FUNA-TWEEZERS" can eliminate all demerits of stainless or plastic tweezers. The stainless stems of Type SS and the Derlin stems with glass reinforcing agent of Type TY-100 give appropriate elasticity.

These show excellent features such as high anti-corrosiveness, heat insulation, high flame resistance, etc. These are also free from plastic deformation, metallic contamination and magnetization, etc.

These tweezers are contributing to the industries and research such as Biotechnology, Electronics, etc.

Quantitative receptor autoradiography

M.D. Hall, A.P. Davenport & C.R. Clark

Quantifying receptor autoradiography is a useful tool, and one becoming increasingly popular, but potential errors exist in the interpretation of results.

RECEPTOR binding studies are powerful weapons in the neurochemist's armamentarium, their present application being predominantly in basic neurochemical research, drug discovery programmes and toxicology studies. Recently their status has been elevated by the increasing sophistication of receptor autoradiography. The predominant advantage of this technique over conventional homogenate-based binding assays is enhanced anatomical resolution combined with an increased sensitivity that is reported to be four to five orders of magnitude greater than "grind and bind" assays[1]. The additional advantage of autoradiography is that the distribution of binding sites, revealed as patterns of radioactivity, can be related to detailed structures in the specimen[1].

Here we highlight the dilemma associated with the standardization of receptor autoradiograms, and pinpoint potential errors in the associated calculations.

The technique

Receptor binding to slide-mounted tissue sections is performed essentially in the same way as homogenate-based assays. Sample sections 10 μm thick are mounted onto microscope slides, incubated with radioligand, washed and then dried. Receptor autoradiograms are produced by tightly apposing the tissue to either emulsion-coated coverslips or commercial radioisotopic-sensitive film. Following exposure and development, binding sites are visualized as silver grains in nuclear emulsions or as gray images on autoradiographic film.

Examination of autoradiographic images on emulsion-coated coverslips is facilitated by dark-field microscopy, where the silver grains appear white on a dark background. This technique gives better resolution than film autoradiography because the crystal diameter of the emulsion is smaller than that used to coat films. However, this method is capricious and quantification of silver grains is time-consuming; achieved by literally counting the number of grains per unit area. In contrast, film-based receptor autoradiography is comparatively easy to perform, and allows up to 60 microscope slides to be processed simultaneously. An example of film-based receptor autoradiography is shown in Fig. 1. In film autoradiography the gray levels associated with receptor localization can be readily converted into optical densities using an image analysis system, to allow quantification. The main disadvantage of film compared to the coverslip technique is that the tissue sections are not attached permanently to the autoradiographic image, making the identification of discretely labelled regions more difficult.

Until recently, a serious disadvantage of autoradiography compared to homogenate-based assays was that it was only quantitative. In 1981, the use of calibrated radioactive standards that were co-exposed with the tissue sections under study was introduced[4]. Two types of standards are currently used. The first is commercially available, and consists of increasing quantities of [^{3}H] or [^{14}C] embedded in blocks of polymethylmethacrylate. Alternatively, standards can be prepared[5] in the laboratory by mixing increasing quantities of radionuclide with a tissue paste prepared from the same tissues as those used in the receptor assay. For the assay, a set of calibrated standards (polymer or tissue paste) are cut at the same thickness as tissue sections and are developed alongside the tissue sections. Thus optical densities can be converted into molar quantities of receptor-bound radioligand by comparing the optical density of the tissue sample to the known standard. Figure 2 shows a photograph of a series of [^{125}I] brain paste standards exposed to Ultrofilm for 10 days (*a*) together with a natural log plot (*b*) of optical density versus radioactivity contained within each standard section.

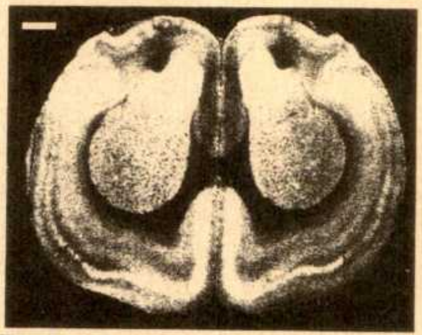

Fig. 1 *a*, An autoradiograph demonstrating film-based receptor autoradiography for the binding of cholecystokinin in rat brain.

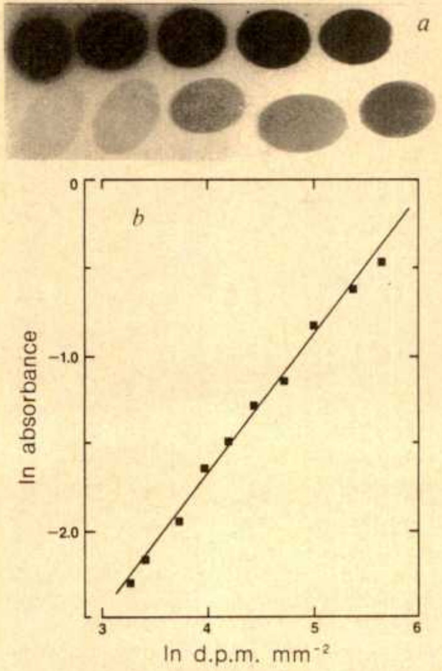

Fig. 2 *a*, Photograph of an autoradiographic image for a series of calibrated [^{125}I] brain paste standards. *b*, A natural logarithmic plot of optical density vs. radioactivity per mm^2 for the series of [^{125}I] brain paste standards[5] in *a*.

Dilemmas of standardization

A major consideration when using [^{3}H] standards is quenching, or the absorption of the low energy β-particles by the medium before they can reach the photographic emulsion. The generation of tissue paste standards is an attempt to circumvent this problem since it is reasoned that the degree of β-particle absorption in tissue paste is the same as that occurring within tissue sections. However, this does not completely overcome the problem, because the degree of quenching of [^{3}H] may differ within tissue types. Absorption in tissues from the central nervous system, for example, has been demonstrated to be different in gray and white matter[6], and methods for coping with this regional absorption have been discussed[7]. In contrast, self-absorption of β-particles from [^{125}I] has been shown in central nervous system tissues to be less significant because [^{125}I] emits electrons of higher energies than [^{3}H]. Since [^{125}I] polymer-based standards are not yet available, tissue paste standards represent the only way of quantifying receptor autoradiograms in molar terms using [^{125}I].

A second problem concerning the standardization of receptor autoradiograms using any radioisotope concerns the frequent, but incorrect interchange of two unrelated terms, "molar quantities of receptor bound ligand per mg of tissue protein" and "molar quantities per mg of standard protein". These are not synonymous, because the protein concentration of tissue paste may not be the same as that of the tissue under investigation. We therefore recommend adoption of the term dpm mm^{-2}, which can be converted into molar quantities per surface area[5] since the absolute values for amount of radioactivity, surface area and optical density can be readily obtained from standard sections.

Recently, a further problem concerning standardization has been encountered, during the conversion of dpm mm^{-2} to fmoles bound mm^{-2}. When using [^{3}H] labelled material the potential error is negligible because this isotope has a long half-life of 12.35 years. In contrast, the relatively short 60-day half-life of [^{125}I] necessitates the regular production of tissue paste standards. In practice, these [^{125}I] standards are not prepared at the same time as the binding assay, and are used repeatedly over two half-lives. Calculation errors result when the specific activity of the standard instead of the specific activity of the radiolabel used in the binding assay is used to make the conversion of dpm into fmoles. Depending upon the relative age (or decay) of tissue paste standards compared to the radiolabel used in the assay, up to two-fold under- or overestimations of specific binding can occur, and this might have contributed to the considerable differences reported between laboratories of values for fmoles of radioligand bound per unit area.

Future potential

Considerable advances have been made in the standardization and quantification of autoradiograms over the past five years. To further improve the technique, the anatomical resolution could be greatly enhanced if the crystal diameter of the emulsion used to make the films was reduced significantly. Theoretically, the sensitivity of the emulsion would also be reduced, but this could be overcome by increasing the time of apposition. The development of three-dimensional image analysis of receptor autoradiograms is inevitable with the rapidly increasing capacities of new computer systems, and this will definitely expand the range of possibilities for the applications of receptor autoradiography.

Martin Hall and Anthony Davenport are at the Parke–Davis Research Unit, Addenbrooke's Hospital Site, Hills Road, Cambridge CB2 2QB, UK, and Colin Clark is at the Pharmaceutical Research Division, Warner Lambert Co., 2800 Plymouth Road, Ann Arbor, Michigan 48105, USA.

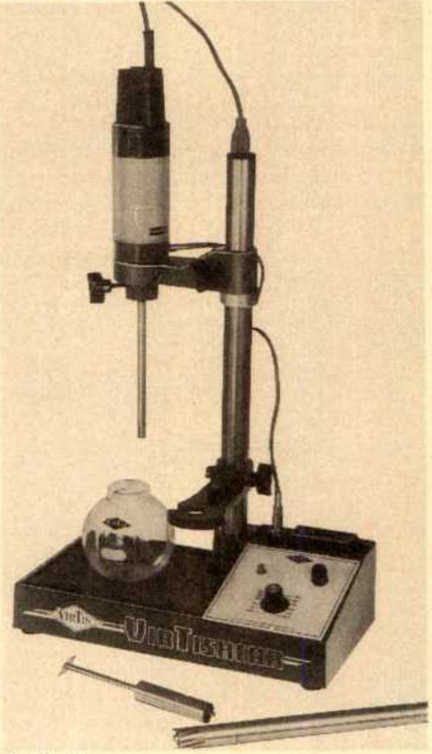
International exhibits

Highlights from the Salon du Laboratoire and Interchemie '86 in Paris, and from the American Society for Cell Biology meeting in Washington, DC

PROMEGA'S X-Cell **electroporation systems** are designed for plant cell, mammalian, and bacterial electroporation (Reader Service No. 100). The $4,950 (US) X-Cell 450 provides a variety of parameter combinations, with a voltage range of 0–450, and a capacitance of 50–1,550 µF, used for mammalian and plant cells, while the $3,950 (US) X-Cell 2000 provides higher voltages (0–2,000 volts, 5,000 optional) and lower capacitance (14 µF; suitable for mammalian and bacterial cell electroporation. Both systems employ disposable cuvettes. Promega will be in booths 925 and 927 at the American Society for Cell Biology meeting.

VirTis now offers a **mechanical tissue homogenizer**, designed for the rapid dispersion, emulsification and homogenization of solids, biological tissue and liquids (Reader Service No. 101). The $895 (US) VirTishear can accommodate both open-blade and rotor/stator assemblies (sold separately), and all shafts can be removed for cleaning and autoclaving. The interchangeable shafts allow the operator to process samples from 0.5 ml to 2,000 ml, and standard and specialized accessory glassware is available. For reproducible results. VirTis provides an optional panel-mounted digital speed indicator. Inquire about the VirTishear and other VirTis products at booths 524 and 526 at the American Society for Cell Biology meeting.



Really churns up a culture

Controlling the temperature of samples immersed in a water bath is often critical for reaction studies. Gallenkamp is distributing a new control head by Haake that sets out to make **temperature regulation** easier (Reader Service No. 102). The Haake F3 control head monitors the temperature of the sample directly from a pt100 sensor positioned in the sample. Temperature controllers are available for a wide range of Haake baths for temperatures between — 100 °C and 250 °C, and can be coupled to accessory programmers or computers. Haake's products will be at the Salon du Laboratoire.

Alfa-Laval has been in the fermentation business for a long time, and provides equipment scaled down for the research laboratory, as well as larger setups for industry (Reader Service No. 103). In addition to fermenters, Alfa-Laval has created a **vertical stirrer**, the Vibro-Mixer. The stirrer consists of horizontal plates with vertical cone-shaped nozzles, and as the stirrer moves up and down, liquid is pumped through the cones by the venturi effect. Alfa-Laval says it is ideal for mixing protein solutions that must not be subjected to shear. The laboratory-sized 4-litre E-1 model has a sterile seal, and starts around £500. Interchemie will have an exhibit by Alfa-Laval.

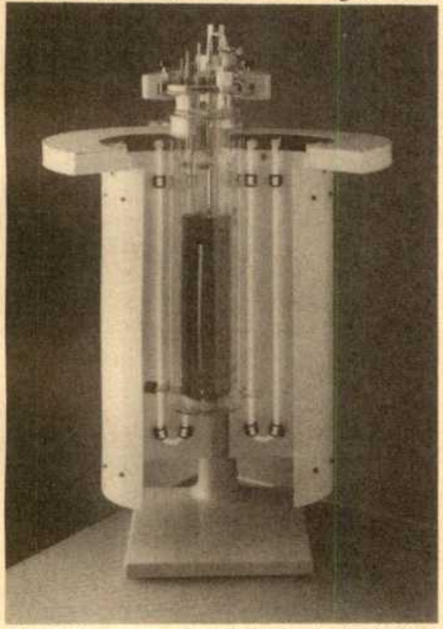
Growth enhancers

Amgen Biologicals is bringing a host of new **recombinant growth factors** to market (Reader Service No. 104). Platelet derived growth factor, the principal mitogen responsible for the growth of many serum-dependent cell cultures of mesenchymal origin, is prepared from a eukaryotic recombinant DNA host harbouring the *v-sis* gene from simian sarcoma virus. Although it differs from the cellular peptide in four amino acids, it has the same spectrum and potency of biological activity, according to Amgen. Also produced by Amgen is a potent mitogen for vascular endothelial cells and other cells of mesodermal and neuroectodermal origin, basic fibroblast growth factor, for the maintenance of cultures requiring serum-free media preparations. A newly cloned granulocyte colony stimulating factor is offered for research investigating the maturation of neutrophils and the activation of granulocyte-mediated immune responses, and tumour necrosis factor is available, shown to have tumoricidal activity *in vivo*. The growth factors are sold as 5–100 μg samples ranging in price from $225 to $775 (US). Amgen will be exhibiting at the convention of the American Society for Cell Biology in booths 19–21.

For the **radioimmunoassay of growth factors**, Amersham has launched a new line of reagent packs (Reader Service No. 105). The kits for IL-2 and IGF-1 contain one iodinated tracer, matched antisera, a buffer formulated for use in Amersham's Amerlex-M magnetic separation system and a protocol booklet. Ask about this and other Amersham products at its booth at the Salon du Laboratoire and in booth 1018 at the American Society for Cell Biology meeting.

Cell specifics

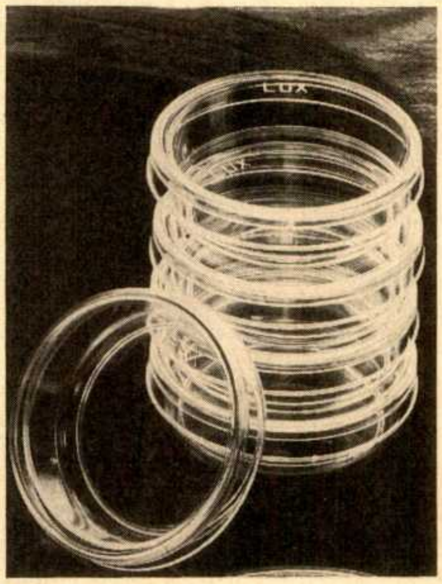
For the **cultivation of photosynthetic organisms**, LH Fermentation Ltd makes a light bank for the LH500 series of airlift fermenters (Reader Service No. 106). The light bank is mounted on the pillar of the airlift fermenter stand, and fully encircles the fermenter with light. The £1,329 (UK) light bank consists of two semicircular halves, each containing three U-shaped fluorescent lamps, that open to allow access to the fermentation vessel. The intensity of illumination can be varied to accommodate the needs of different cells. See LH Fermentation's products at the Interchemie Exhibition.



The LH Fermentation light bank sheds light upon photosynthetic cell cultures, stimulating their growth.

To sterilize complex culture media without autoclaving, Gelman Sciences, Ltd produces a disposable, **ready-to-use capsule filter** (Reader Service No. 107). The presterilized capsule incorporates a double layer 0.2 μm low-protein binding HT Tuffryn membrane that sterilizes up to 10 litres of serum-free media. The capsules cost £10 each. A selection of Gelman Sciences' other cell culture products will be on display in booth 514 at the American Society for Cell Biology meeting.

The Permanox **tissue culture dishes** developed by Miles Laboratories are formulated to transmit extremely low levels of molecular oxygen, thereby facilitating the anoxic growth of cancer cells for research purposes (Reader Service No. 108). The non-styrene material is also highly resistant to chemicals such as acetone and propylene oxide, so cultures may be grown, fixed and embedded for electron microscopy in the same dish. The Permanox products are a 35 × 10 mm dish, a 60 × 15 mm dish, and a 25 × 76 mm slide. The new 35 × 10 mm dishes are sold for $189 (US) in lots of 500. Miles Laboratories will be exhibiting at the Salon du Laboratoire, and at booth number 623 at the American Society for Cell Biology convention.



Grow, fix and embed for electron microscopy all in one oxygen-free dish

Uniscience, Ltd. is now distributing Wheaton's **roller culture apparatus** (Reader Service No. 109). Wheaton's modular cell production apparatus is designed for the large-scale propagation of monolayer cell cultures, and up to eight decks, holding five bottles each, may be added to the base unit. The £3,600 (UK) roller (including eight decks) features a control unit with a locking shaft, and rotates the bottles at speeds of between 0.125 and 6.9 r.p.m. with an accuracy of ±1%, according to Wheaton. See Wheaton's other wares at their booth at the Salon du Laboratoire, and at booths 610 and 612 at the American Society for Cell Biology meeting.

LIPOSOMES

NEW

REPRODUCIBLE – HOMOGENEOUS – EXTREMELY RAPID

Our new LIPOSOMAT guarantees rapid (5ml within 60 minutes) preparation of uniformly sized unilamellar liposomes. Liposome size is selectable between 25 and ca. 600 nm diameter. Sample volume is normally 5-10ml or up to 200ml if used in combination with an additional instrument. Lipid concentration can be up to 300 mg/ml.

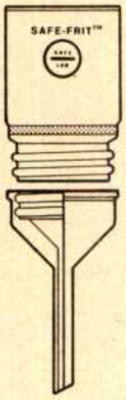
SAFE-FRIT™ FUNNELS



Safe-Lab's NEW fritted glass funnels feature a removable, unbreakable polypropylene stem just below the fritted glass disc. This unique design eliminates the danger of broken glass funnel tips and permits easy cleaning from both sides. Removable stem allows you to set the funnel top on counter or directly inside an oven or desiccator for drying, without the danger of tipping or spilling. Polypropylene has excellent chemical resistance and threads will not leak, even at high-vacuum.

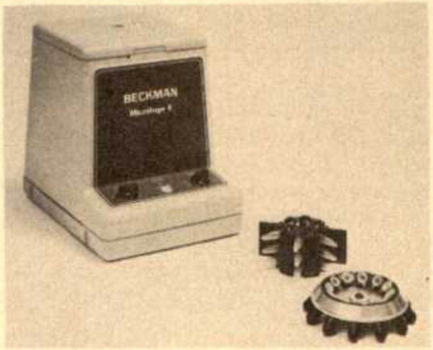
Sample spins

The CT411 **thermostated benchtop centrifuge** sold by Jouan, Inc. has both a refrigeration and a heating unit, with the temperature range 0–60°C (Reader Service No. 110). Jouan says its $5,500 (US) centrifuge can attain a speed of up to 5,840*g* and that its digital readout is accurate to 10 r.p.m. Standard features are a safety lid interlock, a continuously variable braking rate and an imbalance detection and shutdown system. Jouan will have a booth at Salon du Laboratoire.

Spins hot or cold

Beckman sells a miniature **tabletop centrifuge** that it says is ideal for repetitive runs of small biological samples (Reader Service No. 111). The $845 (US) Microfuge E uses either a horizontal rotor ($130 US) capable of speeds of up to 14,500 r.p.m. at forces of up to 13,490*g*, or a fixed angle rotor ($150 US) that runs up to 15,000 rpm at centrifugal forces of up to 15,850*g*. It holds from 12 to 48 microtubes, 250 µl to 1.8 ml in size and has a "momentary" button for one-second spins. Beckman will be displaying its centrifuges at the Salon du Laboratoire and at the American Society for Cell Biology meeting.



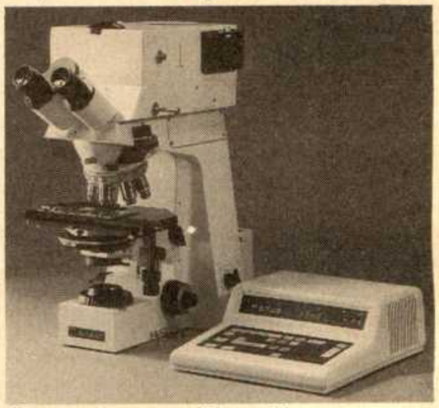
Just the thing for tiny amounts

To make sure the right bottle is being used for the right rotor, Nalgene has compiled a *Centrifuge Tube and Bottle Rotor Matching Guide* (Reader Service No. 112). The free 12-page guide contains tables matching the appropriate Nalgene tube or bottle to the rotors of nine different manufacturers. Tips on sterilization, sealing caps and cap assemblies, and a chemical resistance chart are also included. Nalge has an exhibit at the American Society for Cell Biology meeting, booth 301, and will also be present at Salon du Laboratoire.

Costar's **microcentrifuge filters** can filter volumes of 25 µl to 500 µl with a retained volume of less than 5 µl, according to the manufacturer (Reader Service No. 113). The Spin-X filters are available in two pore sizes, 0.22 µm or 0.45 µm, and several membrane types, including an ultra-low binding cellulose acetate. Costar is in booths 54 and 536 at the American Society for Cell Biology meeting.

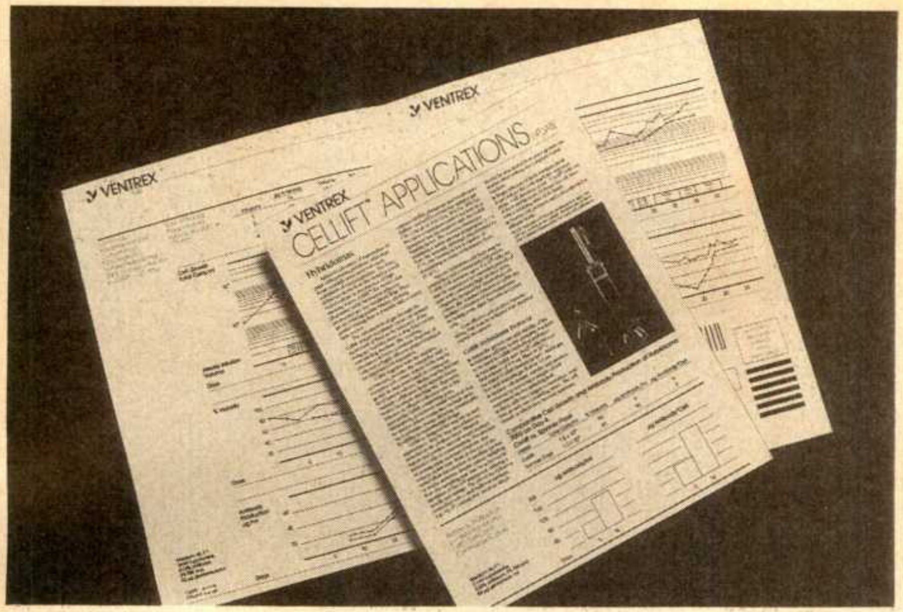
The better to see...

For improved resolution and image quality in **photomicroscopy** with no sacrifice in field of view, Carl Zeiss, Inc. has developed the Axiophot advanced research microscope (Reader Service No. 114). The Axiophot contains ICS (infinity-colour-corrected system) optics to ensure clear, aberration-free images over a 25 mm field, according to Zeiss, and all components are system-integrated (SI Design). The Axiophot has two 35 mm built-in microprocessor-controlled cameras operated with an external keyboard, and carries a $32,000 (US) price tag. Carl Zeiss has an exhibit booth at the Salon du Laboratoire and will be in booths 618–626 at the American Society for Cell Biology meeting.



Captures important slides on film

The PL Fluotar series of **microscope objectives** from Leitz are ideal for fluorescence microscope and interference contrast work, according to the manufacturer (Reader Service No. 115). They offer high near-ultraviolet transmission, minimal autofluorescence and negligible strain, and provide neutral colour reproduction and a field flat to 25 mm. The objectives range in price from £329.50 (UK) for the 6.3× objective, to £348 (UK) for the 25× objective. More information on Leitz's objectives will be available from the Leitz booth at the Salon du Laboratoire, and from booths 1036 and 1038 at the American Society for Cell Biology meeting.



The book with the lowdown on the Ventrex range of airlift fermenters

Lots of literature

A recent release from International Bio-Technologies Ltd, ***Cancer Research News***, outlines the role of extracellular matrix (ECM) in the field of cancer research (Reader Service No. 116). The six-page brochure aims to introduce International Bio-Technologies' line of ECM-coated labware, but also contains several interesting articles on the culture of cancer cells in general. *Cancer Research News* also offers an introduction to International Bio-Technologies' library of other free brochures, on topics ranging from immunology to neurobiology. International Bio-Technologies will have a display in booth 1035 at the American Society for Cell Biology meeting.

Ventrex Laboratories, Inc. will be on hand in booth 806 at the American Society for Cell Biology meeting, and will be able to provide information about ***Cellift Applications Update*** (Reader Service No. 117). This technical publication outlines the procedures for using Ventrex's Cellift disposable airlift bioreactor. Ventrex says Cellift's advantage is the provision of a well-mixed culture in the absence of high shearing forces, and is ideal for the culture of a wide range of cells, from mammalian to yeast.

Free **custom culture optimization** is only one of the services provided by Scott Laboratories (Reader Service No. 118). With the guaranteed purchase of a minimum order of growth media, Scott will work out the optimum growth conditions of a customer's culture, using a client-supplied cell line sample and analysis of spent media. Scott claims a 70 per cent success rate for its service so far, with past results yielding 2–50 fold increases in product. Scott's new catalogue, giving full descriptions of their other services, media, and growth factors, will be on display at booth 330 at the American Society for Cell Biology meeting.

An easy **wall chart reference for the preparation of cell culture media** is available free from Imperial Laboratories, as a product insert (Reader Service No. 119). It gives the formulations of the most commonly used media, including information on reconstitution, and quantities of sodium bicarbonate and L-glutamine required for various media. ☐

These notes are compiled by Carol Ezzell from information provided by the manufacturers. To obtain further details about these products, use the reader service card bound inside the journal. Prices quoted are sometimes nominal and apply only within the country indicated.

ADVERTISEMENTS

LIMUTESTER

(gelation-capillary method)

Precise Detection of Endotoxins

This LIMUTESTER detects Endotoxins promptly, applying to gelation reaction of LAL and a glass capillary.
The LIMUTESTER is simple, economical and usable anywhere, especially needs no endotoxin-free laboratory glass wares.
LIMUTESTER INCUBATOR is available.

Eliminates evaporation loss and contamination. Easy to use – flush with gas mixture, seal, place at appropriate temperature. Stackable, see-through. Quantity discounts. **billups-rothenberg, inc., pob 977, Del Mar, CA USA 92014. Call 619-755-3309 or contact your Flow Laboratories representative.**

Reader Service No.7

Strategy for higher education

Richard Pearson

Modest increases in government spending on universities announced recently do nothing to fulfil the urgent need for a long-term strategy for higher education.

It is now 18 months since the government published its consultative Green Paper on the future of higher education. Since then higher education has staggered on, responding to piecemeal evolution of a policy, which until last month has mainly resulted in a tightening of the financial screw. November saw a slight improvement, however, with a small increase in the universities' budgets as part of the government's boost to public spending. Whether this signals a change of policy is not clear and the government's White Paper on the future of higher education still seems many months away. Higher education will remain in a state of crisis and policy decisions by students and institutions will have to be taken on an *ad hoc* basis until the government sets out a long-term strategy.

Although some academics still fear a threat to academic freedom, it is clearly right that the role and running of a higher education system costing the public purse over £3,500 million each year should be a matter for public debate and scrutiny. But it would be wrong to seek change through a series of partial solutions and short-term actions that cause damage in the long term, while providing no strategic direction for the future. Major unresolved issues include those of student numbers, subject balance, student finance, and academic salaries and resources.

In the past the driving force influencing the size of higher education has been student demand, and particularly the wishes of 18-year-olds. But, with a student population of about 500,000, the United Kingdom has low participation rates in higher education by international standards especially by women in technological subjects, mature entrants and ethnic minorities. The proportion of entrants from working class homes, at under 10 per cent, has barely changed for a decade. Participation by these groups needs to be increased, both for social reasons and to broaden the quality and range of experience in the graduate population which is too narrowly based. Such an increase would counteract the reduced demand for places due to the expected fall in the number of 18-year-olds in the period to 1995. Demand for graduates is now at record levels and expected to increase significantly, and the longer term need is for a better educated and more skilled workforce.

These social and economic objectives of higher education need not be incompatible. For example, the labour market too needs higher education to have a broader base than is provided by simple reliance on vocational subjects, because employers need a broad cross-section of skilled and educated staff. In the vast majority of jobs and careers, indeed there is no close link with degree subject, so that one in three of current vacancies for graduates do not specify a degree subject. This allows flexibility in the provision of courses for the majority of places and responsiveness to student demand and other criteria when planning subject balance. It also allows rebuttal of the complaint that precise manpower planning does not work, because such accuracy is simply not needed.

There is, though, a need to improve the content and quality of many courses to encourage communication skills, team work, numeracy and literacy. In addition a clarification of which are truly vocational courses needs to be undertaken and a better understanding of employers' current and future needs for specialist trained graduates is required.

More students, better salaries to retain and attract good teachers and adequate, up-to-date resources all cost money. They cannot realistically be paid for by savings from a loan scheme to replace student grants. Industrial support by sponsoring students, donating equipment, funding research, paying for visiting lecturers and financing higher academic salaries, all help higher education as well as the recruitment and research of the firms themselves. There are no exact figures on the full extent of direct industrial support, but overall it is probably less than £100 million, or under 3 per cent of the higher education budget. Thus even the expected significant increases over the next decade will not be enough to relieve the burden on the public purse, though it will continue to make a valuable contribution in selected areas. While improvements in efficiency can also undoubtedly be achieved, the necessary improvements in higher education cannot be realized within a reducing budget; public financing has to be increased in real terms, not reduced.

A better way of distributing finite resources may be through the introduction of the two-year general degree, topped up by a two-year specialist degree. The first degree would be available to all; it would offer a broad-based curriculum and would attract a maintenance grant. Student demand could strongly influence subject balance as long as there were some core general subjects which would compensate for any over specialization in the schools. Such degree courses could offer far more flexible entry qualifications, which would allow more mature students and those from less conventional backgrounds to enter higher education.

There would then be a smaller number of places on second degrees which would be more specialized, focusing on particular disciplines. The balance would be determined more by national or occupational criteria, as already happens in subjects such as medicine and architecture, or by the need for advanced study, as is the case for postgraduate courses in the arts and many of the social sciences. These subjects would attract further grants, scholarships or industrial sponsorship in key areas of the labour market and loans could also be available. A critical factor in their implementation would be that all degree courses should follow this pattern — otherwise the new two-year degree courses would be instantly dubbed second class.

Whatever the strategy for higher education — and the options are diverse — there must be a long-term perspective and an improved planning framework, which would require better information about inputs, processes and outcomes. If market forces are to play a key role then participants have to be better informed: students about job prospects to help in the choice of subject and course, institutions about economic needs to tailor a proportion of the courses accordingly, and government in terms of deciding how much money to spend, and where and how to allocate it. All these groups require a better articulation of the longer-term relationship between economic and industrial needs and the provision of higher education, so that priorities can be considered, and flexibility built into the system to cope with uncertainty. The performance of higher education as a whole also requires regular monitoring and policies must respond to changing economic and social needs.

Whatever the complexion of governments in the next decade there is unlikely to be a significant increase in the funding of higher education. Piecemeal policy adjustments are likely only to reinforce the downwards spiral and inhibit a successful transition into the 1990s. A longer-term strategy is vital. □

nature

Another nuclear power station?

Not much has happened in the nuclear power industry since Chernobyl. But now the British government has to make a decision that will determine not only British plans, but influence what others do.

For understandable if not particularly good reasons, the managers of nuclear power enterprises outside the Soviet Union have been circumspectly unostentatious since the Chernobyl accident. The world's two hundred or so power reactors have kept on producing electricity, and the economic benefit that goes with it, without further incident, but otherwise it has been a slack time. Even in France, which manufacturers more than 70 per cent of its electricity from uranium, there promises now to be something of a pause in the building programme. In West Germany, Chernobyl has helped to bring nearer the end of the high-temperature reactor project at Kalkar, while talk of other fresh initiatives has almost ceased.

Part of the explanation is economic; oil prices (in absolute value) are lower than for two decades, while fears of physical shortage of oil are belied by the many decisions now being made not to exploit known reserves, from Alaska to the China Sea. But a more interesting part of the explanation is the nervousness induced by the Chernobyl accident. If a crew of foolhardy reactor operators can, by wayward disregard for operating procedures, cause an accident which, tragic even in the scale of the Soviet Union, could have made many smaller countries uninhabitable, can any reactor be called "intrinsically safe"?

That is the dilemma that now confronts Mr Peter Walker, Secretary of State for Energy in the British government, who last week took delivery, at last, of the report of the government inspector, Sir Frank Layfield, who has been inquiring for the past three years into a proposal by the Central Electricity Generating Board (CEGB), the still-nationalized British electricity utility, to build a pressurized-water power station at Sizewell on the Suffolk coast. Walker, and the British government as a whole, may be forgiven for thinking it bad luck that they must decide on Sizewell now, less than eight months after Chernobyl and, even worse, no more than 18 months before the next general election in Britain.

So it is. The Layfield process has been under way, on one view, since 1972, which is when CEGB told a parliamentary committee that it would like to give the pressurized-water reactor a try. Five years later, Mr Tony Benn, one of Walker's predecessors in a previous government, said that he would sanction such a development only after a public inquiry. When in 1979 Mrs Margaret Thatcher, newly elected as prime minister, outlined a programme to order roughly one nuclear power station a year for the then decade ahead, she seemed not to feel bound by Benn's commitment. But in the event, British reactor designers have been occupied since 1981 in preparing material for Layfield. The long process could have ended at many other more convenient times. The only consolation, for Walker, is that somebody must jump first.

Content

In the British manner, the Layfield report has not been published. Walker would be technically within his rights to decide that it should never see the light of day, although that is so obviously a recipe for ructions as to be unthinkable. In any case, the content of the document, and its faults, are easily surmized. To the extent that safety of nuclear reactors in general and of pressurized water reactors in particular were central to the inquiry, the inspector can only say that there is no essential reason why they cannot be operated safely; to demonstrate that he was not asleep during the two long years of the public hearings, he is bound to seize on a few points in the design at which assurance could be made doubly sure by further attention to safety measures. If it had not been for Chernobyl, CEGB and its design partner Westinghouse would have sighed with relief, budgeted for the extra costs and ordered the equipment. The most obvious point on which the report (when eventually published) will be attacked is that the public hearings were completed a year ago, before Chernobyl. If the inspector has been prudent, he will have added an appendix showing that he has thought of how the inquiry might have been changed by that event. If he has not, Walker (for everybody's sake) will no doubt ask him for another piece of paper.

Scope

As public inquiries go, the Layfield exercise was unusual not only because of its length but for its scope. The intention had been to settle once and for all the issue of whether pressurized-water reactors can be safely operated in Britain, so that it might be possible to avoid the same procedure whenever another of the type seemed desirable. But, in the event, the proceedings took in all the questions relative to the good sense of generating electricity from uranium. Is all that electricity needed anyway? Will not the continued manufacture of plutonium assist the spread of nuclear weapons? And what will be done with the radioactive waste? The inquiry might have been a unique exercise in public education if it had been joined by a representative section of unofficial opinion-holders (which would have been more likely if half the time had not been spent in a remote seaside town). A wise inspector will have said that these general matters are not for him but for others, mostly for the government, the British parliament and its electors, and will then have gone on to make a few privileged unassailable observations on them. Alternatively, he may have taken a view on some general issue of policy whose delegation to him would be constitutionally improper, and may have undermined the value of his report as a whole. Either way, accepting that the British need be no less successful at operating pressurized-water reactors than people in a dozen other countries, the hard question will be left with Peter Walker.

Is nuclear power necessary, for example? That question, disarming as it may seem, is too simply asked. In the economics of energy supply, there are no categorical imperatives. Oil is an important source of energy in most industrial economies, and is a particularly convenient source of liquid fuels and of hydrocarbons in general, but economies denied access to petroleum could probably manage in other ways, but at a cost. The question to ask about the usefulness of nuclear power stations is one about the economic benefits that may be derived from them, which can be answered fully in one place only with a knowledge of what is likely to be the pattern of their use elsewhere. It goes without saying that, in present circumstances and especially when oil is cheap, it could well emerge that extra safety measures could price even the most efficient reactor designs out of the market. But Walker will also know that the fluctuating price of oil can only, in the long run, increase relative to the prices of other fuels. The need for nuclear power in Britain or anywhere is not an absolute but a matter for intricate judgement. Walker's decision will be the more convincing if he makes that plain. The Layfield report itself could turn out to be an invaluable guide to the often contradictory economics of those with opinions of the value of nuclear power — optimistic, sceptical and downright perverse.

Research

For the research community, another economic question may be even more important. Britain is not the only country whose government has decided that the technology of nuclear power is potentially too important to be left to others. Direct spending of taxpayers' money on research and development in nuclear power is probably not much short of £100 million a year, with perhaps a comparable sum creamed off electricity bills. If the decision goes against Sizewell, it will make little sense to keep up the research. But a decision to build the Sizewell plant will leave unanswered the question how research and development in this field should be financed in relation to the numbers of nuclear power stations likely to be built in the years ahead. Walker or one of his successors is going to have to tackle that question soon. It should be more easily decided now that the UK Atomic Energy Authority has been made a trading fund, required to keep books as if it were a company.

The more immediate question of safety is similarly not absolute. But the fact that there is not yet an absolutely safe nuclear reactor does not imply that reactors cannot safely be accomodated with people in the same tract of land. Both Chernobyl and, earlier, the Three Mile Island reactor accident in the United States, were illustrations of how reasonably (but not perfectly) designed machines were induced to behave badly by their operators. The Three Mile Island accident is the more worrying because the operators acted sensibly in the period leading up to the accident. The moral, for those who would build reactors, is that much more attention even than at present must be lavished on the training, discipline and performance of the operators. Those in charge must be regarded as if they were airline pilots; accidents develop more slowly in nuclear reactors than in aircraft, but their consequences are greater. If Walker wishes to convince the British public that the Sizewell station could be safely built, he could do worse than to offer what countries such as Britain need in any case (and which is partly provided in the United States by the cumbersome procedures of the Nuclear Regulatory Commission), regular and public invigilation of the management of these plants.

But what should the minister and the British government decide? The Sizewell inquiry may have dealt with the need in Britain for a nuclear power programme as such, but the immediate proposal is that there should be a single pressurized-water reactor station five years or so from now. A single plant, especially one built in the present climate, is almost certain to be put together accurately and well. CEGB says it wants to build the machine; if it can confirm, in the light of information gathered since the Layfield inquiry ended, that the electricity is still worth having at the price, why not let it go ahead? The fact that the Labour Party has said that, if elected at the general election, it would "phase out" nuclear power, in any case argues for such a step-by-step approach. No doubt a decision by the government to sanction a single plant would be called provocative, but this is part of a legitimate disagreement; but committing public resources now to a long-term programme could risk an imprudent waste. What nuclear power in Britain and elsewhere now most needs is a show of cautious deliberation by sponsors willing to insist that its virtues are judged on strictly economic grounds and that its custodians, the plant operators and their bosses, shoulder their public responsibilities squarely. □

Shades of 1968?

The Chirac government in France seems to have made a hash of its intended university reform.

JUST why General de Gaulle's government took such fright when the students built barricades in the streets of Paris in 1968 has never been crystal clear. The immediate fear was that the survival of a nationalist government representing a deeply conservative people would itself be threatened if the students' anarchical protest at a modest package of educational reforms were allowed to run its course. But the whole of France was shocked by the violence of the students' anger at M. Edgar Faure's proposals for reforming the French universities. The police fought the students at the barricades, but the government withdrew its reform package, replacing it by a more anodyne reform.

It is odd that the new Chirac government should have fallen into the same trap. Not much seems to have changed in a decade and a half. Although the Chirac government's proposals for university reform have many objectives in common with those of 1968, the ostentatious orderliness with which last week's protest began shows that the students were not at first out to make a revolution. The death of one student at the weekend after a beating from the police has inevitably changed the mood. The government, having backed down half-way in stages, is likely now to have to give in altogether.

So are the reforms dead and buried? Not quite. The issues that have angered the students will surface once again in the next few years. So they should, for they are necessary reforms. The complaint against the Chirac government is not that it has made itself look weak and even foolish, nor that it launched the reforms in the first place, but that, with such an important objective to accomplish, it assumed that it would be sufficient to use its majority in the French parliament to get the reforms on the statute books, without attempting to carry academic opinion with it.

The truth, nevertheless, is that the French university system is one of the more enduring relics of the eighteenth-century revolution. The principles are grand, as has been their practice for much of the intervening period. Able teenagers at generally excellent secondary schools qualify for university entrance by means of the nationally uniform school-leaving examination and are then, in principle, free to choose the university at which they enrol. France being France, it is inevitable that the University of Paris should have had to grow fastest under the pressure of unregulated demand, but most good institutions have been overwhelmed by numbers. One of the government's now-postponed goals was that institutions should be more able to regulate external demand by setting their own entrance requirements; a by-product would have been an element of diversity within a system which, for all its virtues, remains too much of the same piece. Can that be bad?

So what went wrong? The French government's most obvious miscalculation is to have underestimated the passions attaching to the right to university education. But in the absence of positive proposals for helping students find and choose the institutions that would best meet their individual needs — financial assistance for students in France goes very little further than the nominal tuition fees (which were in any case to have been increased) — it is inevitable that the proposals would have seemed unjust to many potential students. That is why whichever minister of education brings these proposals back to the French parliament should take care to do so within a wider framework. France is no different from most other countries in Western Europe in facing a long period during which the student age-groups will decline numerically just at the time when greater skill and technical competence are more necessary than ever. The case for managing an element of diversity within the university system is strong, but not at the cost of the quality and even quantity of the students it trains. □

After the riots the politics

Chirac drops university reform bill to buy time

FRENCH Prime Minister Jacques Chirac appeared on national television on Monday morning to save his government. He announced the abandonment of the university reform bill that had led to demonstrations, then riots and finally the death of a student in Paris on Friday evening. Chirac's fragile coalition of right-wing parties was in danger of breaking up under the pressure of these events. Alain Devaquet, the universities and research minister, handed in his resignation on Friday night after the education minister René Monory announced, also on television, that he was to take over the steering of the bill; on Sunday, Alain Madelin, industry minister, said that the reforms "were not worth a life"; and others had begun to distance themselves from an administration that was rapidly being tainted as "anti-youth".

Just eight days earlier, Chirac had offered concessions to students on the three key points at issue — selection on university entry, local university degrees (they are at present national) and an increase in entry fees, which would vary from university to university But these proved not to be enough for student leaders who demanded complete renunciation of the whole bill.

Some, though, believe that the battle was won not by the students — who claimed to be apolitical in their protest — but by more violent elements that began to attach themselves to the previously peaceful demonstrations.

Where this debacle leaves the French universities and research is by no means clear. Devaquet had spoken of the "irony" of being tarred by students as an extremist, when his whole effort has been to tone down some of the more extreme libertarian elements of the bill that emerged from the right wing of Chirac's party and while he has successfully defended against that same wing other academic institutions such as the national research centre (CNRS). His resignation leaves a gap which Chirac will find difficult to fill.

But is Chirac's attempt at university reform dead?. Chirac is an authoritarian (if realistic) prime minister, who said only a few days ago that he had been elected to "govern", so a new bill may yet emerge once tempers are cooled.

As to why the French students — and high-school children — were so determined to resist selection, and increasing university autonomy, the answers are more social and psychological than political.

5 December: a demonstrator with sling faces riot police.

Selection does operate in French universities already, but it bites late on entry to the second and third years. It is made by university staff on new grounds; so a schoolboy or girl who has failed to make good progress at the very authoritarian French schools has a second chance in the first year of university (provided he or she passes the school-leaving *baccalaureat*). Pre-university selection means denying that second chance; and that can mean the dole queue.

The previous government planned to increase the entry to the first year of university, and making it explicitly a year of 'orientation' that could lead to jobs or other educational institutions as well as onwards in the university; but it failed to provide the resources to accomplish the task and created resentment among university staff. This government attempted to please that staff. But it forgot about the students. **Robert Walgate**

Vera Rich was in Paris when the students' patience ran out . . .

PARTICIPANTS in last week's clashes between French university students and the police were at a loss to explain how matters had got so out of hand. What was planned as a peaceful, silent, non-political protest on Thursday escalated into disturbances which, on Friday night, culminated in the death of the 22-year-old student Malik Oussekine. Certainly the Thursday demonstration was "politicized" by participants who, contrary to the organizers' appeals, brought political banners. But a high police profile at the march aggravated the situation. By Friday, the nationwide protests had taken on a frankly political tone, and on Saturday trades union leaders were being asked to sit in on the meetings of student delegates from all over France, and calls were going out for a one-day general strike.

The government's reactions — as so often in such situations — were too little, too late. The first, partial climb-down over the bill might have been effective on Thursday, before violence developed but it came only on Friday, a few hours before Oussekine's death. Security Minister Robert Pandraud's statement, on Saturday, that if there had been "individual faults" on the part of the police, sanctions would be imposed, was coupled with a refusal to dissolve the special police 'anti-vandal' motorcycle squadds introduced early on Saturday morning.

Interestingly, by Saturday night, even students involved in the growing disorders were convinced that the genuine protests had been "manipulated", although opinions differed as to whether the alleged manipulators came from the extreme right or the extreme left.

From the beginning, there has been an emotional and in some degree irrational element in the students' and *lycéens'* opposition to what, viewed more logically, might have been seen as an unpleasant but necessary reform, given the current economic state of France and the problems of graduate unemployment. But *lycée* scholars have grown up considering it an inalienable right that all school leavers who pass the *baccalaureat* can automatically go to university, while restrictions on choice and combinations of subjects, and the possible development of a hierarchy of excellence among the universities, seemed a direct affront to liberty, equality and fraternity. Some students, too, seem to have been stung into their decision to take part in the demonstrations by the accusation, voiced on French television only a couple of weeks before by Daniel Cohn-Bendit, the 1968 student leader, that the present generation of French students are "apolitical".

In reality, as several university lecturers have been at pains to point out, the hierarchical principle has long been established *de facto* in France, with prospective employers at least as interested in where an applicant studied as in his or her subject and academic record. The new law, they said, would simply validate the existing system. But as early as Friday afternoon, and particularly since the death of Oussekine, these same lecturers began privately to adopt a different stance. "I do not know whether I am on the side of the students over the law", one said, "but I am certainly not on the side of the police against the students!" Vera Rich

European summit

Unanimity but little of substance

EUROPEAN leaders confronted with the massive overproduction and costs of the Common Agricultural Policy and the need for technological cooperation to face competition from the United States and Japan, laboured mightily to produce a mouse last week: an anodyne communiqué, the result of the London summit marking the last month of Britain's six-month presidency of the European Communities, which failed to mention agriculture at all, put off budget questions to a later summit, and included lukewarm support for research in Europe only on the last-minute insistence of the French President, François Mitterand.

This time, the presidents, prime ministers and chancellors of the 12 states of the European Communities were in no mood to tackle controversial topics, at least in public. Foreign Office sources in London indicated not entirely in jest that the present disablement of the US presidency over the Iran arms sales affair, and the confusions over US defence policy, obliged Europe to present a united face to Moscow: squabbling in the Community would not help. Moreover, Chancellor Helmut Kohl of West Germany faces general elections next month, so this was not the best time to ask him to be hard on his farming voters. Prime Minister Jacques Chirac of France was preoccupied with the student protests (and late on Friday, the death of a student) in Paris; and the United Kingdom, meanwhile, did not want to bow out of the presidency on a sour note after its efforts these six months to prove itself a hard-working, constructive member of Europe.

The resulting bland unity was not good news for the research programme of the Communities' think-tank and administration, the European Commission, which the Commission has proposed to double. Jacques Delors, Commission president, had hoped the summit could send a strong signal in favour of the programme to the research ministers, who were to meet on Tuesday. During the summit, Delors emerged to say that many delegations had stressed the importance of the Commission's 'framework programme' for research and "approved it totally". Finally, however, the summit communiqué merely "urged" research ministers to agree, but gave no indication on the level of spending on which agreement should be reached, the matter which seemed likely to be the final sticking point on Tuesday between the big three — Britain, France and Germany — which oppose the proposed increases, and the rest, which support them.

President Mitterand, pressed on the research question after the summit — as he had been the first to introduce such matters to summitry — claimed credit that any clause on research at all had been introduced into the communiqué. The British Prime Minister, Margaret Thatcher, also questioned on research, avoided the matter of budgets and stressed the importance of agreement on standards for high technology equipment. She singled out the need for a common standard on digital cellular radio. This relatively small item was also the only technology explicitly mentioned in the communiqué for action, leaving the question of whether the leaders might actually have had in mind the need for common standards in the more ramifying systems of integrated digital services networks.

The European leaders also reached agreement to designate 1989 European Cancer Information Year to develop a "sustained and concerted information campaign . . . on the prevention, early warning and treatment of cancer". No mention was made of possible concerted action on tobacco advertising, but the ministers undertook to "follow up" the recommendations of a committee of European experts which is due shortly to report on cancer prevention to the Commission. A programme on AIDS (acquired immune deficiency syndrome) was also agreed, but this was only to compare notes on actions taken by the different member states in public information and prevention. The possibility of "further cooperation in research" on AIDS was to be considered by health ministers, the leaders agreed. **Robert Walgate**

Independence for UK space centre?

THE British National Space Centre (BNSC) is pressing the government to give it financial independence and to allocate an annual space budget of about £200 million without channelling it through other government bodies. The proposals for the budget and plan are at present being discussed at cabinet level.

The proposal for direct support accompanies the 15-year BNSC plan, and would allow more flexibility in managing the UK space effort. At present, the centre is funded by the Department of Trade and Industry, the Department of Education and Science and the Ministry of Defence.

The BNSC plan would increase spending on space, now £108 million, to about £200 million a year within three or four years. The plan has four principal ingredients and puts heavy emphasis on European collaboration. The first part of the space plan recommends strong British participation in the US Space Station and in a polar platform.

The second plank of the plan will ensure the development of new launchers, independently of the United States. Ariane V would form part of that project together with cheaper forms of space transport, including the European space shuttle HERMES and the British Aerospace/Rolls Royce space-plane HOTOL. The plan also includes an expanded space applications programme — Earth observation, microgravity and the like — as well as more space science research. Studies of solar plasma, geophysics and astronomy would also feature in this programme. Bill Johnstone

Super-collider still fighting for funds

Washington

LAST week the threatened Superconducting Super-Collider (SSC) project cleared one of its major political hurdles by gaining approval from John Herrington, the first Energy Secretary to endorse SSC since the agency began work on the programme five years ago.

It is a change of heart as only a month ago Herrington claimed that his mind was not made up on the advisability of the project. But because of the enormous cost, now estimated to be about $3,000 million, formal approval would have to come from the White House Office of Management and Budget (OMB). According to sources at the Energy Department, Herrington has not yet formally met top OMB officials.

Alvin Trivelpiece, director of the Energy Department's Office of Energy Research, has been trying to get other countries to participate in SSC, but such commitments are difficult if the United States is hesitant. Trivelpiece says Japan may invest $500 million in the project. The Soviet Union is another potential participant. For the time being, potential partners from Western Europe have their hands full with LEP and DESY.

While approval from the Reagan administration is a necessary step for the project to proceed, it is far from sufficient. Many believe that the brake on spending achieved by the current Congress was achieved by adopting financial tactics such as delaying payments and selling assets. Any further reductions will require real programme cuts.

Congressional enthusiasm for the National Institutes of Health shows no sign of diminishing, and the administration is rumoured to be considering a large increase in the budget for the National Science Foundation and a request for more funds for the Strategic Defense Initiative. It is uncertain whether spending on SSC will prove to be any more politically attractive. Joseph Palca

Amazon rainforests

Brazil invites RGS explorers

THIS week the first of 60 scientists depart for Brazil to make the final preparations for the biggest European-led research expedition ever to study an Amazon rainforest. The project team, led by Dr John Hemming, director and secretary of the Royal Geographical Society (RGS), will be based on the island of Maraca close to the watershed between the Amazon and Orinoco basins.

The invitation was made to RGS two years ago by the Brazilian Environmental Secretariat (SEMA), but it has taken since then to organize and raise from a mixture of industrial, private and government sponsors the £125,000 that will fund the basic needs of the year-long project.

Hemming says "we jumped at the invitation since, although Brazil contains almost two thirds of the world's surviving rainforests, it is difficult for foreign scientists to obtain permission to work there."

Half of the teams will come from the United Kingdom with Brazil making up most of the remainder. Maraca, an uninhabited island 60 km by 25 km, is covered in forest, contains a lake and has swamps and seasonally flooded areas. As a result of the expedition, SEMA, whose permanent research station on Maraca is at the disposal of the RGS team, will acquire a complete survey of the island, including an inventory of the animals, insects and plants, to help plan future research.

RGS says its five research programmes have "been welcomed by the Brazilian authorities because of the practical benefit to both farmers and conservationists". They involve an ecological survey, the development of management plans for the reserve, an examination of forest regeneration and the behaviour of soil moisture, a medical-entomological review and a survey of land development.

Caracarahy rapids, Rio Branco

The Royal Botanic Gardens at Kew in London will oversee the ecological survey which will record, classify and collect hundreds of species of trees, plants, vines and ferns with the help of specialists from the Royal Botanic Garden in Edinburgh and the New York Botanical Garden.

There will be an inventory of hundreds of species of fauna, particularly snakes, frogs, bats, monkeys, insects and birds. Studies of forest regeneration could help restore destroyed areas to their original state. According to RGS, thousands of hectares of rainforest are felled every year for farming, settling, cattle ranching and mining. But a wasteland usually results, claims RGS, and much of it is soon abandoned. Farming proves impossible because of poor soils and intense parasite and weed activity. Once damaged, the rainforests do not regenerate and the research will try to find out why.

Another research programme will investigate how the litter (or debris) on the forest floor is derived from the foliage and decomposes, the dynamics of the rainfall as it drops from the roof or canopy of the forest and the behaviour of that moisture with the soil. Research on endemic tropical diseases will focus on onchocerciasis and leishmaniasis.

The land development survey will study the settlements within reach of the research camp. According to RGS, millions of settlers are moving to the frontiers of the Amazonian forests in a desperate search for land. "This occupation and disturbance often occurs too fast for there to be any planning based on scientific information. As a result, many pioneer colonists fail."

Bill Johnstone

Space shuttle

Money-saving move on fuel tanks

Washington

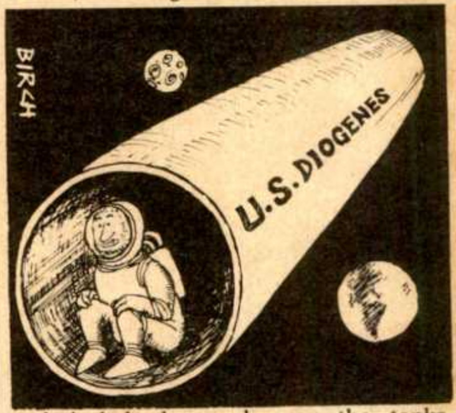
THE idea of making some use in orbit of each space shuttle's huge external fuel tank is not new, but prospects for its realization may have come closer. Hitherto, the fuel tanks have been allowed to burn up in the atmosphere. But now a new company, External Tanks Corporation, wants to make them into warehouses. The company is seeking private capital to finance what it calls the first private "warehouse in space". The project has the backing of the University Corporation for Atmospheric Research (UCAR), a consortium of 57 major research universities. According to Thomas F. Rogers, chairman of External Tanks Corporation and a former member of NASA's space programme advisory council, the first habitable tank could be in orbit by 1993.

The shuttle's external tank carries liquid hydrogen fuel and oxygen for the main engines, and is usually jettisoned just before the shuttle reaches orbit. Its diameter is more than the width of a Boeing 747, and its length is equivalent to a 13-storey building. Twenty-four have so far been discarded, each costing $30 million. To take the tank into orbit would require only an extra 2,000 lb of fuel, according to Randolph Ware, president of the new company.

The company, which is 80 per cent owned by the UCAR Foundation, a non-profit organization established by UCAR, is seeking capital from "companies that have a long-term strategic interest in the exploitation of the space environment", including hotels. The National Aeronautics and Space Administration (NASA) is apparently taking the company's plan seriously. Several studies have recommended that the idea be investigated, and NASA has now formed a special committee to look at it, chaired by general manager Philip Culbertson.

Culbertson says the "very interesting" idea is "feasible", but adds that NASA has not yet looked into all the technical details and that it would in any event leave the business side to External Tanks Corporation. NASA has some plans of its own for using the tanks: it recently awarded a contract to Martin Marietta Corporation to study turning an external tank into a gamma-ray imaging telescope.

Randolph Ware, president of External Tanks, and Rogers, both of whom have technical backgrounds, say the tanks would need minimal modifications on the ground. Once in orbit, the tank would be detached from the shuttle and fitted with a small thruster that would keep it in stable orbit. Subsequently it would be purged, pressurized and fitted as as "the equivalent of high-cost commercial space", according to Ware, who seems to have no doubts that commercial companies will want to rent.



Among the plans being discussed is one for a fully pressurized permanently inhabited laboratory/factory, Labitat, made from two tanks connected together. The operating cost of Labitat is calculated to be so low that accommodation would cost as little as $500 per person per day by the 1990s, roughly twice the cost of first-class hotel accommodation in the United States.

Tim Beardsley

Climatic prediction

Could this be an El Niño?

Washington

SOMETHING is happening in the equatorial Pacific Ocean from the dateline to the west coast of South America. Some believe that the climatic upheaval known as El Niño is in progress, others believe one is ending, some call the events an ENSO episode (El Niño/Southern Oscillation); others claim that all that is happening is that a travelling wave of water is moving through the Pacific from west to east. But there is agreement on one point: something is happening.

The events of interest relate to a warming of the sea-surface temperatures in a band from the dateline eastward, a rise in the water temperature measured from piers along the Peruvian coast, and slackening of easterly sea-surface winds. Whether these events should be termed an El Niño depends on definition. Originally, says George Philander of the National Oceanic and Atmospheric Administration (NOAA), an El Niño referred to warm current flows along the coasts of Ecuador and Peru in January, February and March, and the resulting impact on local weather. But James O'Brien of Florida State University in Tallahassee says no two events have been the same, making the 'classic' definition of little value. The second name, ENSO, more generally refers to events from the mid-Pacific to the South American coast, taking into account the irregular oscillation in pressure between the east and west Pacific.

The National Meteorological Center's Climate Analysis Center (CAC) issued an advisory note on 10 November stating that the warming of sea-surface temperatures in the equatorial Pacific "resembles the warmings associated with ENSO episodes". But the centre was unclear whether El Niño conditions would result. CAC's Don Rodenhouse says the next circular will probably appear next week based on November data, and is likely to confirm that Pacific warming is spreading.

The National Weather Service, CAC's parent agency, is cautious about using the term El Niño. Last March it announced that conditions that could lead to an El Niño were developing. Eugene Rasmusson, now retired from CAC but responsible for the March bulletin, says the warming trend failed to materialize. Many people, mindful of the economic disasters blamed on erratic weather from the 1982–83 episode, mistook the possibility of the event for the event itself, provoking some hyserical behaviour. Now the Weather Service will move very cautiously before making any firm statements about El Niño.

But the government's caution does not extend to the academic community. There is "absolutely no question in my mind that there is a modest El Niño under way", says O'Brien, who is chairman of the ENSO alert group that advises CAC on its Pacific forecasting.

Several members of the group had developed models as early as January predicting the ocean temperatures now observed. But O'Brien says none of them felt that this year's episode would match the 1982–83 episode in scale. From his own model, O'Brien predicts that sea-surface temperatures along the Peruvian coast may soon begin to decline.

Francisco Chavez of Duke University says his data show that decline is taking place based on pier temperatures from Paita, 5° south of the Equator. But Chavez data also show that pier temperatures for the start of November were well above normal.

Tim Barnett of the Scripps Institution of Oceanography has made a statistical model that predicts the behaviour of sea-surface temperature in the equatorial Pacific. Barnett's observations of temperatures in the region show about 1.2 °C above normal. His model predicts that the current warming trend will continue for another month or more.

Mark Cane, Stephen Zebiak and Sean Dalan of Lamont–Doherty Observatory in Palisades, New York, developed a deterministic model based on a coupled ocean–atmosphere system (see *Nature* **321,** 827; 1986). Cane says that if the model is correct, the current warming will have already peaked. His analysis of the latest data from the region supports that view, although the temperature could rise again. Barnett says the exciting thing will be to see how well the models behave in predicting events and to understand why they work as well as they do.

Predicting an El Niño is not necessarily of value in itself. "The term El Niño is useful like the term winter is useful", says NOAA's Philander. The significance of El Niño episodes for global weather is still not well understood. Moreover, Philander is not convinced that the rise in coastal temperature is due to an ENSO episode — a travelling wave, known as a Julian–Madden wave, may be bringing the warm water from the west, rather than a perturbation of the southern oscillation. One measure of the southern oscillation, the pressure difference between the island of Tahiti and the city of Darwin in Australia, has failed to show the difference normally associated with ENSO episodes.

But Rasmusson believes a weak-to-moderate ENSO episode is indeed under way, and the Tahiti-minus-Darwin pressure index is just one of the factors still not clearly understood. **Joseph Palca**

Biotechnology patents

Don't say just what you mean

Rehovot

AN extremely inventive patent covering biologically-engineered "human pink-spider toxinase" was recently presented for examination by Wiezmann Institute's Professor Hermona Soreq and Professor Avigdor Shaefferman of Israel's Biological Research Institute. But the toxinase and the cultured cells yielding a miracle cure for the dread spider bite were all the figments of the inventors' imagination, designed to illustrate the difficulty of patenting intellectual property.

The pink-spider toxinase patent, together with an equally inventive suit claiming patent infringement, was part of an unusual experiment carried out at an international conference on legal aspects of biotechnology held in Jerusalem. The invention was presented for examination by Mr Joel Tzur, the Israel Commissioner of Patents, and it was finally 'approved' after a mock appeal heard by the deputy president of the Tel Aviv District Court, Judge Ellyahu Winograd. Among those attending the Jerusalem meeting were scientists, jurists, patent attorneys, representatives of patent offices and industrialists. The so-called biolegal meeting was the brainchild of Tel Aviv District Court Judge Shoshana Berman. The importance of using precise legal terminology in patent applications became clear at the conference. For example, delegates concluded that it is not appropriate to describe a potentially patentable protein fragment as being of a specific length; instead, it should be described as being *essentially* of a specific length. That extra word makes it far less likely that the application can be successfully challenged. "I learned", Professor Soreq concludes, "that the exactitude demanded of scientists may be counterproductive when they are applying for a patent."

The Israel Patent Office has been issuing patents on genetically engineered microorganisms even before they were patentable in the United States. But Professor Haim Aviv claimed that Israeli authorities have been too liberal in granting broad patent protection to foreign biotechnology companies, which, he charges, are less interested in manufacturing their products than in stifling Israeli innovations.

Aviv, himself deeply involved in the business side of biotechnology, hopes that Israel will soon adopt the US principle of a grace period, so that local researchers, like their US counterparts, will have a full year to patent their findings after publication in a scientific journal.

Nechemia Meyers

Bhopal

Liability for disaster still disputed

New Delhi

THE question of compensation for victims of the Bhopal disaster still remains unresolved on the second anniversary of the leak of methyl isocyanate (MIC). The legal wrangle has taken a new turn with the Union Carbide Corporation (UCC) alleging that it did not own the plant and therefore is not liable for the incident on 2 December 1984.

In a 179-page document filed in the court of Bhopal's district judge, UCC said the Indian claim was based on the "erroneous assumption that the plant belonged to, and was designed operated and maintained" by UCC. It said the plant was designed and constructed by Union Carbide of India Limited (UCIL) in consultation with Indian engineering companies, and that UCC provided only the process design of certain parts of the plant in accordance with the provisions of the design transfer agreement approved by the Indian government. The agreement, according to UCC, specifically stated that UCC "shall not in any way be liable for any loss, damage, personal injury or death resulting from or arising out of the use by UCIL of the design packages". UCC said it was only a shareholder of UCIL which alone "is exclusive owner of the Bhopal plant".

Apart from seeking to transfer responsibility for the plant to UCIL, the US company has denied that the emission of MIC from the plant occurred as a result of defective plant conditions. It said that the incident occurred because large quantities of water were deliberately introduced into the MIC tank by connecting a water hose to the opening from which the tank's local pressure indicator had been removed.

According to UCC, the pressure indicator was in place on 30 November (two days before the accident), but on the morning of the accident it was found to be missing and a water hose was noticed lying on the top of the tank. UCC claims that the plant supervisor's daily notes included a sketch showing that water had entered through a connection to the pressure indicator. It said that somebody deliberately intending to introduce water into the tank could, within a few minutes, close the isolation valve, remove the pressure indicator, connect a water hose from a water service drop only 10 ft away and open the three valves necessary to introduce water.

The case may look straight-forward from down there...
UNION CARBIDE CORP.

UCC said that the facts "establish that a water connection to the tank was found and concealed by the operators and supervisors on the third shift" and that the Central Bureau of Investigation and the scientific advisers, with all the evidence available, "apparently desired not to reach the conclusion that the event was caused by a deliberate act". This "had the effect of aiding the persons involved in maintaining their deception", according to UCC.

The government of India maintain that UCC was liable for the consequences of the incident and is suing the corporation for $3,000 million in damages, saying that 2,347 people died and 30,000–40,000 were seriously injured in the disaster.

The legal arguments are expected to be prolonged, offering no immediate help for the survivors, many of whom, according to the Indian Council of Medical Research, continue to suffer from chest ailments and are without jobs. The Madhya Pradash government has so far spent more than $40 million on health care and rehabilitation; UCC and UCIL have made available about $16 million.

K.S. Jayaraman

Space Station cooperation

Money the root of conflict

Washington

DISAGREEMENT continues over arrangements for European participation in the planned US Space Station. European officials are pressing the United States for assurances on operating procedures and cost-sharing, asking that these be specified in a formal intergovernmental agreement. The United States, however, wants many of the details left to a memorandum of understanding between the National Aeronautics and Space Administration (NASA) and the European Space Agency (ESA). At issue are the financial returns the partners can expect from the collaborative venture and the extent of European autonomy in planning.

Several high-level meetings have been held recently between government and space agency representatives from different countries, including Japan. The negotiations are taking place against a background of uncertainty about the cost of the whole project. Recent NASA estimates suggest that the original figure of $8,000 million will fall far short of requirements unless the station capabilities are reduced. All sides say they want to reach final agreement as soon as possible, frustration is evident. One European official commented that Europe knows from experience that the United States does not take memoranda of understanding to be binding, a reference to the US decision some years ago to scale down its participation in the International Solar Polar Mission.

Officials also concede that serious differences remain over key aspects of management and sharing of costs and space station resources. Europe remains committed to its own $2,000-million pressurized module called Columbus, but is unhappy with the US view that that should limit its share of the total returns to 15 per cent. NASA is required by congressional directive to recoup 80 per cent of space station benefits; one important question, according to Richard Barnes, director of NASA's international affairs division, is whether Columbus should be considered an integral element of the space station system or an adjunct. The same applies to the European plan to develop a man-tended free flier, on which it has insisted despite US misgivings. Questions remain about how shuttle or Ariane launches and provision of payload specialists should appear in the accounts.

Europeans are also unhappy with a US congressional requirement that the United States should be responsible for materials science operations in its modules, leaving biological sciences for the Europeans. Officials say, however, that despite the congressional directive, there is now understanding that Europe will participate somehow in materials science research on the space station and be allowed some of the benefits. It is agreed in principle that commercial companies will have laboratory units that will sometimes be closed to general access in order to keep proprietary information confidential.

Both sides say they want final agreement on both the memorandum of understanding and the intergovernmental agreement by the end of the year or by very early in 1987. The European Council of Ministers is meeting to discuss space next spring, and would like a definite framework established by then; NASA wants to release a final request for proposals for the four main station work packages in January so that detailed development can begin in earnest next summer.

Tim Beardsley

Monoclonal patent

Hybritech versus Abbott

Washington

Hybritech Inc., a subsidiary of Eli Lilly, is suing yet another company for using monoclonal antibody assays in its diagnostic kits. Hybritech has now decided to sue Abbott Laboratories on the grounds that some of Abbott's diagnostic tests may violate its patent for 'sandwich assays'.

The patented Hybritech process uses two monoclonals, each specific to a different site on the same antigen, to make an antibody–antigen–antibody 'sandwich'. This detects small quantities of antigen, allowing early diagnosis of disease.

The interest of the new suit is that Hybritech is asking not only for damages and a permanent injunction against Abbott, but for a preliminary injunction that would prevent Abbott from selling its materials even before the case has come to trial. To persuade a judge, Hybritech will have to prove that continued violation of the patent would cause it "irreparable damage". Patent attorney Jorge Goldstein, of Seidman, Sterne, Kessler and Goldstein, says the chance of winning such an injunction, previously not high, is greater in the present pro-patent legal climate.

The disputed products include Abbott's pregnancy tests and some of its hepatitis and cancer tests, which are sold only to physicians or hospitals and comprise 7 per cent of Abbott's sales of diagnostics. Chuck Weber, a spokesman for Abbott, says that their test for the AIDS (acquired immune deficiency syndrome) virus, which uses polyclonal, not monoclonal, antibodies, is not affected by the suit.

If Hybritech wins this case it could also go after other companies using the sandwich assay technology. Syncor, in Sylmar, California, and Ventrex, of Portland, Maine, both have tests for human chorionic gonadotropin that use Hybritech's sandwich assay process to test for pregnancy. And Centocor, of Malvern, Pennsylvania, has just received US Food and Drug Administration approval for its CA 125 ovarian cancer blood test using the technique.

Hybritech's new suit may have arisen from the latest turn in its earlier suit against Monoclonal Antibodies, Inc. In 1984, Hybritech's suit failed and the patent was ruled invalid due to obviousness, but that decision was overturned, on Hybritech's appeal, last September. This decision returns the case to the federal district court in San Francisco, to determine if Monoclonal Antibodies' products infringe the patent for sandwich assays.

But David Brezner, chief counsel for Monoclonal Antibodies, intends to petition the Supreme Court over the decision upholding Hybritech's patent. There is some possibility that the justices may hear the case, as similar suits will certainly arise over other biotechnology patents in future. Brezner said the Abbott case "will not have a major impact" on his company's litigation with Hybritech.

However the Hybritech cases are settled, their handling by the courts will influence future biotechnology patent cases. Jorge Goldstein predicts a high volume of cases for the coming years. But ultimately, he believes, when several patents have been upheld, fewer companies will be tempted to infringe existing patents.

Carol Ezzell

New hepatitis-B vaccine launched

Brussels

Competition in the potentially lucrative market for vaccines against hepatitis-B virus is hotting up. Following close on the plans of a Korean company to produce a dollar-a-shot plasma-derived vaccine (*Nature* 324, 399, 1986), SmithKline Biologicals last week received official approval (in Belgium) for its new recombinant DNA vaccine. Already extensively tested on volunteers, the SmithKline vaccine will compete directly with a similar recombinant DNA vaccine produced by Merck.

The recombinant vaccines are composed of the coat protein ('surface antigen') of the hepatitis-B virus, made in and purified from yeast. The plasma-derived vaccines are made from particles containing surface antigen that are present in the blood of chronic carriers of the virus. As far as SmithKline has tested it (15,000 doses on 6,000 volunteers), the new vaccine appears to be equally effective and can provide a boost to people immunized with the plasma vaccine. Immunity takes about 4 doses and probably lasts about ten years.

Another antigen that may be important in hepatitis-B virus infection is known as Pre-S; some reports say that antibodies to this antigen prevent the virus attaching to the target cell, others that they predispose a patient to become a carrier. Because of this uncertainty, Pre-S was not included in the current vaccine, but according to Dr Alain Goudeau, who has been conducting clinical trials for the company, they have plans to make and test a vaccine that does contain it.

A course of vaccination with the plasma vaccine at present costs around £90 and SmithKline intends to keep the price levels about the same for the time being; the vaccine has been on sale in Singapore for some months at about 20 per cent less than the plasma-derived vaccine. As the sales increase, it is expected that the price will drop; the company has already invested in a new 1.5 m^3 fermenter to increase volume. SmithKline is confident that it can compete with Merck on price and availability, but the competition with the Korean vaccine on price will probably be the deciding factor.

Rebecca Ward

AIDS research queried

Skulduggery at the lab bench

Washington

"Distrust and dislike" between AIDS (acquired immune deficiency syndrome) researchers is the probable explanation for incidents of tampering at the federal Centers for Disease Control (CDC) AIDS programme laboratory in Atlanta, Georgia, according to a special independent assessment by the Institute of Medicine. The assessment concludes that a "lack of strong scientific leadership" at the laboratory has led to dissatisfaction and low morale among researchers.

The assessment, requested after allegations in the press of data suppression and tampering, says the committee could not rule out minor tampering with equipment. Reports received "suggest that some unusual incidents did in fact occur".

The committee, chaired by Dr Julius Krevans of the University of California at San Francisco, found the AIDS laboratory only "moderately productive" and recommended that CDC make institutional changes to separate basic and applied research. It also says that the director of CDC, Dr James Mason, should "take a substantial and visible role in the implementation of the new arrangements", and called for a review of authorship policy for AIDS research, a "locus of discord". Some individuals said their contributions were not recognized, and others felt that individuals not involved were credited. Some changes have already been made.

Another allegation made in the *Atlanta Journal* and *Atlanta Constitution* that research data were suppressed was not confirmed. The data in question were from experiments investigating the efficacy *in vitro* of Nonoxynol-9, a spermicide, in killing the AIDS virus. Early drafts of a manuscript published in *The Lancet* in December 1985 (Hicks *et al.* **ii**, 1422–23) had been submitted for internal review at CDC in January 1985, but the final version was not submitted until November.

Krevans' committee concludes, however, that although it is understandable that critics wanted to avoid unwarranted extrapolation of the results, "it is not clear why the revision required six months and clearance seven weeks".

Tim Beardsley

Japanese technology

Old computers may prove best

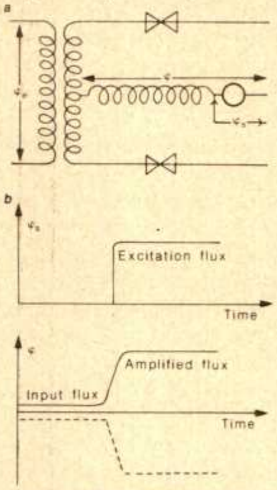
Tokyo

JUST at the time IBM (International Business Machines) drastically scaled down its research and development of Josephson junctions, Professor Eichi Goto of Tokyo University plunged into investigation of the supercooled logic devices, an idea originally developed by him more than 30 years ago. Now, three years later, Goto has been awarded about Y15,000 million ($92 million) by Japan's Research and Development Corporation under the ERATO programme to develop a Josephson junction computer that will process information in the form of minute magnetic fluxes.

The 'quantum magnetic flux logic' project will span five years and will be carried out by three research groups: Hitachi Central Research Laboratory will build the hardware, a team at Mitsui Shipbuilding will develop the software and a group at ULVAC in Chibasaki near Tokyo will be responsible for the magnetic shielding and refrigeration.

Goto achieved worldwide fame in the 1950s with his patenting of the parametron, a resonant electrical circuit that can store binary information by utilizing the two possible phases of oscillation of the resonating current. But although several Japanese companies, including NEC and Hitachi, developed parametron computers, these machines were soon superseded by much faster transistorized computers in the 1960s, and parametron computers can now be found only in science museums.

Nevertheless, Goto believes that a Josephson junction computer using a new type of superconducting parametron could operate at 10 GHz, a hundred times faster than present-day computers, while consuming a thousandth of the power of other Josephson junction devices. The secret lies in using magnetic flux, rather than electrical current, as the conveyor of digital information.



A d.c. flux parametron.

The d.c. flux parametron outputs an amplified magnetic flux the polarity of which is determined by that of a small input signal (see figure). The two possible polarities, positive or negative, can represent the 0s and 1s of binary logic, and by linking parametrons together magnetically, all the basic logic circuits of a central processor can be built. And in fact Hitachi has already linked together three such parametrons to make a clocking device that operates at about 2 GHz.

One major problem, however, remains. The magnetic fluxes on which this computer is supposed to operate are so tiny, on the order of nanogauss, that the computer must be completely shielded from external magnetic fields, such as that of the Earth and underground electric trains.

Undeterred, Goto has already set about trying to build the "perfect magnetic shield". In theory, a superconducting shield encasing the computer could shut out the external magnetic field. But in practice magnetic flux is pinned to the superconducter during cooling, setting up localized internal fields. Goto's plan is to 'sweep' the shield clean of pinned flux with a laser beam, but so far without success.

During preliminary experiments with a superconducting cylinder made of lead, more than 99.9 per cent of the laser's light was reflected by the shiny lead surface and a 'hot spot' for collecting flux failed to develop. Maintaining the cylinder black did not help much either — the paint peeled off on cooling.

If successful, Goto will be able not only to protect the computer from magnetic fields but will also have the ideal detector for magnetic monopoles, which were predicted by the late P.A.M. Dirac.

David Swinbanks

Indian resources

National water policy at last

Bangalore

INDIA has been trying for many years without success to evolve a comprehensive national water policy, but this goal is now a step nearer.

The chief need is for efficient and integrated management of water resources and more effective use of irrigation facilities. Mr B. Shankarananda, Minister for Water Resource Management, says the new policy, which is now getting its final touches, is intended to make available safe drinking water for more than half a million villages and also to link the Himalayan and peninsular rivers so that surplus water can be transferred to areas that need it. Cost-effective techniques for finding water in drought-prone areas, particularly in the north-eastern part of the country, are also being sought.

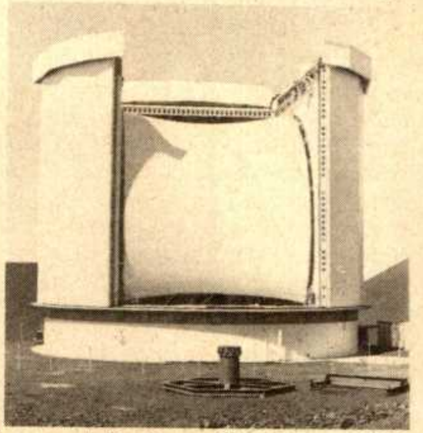
Under the new policy, both central and state governments would share the cost of creating water channels, dams and drinking-water sources. Water would be declared a national asset so as to end interstate disputes.

In the meantime, the Indian Planning Commission has announced that irrigation and flood control projects that do not include plans for 'ancillary aspects' such as soil conservation and protection of the ecosystem will not be permitted.

Water-borne diseases account for the loss of 73 million man-days in India each year. In 1980, it was estimated that out of 570,000 Indian villages, more than a quarter have no source of drinking water within 16 km. Although Rs77 million had been recommended by a working group for rural water supply and sanitation in 1986–90, only Rs34.5 million was allocated.

Radhakrishna Rao

UK–Dutch telescope



LAST week the James Clerk Maxwell Telescope, in the final stages of its initial commissioning tests, received its first radio signals from space. The £20-million instrument, installed at Mauna Kea Observatory on Hawaii, is the largest telescope in the world operating in the submillimetre region of the spectrum.

The telescope, jointly funded by Britain's Science and Engineering Research Council (SERC) and the Dutch Nederlandse Organisatie voor Zuiver-Wetenschappelijk Onderzoek (ZWO) will become fully operational next year.

The first radio signals to reach the telescope last Thursday were those from the Moon, Jupiter and Mars. The telescope has been specifically designed, however, to penetrate the dense regions of interstellar gas, which are opaque to optical radiation. At the infrared and millimetre wavelengths, these regions are transparent.

Bill Johnstone

Italian research reorganization

SIR—Your article on research in Italy (*Nature*, **323**, 751; 1986) depicts the Italian government as working quickly at reorganizing the national research institutions.

As a researcher with 18 years' experience and an employee of the National Research Council (CNR) which, with its 6,189 employees, is the largest of the government research institutions, I would like to express my incredulity at the effects that this difficult reorganization will produce. By the time the reform of CNR is approved by parliament, the most talented and best qualified researchers will have fled to more remunerative positions in universities and industry.

It may be true, as reported in the article, that the average cost per researcher is about 130 million lire. (Please note that public research institutions in Italy employ a mere 14,000 of the 112,884 cited.) But the annual salary of a senior CNR researcher — whose competence, for the information of non-Italian readers, is at the level of a full professor at a university — is no less than 13 million lire, about £6,500.

It is with a sense of shyness mixed with a sprinkling of rage that we watch the CNR president, Professor Luigi Rossi-Bernardi, and the Minister of Research, Senator Luigi Granelli (whose joint efforts to save CNR must be acknowledged), praise the abundant productivity of CNR scientists and the consequent healthy state of CNR. Most of us have spent several years abroad, often working in renowned international research centres, and are all aware of the conditions in which we continue to do research in Italy, and of how they compare with conditions in Britain, the United States and Japan.

Interestingly, the fate of CNR researchers and their hopes of better salaries now seem to be linked to the approval of a government bill (not the reform of CNR) originally devised to exempt the wages of workers at the Mint and of air traffic controllers from the restraints of the anti-inflation finance law, which limits the increase of public employees' wages to 6 per cent a year.

It is well known that Italy suffers from frequent government reshuffles. Experienced observers think it likely that there will be another next March. Whereas I am sure that most of the many "million million" lire projects cited in your article will be funded, I doubt whether the contract for CNR employees (which expired on 31 December, 1984) will be renewed by the end of this year.

Maori victory

SIR—Whether or not he was summarizing the views expressed in Crosby's *Ecological Imperialism, The Biological Expansion of Europe, 900–1900*, Roy Porter (*Nature* **323**, 587; 1986) shows extreme ignorance when he suggests that the Maori people of Aotearoa (New Zealand) "were stuck in the time-warp of the Stone Age and could not compete with European arms, ploughs and liquor". He also describes them as having been ruined by syphillis, a suggestion that might be equally appropriately applied to the English monarchy.

The Pakeha (European) myths about the land wars of last century have now been exposed. The British were defeated militarily by the Maori in spite of General Cameron's 18,000 men, the largest standing army at that time in the British Empire. The Maori applied lessons learned during their own musket wars to counter the superior fire power of mortars, rockets, howitzers and the 118-pound Armstrong gun. The gunfighter's *pa* (fortress) consisted of a system of trenches, parapets, rifle pits, covered walkways, fire-proofing and bomb shelters. The success of the Maori military strategy was evident at Gate Pa where Cameron suffered his heaviest defeat and concluded that New Zealand could not be taken by a war of attrition.

A more efficient way of getting Maori land was devised when the Maori Land Court was created and a system of individual ownership was installed to break up tribal lands. The war between Maori and Pakeha over the land and its resources was transferred to the arena of Pakeha-created courts, where it continues today.

The judgement that European domination of the globe is some kind of darwinian success story is premature. Maori resistance to imperialism has been so strong that the Pakeha population of Aotearoa has now been co-opted into the struggle. The parliament of New Zealand is about to pass a law that the governments of both the United Kingdom and the United States interpret as banning their navies from our harbours. We invite Alfred Crosby and Roy Porter to come to New Zealand and expand their view of global biopolitics, but we should warn them that they may catch the anti-nuclear bug which is said to be reaching epidemic proportions in this region.

Pan(da)selectionism

SIR—I have been following with interest the recent correspondence in your pages on evolution, creation science and neo-darwinsim. The letter from T.D. Iles[1], pointing out the regrettable habit of neo-darwinians of making exclusive claims on the interpretation and exposition of evolutionary orthodoxy, was nicely complemented by the Commentary[2] two weeks later on the ancestry of the giant panda. This article, written by a leading (indeed a founding) neo-darwinian, clearly shows the plasticity of neo-darwinian logic.

I do not wish to support either side in the argument over whether the giant panda is more closely related to the raccoon or to the bear (indeed, this is the sort of argument that seems to excite the interest of neo-darwinians in particular: its significance for evolutionary theory in general is less clear), but instead to point out that Mayr's arguments concerning the data on haemoglobin amino-acid sequence differences are circular, self-serving and without experimental proof.

Mayr is concerned on the one hand to prove the irrelevance of the haemoglobin sequence data that show giant pandas to be more closely related to raccoons than to bears, and on the other hand to explain the near identity of the haemoglobin chains of humans and chimpanzees, despite an apparent evolutionary separation of over 10 million years. The explanation offered is, of course, selective pressure on haemoglobin. To quote: "In the case of man and chimpanzee this influence has been conservative, but in the case of the bears it might well have been centrifugal".

What can one say about such *ad hoc* panselectionist arguments that are not supported by biochemical data plausibly relating haemoglobin structure and function to the physiology, habits and behaviour of pandas, raccoons, bears or primates? It is clear that faith in natural selection alone can explain all in these sermons from the pulpit of neo-darwinism. It is surely time to acknowledge that gene and protein sequence data often support theories of molecular evolution in which natural selection of variants is not explanatory[3], or in which common molecular ancestry is disputed[4], and that the use of these data to support either molecular-clock based phylogenetic trees or neo-darwinism selectionist explanations of evolution should be treated with appropriate scepticism.

When firsts come only second

Too many contributors to the scientific literature neglect the journalistic principle that the word "first" should prudently be avoided.

Researchers should learn from journalists the dangers of words such as "first" Those who describe some event as the first of its kind are almost certain to be assailed by readers saying that it is nothing of the kind But to play safe by using qualifiers as in "the first recorded demonstration " is merely to blunt the clarity of the message Prudent people therefore stick to verifiable firsts

Here is an illustration of the difficulties that may arise In the issue of *Physical Review Letters* dated 24 November, R P Messmer and P A Schultz from the University of Pennsylvania contribute a fascinating account of their calculations of the electronic structure of C_2F_2, acetylene in which the hydrogen atoms are replaced by fluorine atoms (**57**, 2653, 1086) The interest of the paper is its conclusion that the older valence bond description of atomic bonding may be a more accurate starting point for calculations of the electronic structures of molecules than the molecular orbital framework A corollary is that the electrons participating in the carbon–carbon triple bond are more tightly localized on the two carbon atoms than the textbooks say

Familiar? Even this brief description will prompt many to recall a recent paper by Cooper, Gerratt and Raimondi (*Nature* **323**, 699, 1986) That was also an account of a valence bond calculation of an organic molecule, in that case benzene Again the conclusion was that the valence-bond description can be the starting point for an accurate calculation of the electronic properties Again it emerged that the electrons appear to be more tightly anchored to the carbon atoms than the textbooks say

Both papers are important contributions to a reassessment of the utility of the alternative frameworks for molecular calculations

The nearly simultaneous appearance of very similar pieces of work is not surprising Sometimes, the explanation is that science has developed to the point at which a previously unformulated question cries out for an answer, whereupon several people independently design appropriate experiments

On other occasions, a new technique may be the trigger for several parallel developments, which appears to be the case with the recalculation of the electronic properties of molecules The work of Cooper, Gerratt and Raimondi and of Messmer and Schultz has been made possible by computer programs capable of accommodating the very large numbers of alternative electronic configurations required for accurate valence-bond calculations and the availability of the computer power to implement them

The dilemma of quantum chemistry is cruelly stated by the following string of simplifications Chemical bonding is an essentially quantum phenomenon in which electron spin is crucial, if in the simplest of all natural molecules, H_2, each atom is represented by a proton surrounded by a smeared-out electron but is otherwise dealt with classically, simple electrostatics will suggest that chemical bonding is impossible Only the fact of electron spin allows electron wave-functions to overlap without an intolerable energetic penalty If, for H_2, the spatial wave-function is properly antisymmetrized with respect to an exchange of electrons, the electrostatic energy turns up with a minus sign if the electron spins are in opposite directions, implying chemical bonding in a state of zero total spin

Both the valence-bond and molecular orbital schemes are ways of approximating to the wave functions of molecular electrons In the valence-bond framework, molecular wave functions are built as linear combinations of products of pairs of atomic wave functions, not simply those with one electron attached to each nucleus but also those in which both electrons surround the same proton, leaving the other bare Strictly speaking, excited states should play a part For a complicated molecule, a horrendous number of configurations is usually required

In the molecular orbital view of the world, the problem of H_2 can be dealt with almost exactly by means of the solution of Schrodinger's equation for the hydrogen molecule-ion, two electrons slot with opposite spins into the lowest electronic state, making molecular hydrogen a kind of binuclear helium atom But only modestly more complicated molecules present fearsome problems, the simplest molecular orbital calculations start with approximations to molecular wave functions that are linear combinations of atomic wave functions, and yield useful results only by the empirical fitting of parameters In neither scheme is the set of approximate wave functions an orthogonal set, which leads to further complications Roy McWeeny made the compelling argument, in a *News and Views* article (*Nature* **323**, 666, 1986) that there is no philosophical difference between the two approaches, what matters is merely which is the better starting point for calculation

Much of the interest of what Cooper, Gerratt and Raimondi have done is their use of electronic spin as a way of classifying molecular electronic wave-functions, which is how they conclude that Kekulé's picture of benzene, as a structure in which different patterns of double bonds alternate, may be more realistic than the now-common view of benzene in which there is a static ring of electron density above and below the plane of the six-sided array of nuclei Interestingly, their calculation starts with a set of old-fashioned molecular orbital functions on which they perform what is essentially a valence-bond calculation The outcome is the surprising discovery that electrons are more nearly localized on the six carbon atoms than the conventional picture would have them

Messmer and Schultz take a different tack, starting with the familiar way of dealing with carbon bonds which supposes that the four valence electrons of a carbon atom may occupy any hybrid mixture of the four independent wave-functions of the second electronic energy state The conventional picture of the triple bond in C_2F_2 is that of two links between dumbell-shaped electron orbits, at right angles to each other (called π bonds) and a direct link called a σ bond By cleverly loosening the symmetry restrictions, they are able to show that the state of lowest energy is one in which the bonding electrons at each carbon atom are tetrahedrally arranged, and that the three carbon–carbon bonds are symmetrically arranged about the axis of the molecule Again, the electrons are more localized than expected

These developments are interesting and important The only slightly jarring circumstance is that, admittedly with some qualification, Messmer and Schultz describe their work as a "first", a word whose use is belied by the appearance of Cooper, Gerratt and Raimondi roughly a month earlier) The independence of the two pieces of work, which have only one reference in common, is plain, but the claim to be first makes one seem very mildly foolish Should editors now seek to protect authors from themselves by banning the use of the word "first"?

John Maddox

Solid-state chemistry

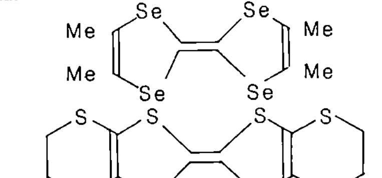
Novel molecular metals

Martin R Bryce

THE scope of materials that display interesting electrical, magnetic and structural properties at very low temperatures has now been extended by Underhill and co-workers, who on page 547 of this issue[1] describe the first two-dimensional organometallic compound that exists in an integral oxidation state The study of the synthesis and solid-state properties of such conducting two-dimensional systems will help to elucidate many fundamental phenomena of solid-state chemistry

Most organic and organometallic solids are electrical insulators, but considerable attention has recently been focused on an ever-increasing number of these solids that exhibit high electrical conductivity and other properties typical of metals This metallic behaviour is caused by extensive intermolecular overlap of systems rich in π-electrons along highly ordered stacks within the crystal The materials are highly anisotropic and are termed quasi-one-dimensional molecular metals[2,3]

Because of instabilities inherent in a one-dimensional electron system, metallic behaviour is almost invariably destroyed at low temperature by a Peierls transition when the materials become semiconducting or insulating (This transition is analogous to the Jahn–Teller symmetry-breaking distortion in molecules) A major goal of research on molecular metals is the stabilization of the metallic state at very low temperatures The report by Underhill and colleagues of a new metal–dithiolene complex with an inherently two-dimensional structure, a feature which suppresses the usual Peierls transition and stabilizes the metallic state down to 1 4 K under a pressure of 12 kbar, is therefore of considerable interest



Top, TMTSF (tetramethyltetraselenafulvalene), bottom, BEDT–TTF (bis(ethylenedithiolo)tetrathiafulvalene)

A significant degree of two-dimensional behaviour has been found previously in molecular metals which are salts of TMTSF and BEDT–TTF (see figure), where X-ray analysis reveals close interstacked selenium–selenium or sulphur–sulphur contacts[4], but two-dimensionality is a new structural feature for highly conducting organometallic salts

The physical basis of the Peierls transition in molecular metals is a direct consequence of the one-dimensional nature of their crystal structures The component molecules crystallize in an orientation such that their electronic states mix to form a continuous band along only one crystal axis The highest energy level within the band that the electrons occupy is termed the Fermi level At low temperatures, long-range order cannot be sustained and lattice distortions lead to the opening of a band gap at the Fermi level When this occurs the conducting chain can be considered to stretch in one region and contract in another, so that the conducting electrons become localized with a filled electron band at a lower energy and an empty band at a higher energy This transition usually occurs at a well-defined temperature (typically between 20 and 100 K) often when the component molecules of the conducting stack dimerize Above this temperature electrons can be thermally excited across the Peierls gap and a uniformally spaced (metallic) stack is energetically preferred

In contrast, for a two- or three-dimensional system, where there is also significant coupling between molecules in a plane perpendicular to the stacking axis, it is less favourable, or even impossible, for the lattice to rearrange and open a band gap The application of pressure to the sample is known to increase the strength of the two-dimensional interactions in TMTSF and BEDT–TTF salts[4]

The discovery by Underhill and colleagues of a complex in an integral oxidation state that nonetheless displays metallic conductivity is also a significant advance When a complex is in a non-integral oxidation state there is only partial charge on each anion This means that energy levels will exist close to the Fermi level that are empty and available to receive the electrons required for conduction along the stack This situation typically arises when there is full charge transfer between donor and acceptor molecules that crystallize in the ratio 1 2 or 2 3, or when there is only partial charge transfer from donor to acceptor that are present in a 1 1 ratio Conversely, for a complex in an integral oxidation state there is a completely filled band and energy is needed to activate electrons into states where they will be available for conduction Such materials are typically semiconductors or insulators In simple terms, movement of electrons along the stack will now necessitate placing two electrons on the same acceptor, with the associated unfavourable coulombic repulsion between these two electrons ☐

Pattern formation

Form and diffusion

Alfonso Martinez-Arias and Philip Ingham

THE question of how cells estimate their location within the body has preoccupied embryologists for the past century, but when posed by Stumpf[1] almost exactly 20 years ago, it seemed to have the beginnings of an answer The concept of gradients, first explicitly propounded by T H Morgan, was entering a new phase of development, and since then it has become almost axiomatic to theories of pattern formation in insects Yet for all that, direct evidence of the existence of gradients has remained tantalizingly elusive The recent discovery[2] of the fruitfly (*Drosophila*) gene *caudal* (*cad*), whose transcripts form a concentration gradient in the early embryo, suggested that the search might at last have borne fruit On page 537 of this issue[3], Macdonald and Struhl report an extensive analysis that argues against a role for *cad* as a primary morphogen In addition, the detailed characterization of primary determinants of polarity in *Drosophila* by Nusslein-Volhard and colleagues[4,5] suggests that a reassessment of the gradient paradigm is timely

Since the beginning of this century, gradients have been invoked as determinants of polarity in a wide variety of organisms[6] Analysis of polarity perturbations in insect segments had in particular provided support for this view In the 1960s both Stumpf[1] and Lawrence[7] realized that the postulated gradients of "unknown diffusible substances"[1] could not only determine polarity, as Morgan had suggested as early as 1905, but also "that a particular level of the gradient might determine the pattern differentiated by cells"[7] at any given position This concept was later embodied in Wolpert's theory[6] of positional information, according to which cells in a morphogenetic field read the local concentration of a morphogen gradient, interpret the information and differentiate accordingly

Shift in developmental capacities of the developing blastoderm (adapted from ref 14) In the stage 10 embryo, when *cad* exhibits a graded distribution, the apparent positions (%EL = egg length) of the segmental primordia (black dots, MP, mouth parts, Lb, labium, T, thoracic, A, abdominal) show a bipartite distribution with clustering towards either pole The shift in these positions between stages 10 and 14 is consistent with diffusion of signals dependent on *osk* and *bcd* Their periodic distribution at stage 14 reflects the expression of *fushi tarazu* and other pair-rule genes

cerned with patterning in secondary fields, the basic concepts of the positional information theory can in principle be applied to the establishment of pattern along the primary body axis during embryogenesis Indeed, Sander's experiments[8] with insect embryos had already led him to propose a role for gradients in generating the insect body plan These experiments excluded the possibility that the cells of the early embryos are specified in response to a fixed set of localized determinants Rather, they encouraged the view that increasing concentrations of morphogens could account for the generation of pattern through the differential activation of genes along the anteroposterior (AP) axis of the embryo[8-11]

At first sight, the *cad* product seems to be a good candidate for such a morphogen Using antibodies raised against the *cad* protein, Macdonald and Struhl[3] and Mlodzik and Gehring[12] find that, like the transcript, the *cad* protein is initially gradually distributed in the early embryo The significance of this distribution is, however, diminished by the results of Macdonald and Struhl's extensive genetic analysis of the locus They have generated mutations that allow them to remove the maternal contribution of the gene from the egg When such eggs are fertilized by normal sperm, the characteristic early protein distribution is barely detectable yet the embryo develops normally

Given the disparity between the levels of *cad* protein with and without the maternal contribution, this result argues that the absolute concentration of the gene product at different points along the AP axis does not have any informational content *per se* Only when the gene is also absent from the zygote is patterning disrupted Thus it seems it is the localized expression of *cad* in the posterior region of the embryo, rather than its initial graded distribution, which is necessary for normal patterning Interestingly, the defects observed are predominantly of the 'pair-rule' type Moreover, they are correlated with alterations in the pattern of expression of the pair-rule gene *fushi tarazu* similar to those caused by the 'knirps-grandchildless' group of mutations[11,13] This suggests that *cad* is involved in the transfer of information between the primary determinants of pattern and zygotic segmentation genes

Some of these primary determinants have recently been identified in a series of elegant analyses by Nusslein-Volhard and colleagues Starting from the premise that the primary determinants of the body plan must be deposited in the egg during oogennesis, her group has isolated maternally acting mutations which disrupt patterning along the AP axis One of the genes so identified, *bicoid* (*bcd*), is required for the normal development of the anterior, whereas another, *oskar* (*osk*), is necessary for normal abdominal development

By carrying out various cytoplasmic transplantations, Nusslein-Volhard and colleagues show that activities dependent on the two genes are initially localized at the anterior and posterior poles of the embryo, respectively In both cases, the mutant phenotype can be repaired by transplantation of wild-type cytoplasm form the appropriate pole In the case of *osk*, the failure to generate the abdominal segments can only be rescued if the posterior polar material is transplanted to the prospective abdominal region of the embryo and not to the posterior pole Normal cytoplasm from the abdominal region does not, however, have rescuing activity This suggests that the material localized in the posterior pole acts as a source which propagates a molecular signal which in some way is transferred to the abdominal region during the early cleavage stages

Similarly, *bcd* activity seems to be localized at high levels in the anterior pole of the egg Transplantation of this anterior polar material not only rescues the *bcd* defect but also can induce anterior structure at any position along the AP axis The concentration of this activity decreases both with distance from the pole and with time, suggesting a dynamic gradient of *bcd* activity in the anterior part of the embryo The status of both gene products as primary morphogens is reinforced by the finding that their transplantation to ectopic sites in the embryo can also induce changes in polarity, its most fundamental property

Despite this compelling evidence for the existence of two sources of diffusible influences emanating from either pole, Nusslein-Volhard's group does not interpret its data within the framework of the clasical gradient paradigm Rather than opposing gradients of *osk* and *bcd* products specifying unique values along the AP axis, both genes are thought to supply more coarse-grained information that would be responsible for the region-specific activation of the zygotic gap genes

In the light of these results, it is interesting to re-examine some of the earlier classical embryological manipulations In 1977 Vogel[14] reported a series of ligature experiments in *Drosophila* analogous to those performed by Sander on other insects On the basis of these, he argued against the generation of the body plan through interacting gradients of morphogens, but instead proposed a regionalization of the embryo consistent with the results discussed above (see figure)

Remarkably, the emerging picture seems not inconsistent with the vision of Driesch[15] who at the turn of this century proposed that "development starts with a few ordered manifoldnesses, but the new manifoldnesses create by interactions, and these are able to provoke new differences and so on With each effect immediately a new cause is provided and the possibility of new specific action"

Although all the new results prompt a re-evaluation of the role and mechanism of action of gradients in primary pattern formation, they do not have any direct bearing on the same aspects of secondary fields originally addressed by Stumpf and by Lawrence Similar experimental approaches will no doubt sharpen our understanding of the latter ☐

Plasma physics

Nuclear fusion comes closer

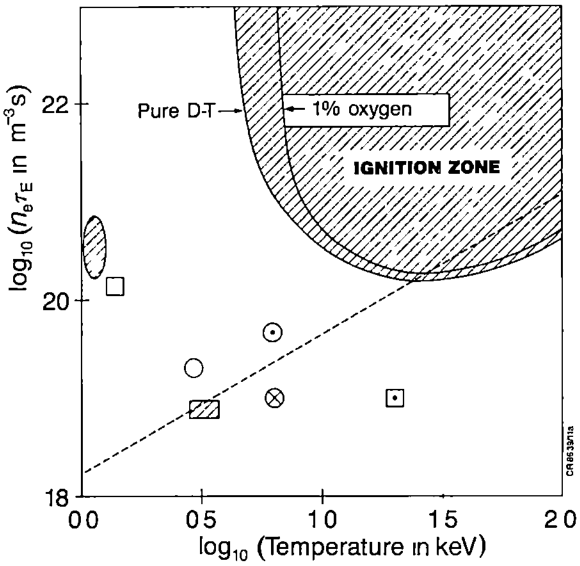
R S Pease

A NEW initiative in international cooperation among the nuclear fusion research community, which may lead to a world engineering test reactor, was announced at a recent meeting* (see below) But the dominant scientific feature of the conference was the experimental results from four large tokamak installations, TFTR (Princeton), D-III-D (San Diego), JET (Euratom, Culham) and JT-60 (JAERI, Japan) All these tokamaks, toroidal electric discharges stabilized by strong magnetic fields, have discharge currents in the range 1 – 5 MA and additional heating in the power range 1 – 20 MW, and are aimed to investigate magnetic confinement of high-temperature hydrogen or deuterium in conditions close to those required for net energy production in a deuterium–tritium (D–T) mixture (see my recent News and Views article, *Nature* **324,** 111, 1986) TFTR and JET, however, are not now planned to operate in D–T before 1990

The results achieved in simple terms of temperature and the critical thermal insulation parameter $n\tau_E$, where n is the ion density and τ_E the energy confinement time, are summarized in the figure, and are compared with the values needed to obtain a self-sustained thermonuclear reaction in a 50 per cent D–T mixture The highest ion temperature (T_i) reported, achieved with the strongest additional heating and at low densities (~ 10^{19} m^{-3}), is about 20 keV, the best thermal insulation, achieved generally with low or no additional heating and at the highest densities, is about 1 5 × 10^{20} m^{-3} s, that is, just at the ignition threshold

The best combination, represented by the triple product $n\tau_E T_i$, is about 2 × 10^{20} m^{-3} s keV obtained both in JET and in TFTR, and is about a factor of five above that reported at the previous conference in 1984, it is still about a factor of ten short of the minimum 3 × 10^{21} m^{-3} s keV required for self-sustained thermonuclear reaction in D–T Up to 10 kW of actual fusion power has been achieved in deuterium alone, which corresponds to more than 1 MW in D–T Typically, such conditions can be sustained for several seconds in JET, the largest tokamak

After allowing for the various differing features of these machines, and for the initial nature of the experiments in D-III-D and JT-60, the major experimental results are all in substantial agreement Moreover, the results from these large tokamaks are supported and supplemented by a wide range of heating and confinement experiments conducted on numerous smaller tokamak installations such as the T-10 (Kurchatov), the DITE and CLEO assemblies (Culham), the HL-1 tokamak in Leshan (China) and high-field tokamaks such as ALCATOR C Generally, all the additional heating methods raise the plasma temperature markedly, have high efficiences and are understood The main phenomenon observed is that the best confinement times are found in high-density operation (Alcator scaling) and in the largest machines But the scaling with temperature and magnetic field is otherwise not very marked



Experimental achievements of ion temperature T_i (generally, the central ion temperature) and density–energy confinement time product ($n\tau_E$) for the four large tokamaks[†] and the NOVA laser compression experiment (E Storm, Livermore) These results are compared with the theoretical values needed for ignition in a D-T plasma (see my review, *Phil Trans R Soc*, in the press) Below the dotted line, the ion and electron temperatures can be significantly different Experimental results of ○, JET (ohmic), ⊙, JET (X-point operation), □, TFTR (ohmic with pellet injection), ⊡, TFTR (best temperature), ⊗, JT-60 (neutral beam heating), hatched rectangle, D-III-D (ohmic), hatched ellipse, NOVA laser compression ([†]R Hawryluk *et al* and S Milora *et al*, Princeton, I Tanga, JET, P -H Rebut, JET, M Yoshikawa, JAERI, and J Luxon, San Diego)

The chief lacuna is that the physical mechanisms underlying the observed energy confinement time remain unidentified Ideally, if the heat transport across the magnetic fields were caused by only ion–ion and ion–electron encounters, then the observed value of τ_E (0 1 – 1 s for large installations) should be about ten times larger, and the corresponding values of $n\tau_E$ should increase as the square of the current In this sense, all four installations have the potential to achieve substantially improved confinement There is growing evidence that this can be done

Pellets

One practical route to better values of $n\tau_E$ is to increase the number density, for example by injecting high-speed (about 1 km s^{-1}) pellets of frozen deuterium This approach is used particularly by the TFTR group and, because τ_E at least does not fall with density (in fact it usually increases), it has met with success which should improve as better pellet injectors are installed Another approach is to adjust the field configuration in the outer regions (X-point operation) This technique, discovered experimentally on the German tokamak ASDEX (Wagner, F *Phys Rev Lett* **49,** 1408, 1982) has met with success in the first reported experiments on JET and on D-III-D The adjustment eliminates the further degradation of confinement time which normally accompanies the additional heating The radial profile of the current density (in the minor cross-section) can be more generally altered by non-inductive current drive up to 1 7 MA was generated by travelling wave radio frequency (2 GHz) fields in JT-60, but the favourable effects on τ_E are restricted so far to low densities Lastly, under a number of conditions, the thermal insulation is observed to show transient improvements localized near the plasma centre, which leads to a strong rise of temperature lasting about a second, followed by a collapse This, again, suggests that long-lasting improved confinement can be obtained

Theoretical studies of the transport problem, stimulated by new, well-diagnosed experimental data, are growing No major instability is, it seems, predicted that could inevitably preclude achieving the required thermal insulation Those that are predicted depend noticeably on the detailed profiles of density, temperature and current, and are governed by the detailed velocity distribution of the ions or electrons and their collision rates None, so far as was reported at the meeting, gives a convincing numerical explanation of the observed heat losses It is quite probable — indeed almost certain — that different mechanisms predominate in different regions of the discharge, so that reducing complex theory to a simple confinement time is no easy task An encouraging development of the experiments is that the impurity levels (~ 1 per cent of O and C) are insufficient to produce a crippling radiation loss

---

*Biennial IAEA nuclear fusion research meeting at Kyoto, Japan, 13–20 November 1986

Taken together, the experiments on the large tokamaks reported substantial improvements in temperature and confinement time arising from the larger dimensions of the new apparatus, from the pellet injection and the powerful additional heating There is a broad empirical basis for expecting further improvement in these parameters to be achieved on these installations, and there are good prospects that the extra experimental diagnostics and the theoretical efforts will lead to the required understanding of the transport process The question of whether even the largest of the installations, JET, can reach partial thermonuclear ignition in D–T fusion is not yet resolved, but tokamak research is clearly flourishing

From the experiments in other magnetic confinement systems reported at the meeting, progress is largely resulting from improvements to already established assemblies For example, a several-fold improvement in confinement time was reported from the HBTX reverse-field pinch experiment at Culham, resulting from careful elimination of defects in the magnetic field system However, the confinement time and temperature in these systems are below those achieved by the strong field stabilization of the tokamak, and are further from the theoretical ideal Both the Japanese (Heliotron E) and German (Wendlestein) groups are operating stellarators using essentially the same apparatus as before Big advances can be expected only when apparatus designed to explore more advanced conditions is brought into operation, for example, new stellarators under construction in Garching, in Canberra and in Oak Ridge, and the reverse-field pinch RFX at Padua

Lasers

Competition for the tokamaks was also reported from inertial confinement experiments, mainly from laser installations in the United States, the Soviet Union, Japan and Europe, but especially from the major new laser installation NOVA at Lawrence Livermore Laboratory, United States and Gekko 12 at Osaka with 70 and 30 kJ output pulses from neodymium glass and phosphate glass, respectively Temperatures of up to 10 keV and densities of up to 50 times liquid were reported Using neutron pulse duration as a measure of τ, the Livermore group reported 2–4 × 10^{20} m^{-3} s as a value $n\tau_E$ at 1 keV, but it was unable to give details of the derivation because its work is classified The direct implosion of D–T contained in thin-walled glass microspheres, where time-profiled radiation pulses were used to mitigate Raleigh–Taylor instabilities, were reported to give the best promise of a net useful energy yield Compression by hohlraum radiation was reported, as also were new target designs using CH_2 foam to stabilize the implosion Both groups reported neutron yields at record values of 10^{13} neutrons per pulse, corresponding to about 10^{-5} burn up of the pellet fuel, and a 2 × 10^{-3} energy yield compared with the absorbed laser energy The laser approach is hampered by the low energy efficiency of lasers, the first engineering tests of the pulsed beam fusion assembly (PBFAII) at Sandia laboratory are therefore important because the charged-particle beams offer the prospect of much higher efficiency The formidable technology problems of 30-MV pulsed transmission lines for nanosecond operation are being overcome, a liquid-lithium ion source based on a dense array of electrostatically induced Taylor cones (J Vandevender, Sandia) is being developed to provide ion emission intensities of 5 kA cm^{-2}

The impression given by these and about 20 papers from smaller installations in France, United States, Britain, China, Canada and Japan is that inertial confinement of high-temperature dense matter is a fast-developing area of physics with many new ideas and results The standard of experiments led by the new US and Japanese facilities is very high

In the sessions devoted to envisaged fusion reactors and reactor technology, one new feature was the first design of a fusion reactor based on the muon catalysed fusion reaction (S Elezier *et al* Israel and Texas), muon catalysis being the dark horse of the fusion race An outstanding feature of the engineering is the successful operation by Kyushu University, Japan of the first superconducting tokamak operating with $NbSn_3$ coils The first experiments with plasma use up to 170 kA and the full fields of 11 tesla (at the coils) There is agreement between experiment and theory on the important issue of shielding the superconducting winding from magnetic transients generated by violent plasma current disruption The engineering problems of the difficult $NbSn_3$ coils, which have delayed completion of the larger Soviet T-15 tokamak, seem to have been overcome in this relatively small scale (major radius 0 8 m) Triam apparatus

The generally bullish outlook on the potential for progress of the magnetic confinement approach to fusion was emphasized by the announcement (J F Clarke, Artsimovitch memorial lecture, 13 November, 1986) of a new proposal for international cooperation Following discussions at the Reykjavik summit meeting, the US government on 30 October transmitted a formal proposal to the Economic Summit nations and to the Soviet Union According to Clarke the proposal is to join together to prepare a conceptual design report (CDR) for an engineering test reactor The proposal indicates that the United States is prepared to commit sufficient resources to accomplish this task within three years If accepted, Clarke believes that this proposal could lead to a major commitment of international resources on preparing for an engineering the most widely accepted element of a common fusion plan ☐

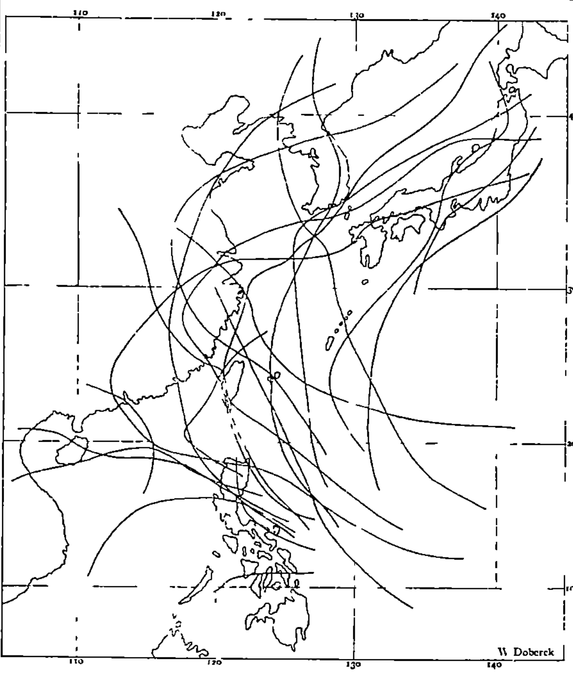
THE LAW OF STORMS IN THE EASTERN SEAS



From *Nature* 35, 135, 9 December 1886

PRINCIPAL typhoons 1884–1885 Nearly all the typhoons appear to have their origin east or south-east of the high-pressure area that covers the northern Pacific in the summer season, which part of the ocean is characterised by high sea-surface temperature Typhoons are sometimes formed in the China Sea, but then they seldom develop much energy, as they usually move quickly northwards and enter the mainland of China or Formosa Owing to their small dimensions they are easily avoided by such ships as may fall in with them If, however, a typhoon of this kind passes northwards up through the Formosa Channel, it soon becomes as formidable as any of those that originate in the tropical Pacific

Biological diversity

How many species are there?

Robert M. May

ONE of the first things that an extraterrestrial might ask about the planet Earth is how many species are on it. If this extraterrestrial had only our own current knowledge to rely on, the answer would be astonishingly vague: somewhere between 1.5 and 30 million species of plants and animals.

At one end of this spectrum, the number of genera and species of mammals, birds and other large animals are fairly accurately known. As summarized by Diamond[1] in a News and Views article last year, new mammals and birds continue to be discovered (at the rate of about one genus of mammal and three species of birds per year), mainly in the tropics. When we consider the insects and other smaller creatures, however, great uncertainties arise.

Until a few years ago, the uncertainties seemed somewhat less than they do today, and the total number of species was widely believed to lie in the range from 1.5 to 3–5 million. This estimate was obtained roughly as follows. For the species of mammals, birds and other larger animals that are relatively well enumerated, there are roughly two to three times more species in tropical regions than in temperate ones. The total number of species actually named and catalogued is just over one million. Most of these are insects. Indeed, to a good approximation, all species are insects! But most insects that have actually been named and taxonomically classifed are from temperate zones. Thus, if the ratio of numbers of tropical to temperate species is the same for insects as for mammals and birds, we may expect there to be something like two or three yet-unnamed species of tropical insects for every one named temperate species. Hence the overall crude estimate of a total of roughly 3 times the number currently classified, or around 3–5 million.

Estimated numbers of host-specific canopy beetles on *Luehea seemannii*, classified into trophic group (from ref. 3)

Trophic group	Number of species	Estimated fraction host-specific (%)	Estimated number of host-specific species
Herbivores	682	20	140
Predators	296	5	15
Fungivores	69	10	7
Scavengers	96	5	5
Total	1,100+		160

The dramatic upward revision of this estimate results from Erwin's careful studies of the insect fauna in the canopy of tropical trees[2-4]. Erwin used an insecticidal fog (generated by a machine hoisted into the canopy) to 'knock down' the canopy insects; because of their inaccessibility there have been few previous studies of the insect fauna in tropical canopies. Erwin's studies suggest that most tropical arthropod species in fact live in the tree tops, which is not so surprising as this is where there is most sunshine as well as most green leaves, fruits and flowers.

Erwin first collected the arthropods from 19 *Luehea seemannii* trees in Panama over three seasons[2,3]. This tree, a medium-sized evergreen of seasonal tropical forests, has an open canopy and large and well-spaced leaves. The trees chosen for sampling had few epiphytes or lianas, and yielded more than 1,100 species of canopy-dwelling beetles (including weevils), distributed among the categories of herbivore, predator, fungivore and scavenger as shown in the table. To use this information as a basis for estimating the total number of insect species in the tropics, one needs to know what fraction of the fauna are specific to the particular three species or genus under study. Unfortunately, as Erwin emphasizes[3], "No data are available with which to judge the proportion of host-specific arthropods [on trees] per trophic group anywhere, let along the tropics. So, conservatively, I allowed 20 per cent of the *Luehea* herbivorous beetles to be host-specific (that is, they must use this tree species in some way for successful reproduction), 5 per cent of the predators (that is, tied to one or more of the host-specific herbivores), 10 per cent of the fungivores (that is, tied to fungus associated only with this tree), and 5 per cent of the scavengers (that is, are associated in some way with only the tree or with the other three trophic groups)." The results summarized in the table (which is slightly modified from Erwin's work in that I thought it inappropriate to go beyond two-figure accuracy in the last column), suggest about 160 host-specific canopy beetles per genus-group of trees.

Several other assumptions are needed to extrapolate from the estimate of 160 host-specific species of canopy beetles per tree to 30 million species in total[3,4]. Slightly simplified, the argument runs as follows. First, Erwin notes that beetles represent roughly 40 per cent of all known arthropod species, leading to an estimate of 400 canopy arthropod species per three species. Next, he suggests the canopy fauna is at least twice as rich as the forest floor fauna, and is composed mainly of different species; this increases the estimate to around 600 arthropod species that are specific to each genus-group of tropical tree. Citing an estimate of 50,000 species of tropical trees[5], Erwin thus arrives at the possibility that there are 30 million tropical arthropods in total.

It is easy to cavil at each step of this chain or argument. For instance, the fact that 40 per cent of taxonomically classified arthropod species are beetles is of doubtful relevance if in truth essentially all arthropods are unclassified tropical canopy dwellers; what we need to know is what fraction of this canopy fauna consists of beetles. Furthermore, the overall estimate depends almost linearly on the necessarily arbitrary assumption that 20 per cent of the herbivorous beetles are specific to a genus-group of tree; changing this number to 10 per cent would halve the global estimate to 15 million species. Nor is it clear to me that each of the 50,000 species of tropical trees constitutes a 'genus-group' in the sense used by Erwin. These reservations do not, however, detract from my admiration of his work, which has advanced us to the point where we can begin systematic investigation of each of the links in his chain of argument; in comparison, the earlier estimate of 3–5 million is pure hand-waving.

There is a different argument, altogether independent of any of those I have discussed so far, which suggests the total number of species exceeds 10 million. A plot of the number of species as a function of the physical size of the constituent individuals (on a log–log plot) gives an almost linear regression line, with a slope around −2, for species with characteristic linear dimensions above 1 cm or so[6]. That is, for the relatively well-catalogued larger species a tenfold reduction in linear dimensions results in roughly a hundredfold more species; there are roughly 100 as many species of characteristic size 10 cm than of size 1 m. But as we move below 1 cm or so, the number of classified species falls further and further below the regression line that fits larger size categories[6]. Were this regression extrapolated down to around 0.5 mm, we would increase the species total from the known 1 million or so to more than 10 million. As we lack a fundamental understanding of the size-species relation itself, there is no reason to expect such a simple extrapolation to estimate accurately the number of unclassified smaller species, but it is interesting that the number is not inconsistent with

Erwin's more biologically based estimate.

Moving on to smaller organisms, we have to consider protozoa, bacteria and viruses. Some would argue that the species concept breaks down when applied to viruses and bacteria, with their recombining plasmids and the like. Others observe that the small number of species of 'microparasites' currently classified are disproportionately pathogens of *Homo sapiens*, and that a highly conservative estimate would be one such microparasite species particular to each species of invertebrate or vertebrate animal or plant. This would double the total species count at a stroke. Whether anyone cares for the preservation of these microparasite species is another question. A touching note in the Smithsonian Museum of Natural History records the passing in 1914 of Martha, the last passenger pigeon; no-one wept for the passing of the last wild smallpox virus. Many popular ecology books explain how predators help the prey species by culling diseased individuals, but I have yet to see the suggestion that microparasites are beneficial in supplying weakened prey to sustain predator populations.

In between the furries and featheries that excite compassion and the viral, bacterial and protozoan pathogens that we try to eliminate lie the insects, to which both taxonomists and conservationists have been relatively indifferent. Erwin's work is important in focusing concern on this huge class of animals that has been neglected for too long. □

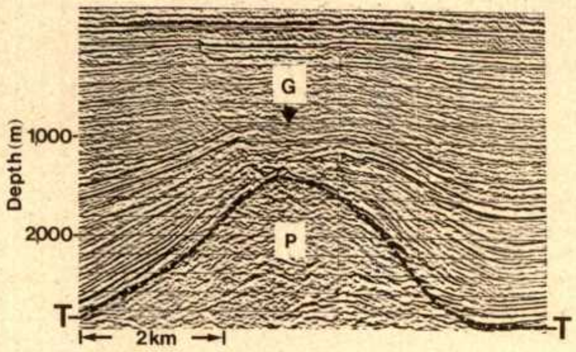
Halite rheology

Salt with a pinch of water

Malcolm K. Jenyon

THE connection between the rheological behaviour of the mineral halite (NaCl) in the presence of very small quantities of free water and radioactive waste disposal may at first seem obscure. There is a strong link, however, some aspects of which are described by Urai *et al.*[1] on page 554 of this issue. Adding to previous work[2,3], these authors go some way towards elucidating the marked effects on halite rheology of the very small quantities of brine inherent in a polycrystalline salt mass. The investigations have important implications for the determination of long-term stability in any rock salt body that is being considered as a repository of radioactive waste or for material storage. Their findings are also of importance in the wider field of salt tectonics.

Natural deposits of rock salt, the main constituent of which is halite, usually occur as members of evaporite cycles in stratified layers or as the thickened 'pillows' and piercement structure (diapirs) resulting from plastic deformation of the source salt layer. These salt masses are attractive as sites for material storage or waste disposal for two main reasons: first, rock salt at depth is impermeable to the types of material involved; and second, by solution mining it is relatively easy to create storage caverns in the salt of sufficient volume to be economically viable. Statistics of usage are not easy to come by (particularly in the case of radioactive waste), but as an example of use for hydrocarbon storage, Dreyer[4] mentions that about 140 caverns (most being in salt bodies) with a total volume of 22 million cubic metres were either completed or under construction in the Federal Republic of Germany in 1982.



Seismic section through a salt pillow (P) produced by plastic deformation of the salt source layer, the top of which is indicated (T). The overburden above T consists of Mesozoic and Tertiary clastic sediments. At G a collapse-graben is seen, resulting from subsidence of the overlying sediments into the incipient void following dissolution and removal of salt by under-saturated water circulation in overburden fractures above the pillow crest, and in the crestal zone of the salt feature. Thickened salt bodies of this type, and the diapiric (piercement) structures into which they frequently evolve, may be considered as sites for cavern construction and the storage/disposal of various materials including radioactive waste. Scales are approximate; vertical scale exaggerated approximately 2.5:1.

In the case of radioactive waste disposal, it is clear that determination of the long-term stability of a salt cavern is a priority for reasons of safety, needing a wide range of investigations to study the tectonic framework of the area (including the fault systems and local seismicity) and to measure the stability of the bedrock beneath the salt; that of the groundwater system; the permeabilities of salt and 'country rock'; the geothermal gradient; the internal integrity of the salt body itself; and the stress patterns and movement history of the salt body (see figure).

The question of the movement history of the salt body is important in assessing the long-term stability of any cavern that is constructed; however, the rheological behaviour of halite is still imperfectly understood. It is known that over a range of temperatures far below its melting point of about 800 °C, halite deforms plastically by intragranular dislocation and gliding, and probably by diffusive mass transfer (pressure solution) through thin, intergranular aqueous films. Increasing the temperature reduces the yield strength of halite, as does the application of differential pressure, although increasing the confining pressure seems to have a much smaller effect. The presence of free water also reduces the yield strength of halite; however, as a polycrystalline halite mass buried to depths greater than about 300 metres is thought to be impermeable (see, for example, ref. 5), the effect of free water on plastic deformation in buried salt masses has been little studied.

The work of Urai *et al.*[1] shows that water need not enter a salt body from outside for the weakening effect of free water to be a factor. The authors demonstrate that even the minute quantities of inherent brine in a salt body (that contained in fluid inclusions in the halite crystals, and particularly in intergranular films) may have profound effects on the rheology of salt. Of particular importance are indications that, whereas at higher strain rates the deformation mode is that of dislocation/gliding, at very low strain rates there is a transition to pressure solution, by grain boundary diffusion with dynamic recrystallization along the boundaries. Also, lattice diffusion can occur, with water molecules passing through the NaCl lattice, and this, together with the brine inclusions

available within halite crystals, may affect the dynamics of the dislocation mode of deformation.

The findings go a long way towards explaining apparent inconsistencies (based on current ideas) in salt deformation at different depths and in different areas of some salt basins. They may also explain unusual phenomena such as the marked increase in flow rate during the wet season of the rock salt under normal temperature and pressure at the surface in the emergent Hormuz salt diapirs of Iran, and also the Joffé effect, in which a halite crystal exhibits a marked increase in ductility when deformed under fresh water[6].

Plainly, the results obtained so far demand that attention is paid to the amount and distribution of inherent brine in the rock salt members of evaporite sequences in any basin, to make an effective analysis of the causes and results of plastic deformation. The message that low-stress conditions acting over long periods can produce significant plastic deformation in salt rock will have a considerable impact on our ideas about salt deformation in general. □

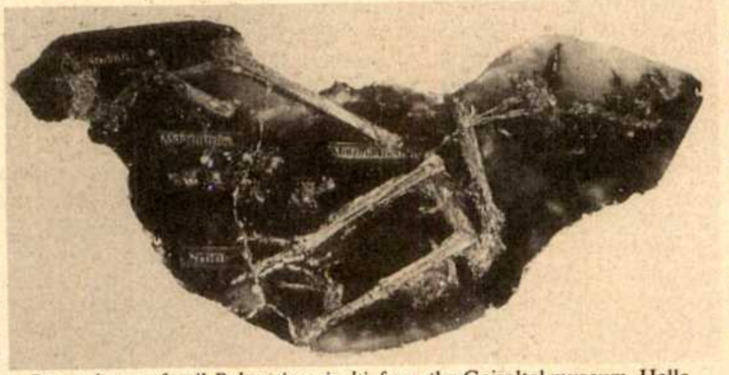
Phylogeny

The German 'ostrich' and the molecular clock

Michael E. Howgate

ONE of the major problems with molecular clocks is that they need to be located in an absolute time frame determined by the fossil record. Undoubtedly the best such clock available at the moment is the DNA–DNA hybridization clock of Sibley and Ahlquist[1], but Peter Houde on page 563 of this issue[2] argues that the DNA–DNA clock needs to be reset.

This molecular clock takes as one of its reference points the divergence of ostrich DNA from rhea DNA. This divergence has been timed from the break-up of the super-continent Gondwanaland which isolated the supposedly already ground-dwelling ratites (ostrich, rhea, emu, cassowaries and kiwi) on the different parts of the fragmenting supercontinent during the late Mesozoic. The palaeontological basis for such a reference point has always been weak as fossils ascribable to the modern genera of the ratites have not been found in strata lower than the Miocene. So it is purely speculative that the ratites were grounded before the break-up of the Gondwanaland supercontinent.



Boney issues: fossil *Palaeotis weigelti*, from the Geiseltal museum, Halle.

The ratites are a rather odd assemblage of ground-dwelling birds confined to the southern continents and with a basic overall similarity due to their adoption of a flightless condition. What separates them from most other birds, even some which have become flightless, is the relatively primitive, reptilian (palaeognathous) structure of the palate and the presence of rhamphothecal grooves in the mandible. The ratite paletal structure, which is shared with the tinamous (themselves poor fliers) of South and Central America, is intermediate between the palate of archosaurian reptiles and that seen in all other birds — the neognathous condition. This 'primitive' avian palate involves a characteristic arrangement of skull bones, with comparatively large vomers and palatines, the latter being firmly united to the pterygoids producing a less flexible skull than that observed in neognathous birds.

The current consensus of palaeontological and biochemical data indicates that ratites and tinamous are a monophyletic assemblage, although whether they arose from a neognathous ancestor or are primitively palaeognathous is still a matter of contention. Olson[3] outlines five possibilities to account for the palaeognathous condition of these birds: (1) that they are monophyletically derived from neognathous birds; (2) that such a derivation is due to neotony; (3) that their derivation is completely separate from the neognathous birds, with the different ratites evolving from a 'proto-tinamou'; (4) some living palaeognathes are derived from a primitively palaeognathous stock, whereas others are derived from one or more neognathous stocks; and (5) all living palaeognathes are derived from different neognathous stocks.

Houde now suggests that an assemblage of palaeognathous birds with well-developed wings and pectoral girdles — the *Linothis*-cohort — are the direct ancestors of all living ratites and evolved distinctive features of the ratite palate and bone histology during the Palaeocene and early Eocene in Europe and North America. This confirms the third of Olson's suggestions except that according to Houde the ratites diversified from a post-tinamous rather than a pre-tinamous condition. Houde further hypothesizes that a bird that retained the power of flight at this time must have flown to New Zealand to give rise to the extant kiwis, which retain some of the primitive characteristics of *Linorthis* that have been lost by other more derived ratites.

Meanwhile in Europe the *Linorthis*-cohort gave rise to an ostrich-grade palaeognath *Palaeotis weigelti* during the middle Eocene (see figure). Thus, ostriches appear to have evolved in Europe and subsequently emigrated overland to Africa at any time from the late Eocene onwards.

If the picture envisaged by Houde is correct and flying ratite ancestors inhabited North America and Europe during the Palaeocene and Lower Eocene and gave rise to an ostrich-grade descendant in the middle Eocene in Europe, long after the break-up of Gondwanaland, then the datum on which DNA–DNA hybridization data is tied in to the fossil record is out by tens of millions of years.

What may be true for ostriches may not apply to the other ratites, and although Houde does not mention it he must hypothesize an almost world-wide distribution for his *Linorthis*-cohort to explain the distribution of the ratites, and he does suggest they must have flown to New Zealand. The lack of fossil evidence for *Linorthis et al.* in the southern continents may only be Northern Hemisphere collecting bias and misidentification of the sort which plagues avian palaeontology. How else is one to explain the presence of the presumed flightless palaeognath *Diagenornis fragilis* from the Palaeocene of Brazil? The problem of the fossil record, however , does not conflict with his critique of the DNA–DNA clock; it is clear the calibration will require further scrutiny. □

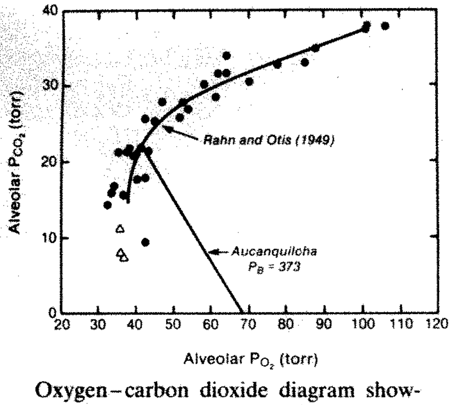
Highest inhabitants in the world

SIR—In 1935, members of the International High Altitude Expedition went to the Aucanquilcha sulphur mine in north Chile (21°12'S, 68°28'W) to study their own physiological adaptations to extreme altitude, and also to make some measurements on the local residents[1]. They described a group of miners who worked at the mine, which was said to be at an altitude of 5,800 m, but lived at an altitude of 4,340 m, preferring to climb 500 m on foot every day, which took about an hour and a half, rather than live at the extreme altitude of the mine.

The fact that the miners did not live at the mine itself has often been cited as evidence that people cannot live that high. Furthermore when eight physiologists on the Himalayan Scientific and Mountaineering Expedition of 1960–1961, under the scientific leadership of L.G.C.E. Pugh, spent up to 100 days in a prefabricated hut at an altitude of 5,800 m where the barometric pressure averaged about 380 torr, they seemed to confirm the view. In spite of reasonably good living conditions, ample food, and a healthy exercise programme, they steadily lost weight at the rate of 0.5–1.5 kg per week[2].

It is remarkable that although the Aucanquilcha miners have often been cited as the highest inhabitants of the world[3,4], and therefore are of considerable scientific interest, there is no report of them being visited by physiologists since 1935. Last year, however, I had the opportunity to visit the mine with the Chilean physiologist, Raimundo Santolaya, and was astonished to find that four caretakers were living at the mine itself in a galvanized iron hut. One man had been living there for two years when I met him, but most of the caretakers live there for shorter periods and they all descend by truck to Amincha (4,200 m) on Sundays to play football. Conversations with the manager of the mine made it clear that only a small subset of miners are able to tolerate the altitude. Nevertheless it is clear that some people can live at this altitude for indefinite periods of time. The miners are mostly Bolivian natives who normally reside between 2,000 and 4,000 m.



Oxygen–carbon dioxide diagram showing alveolar gas composition of both permanent residents and lowlanders acclimatized to high altitude. Most of the data were collated by Rahn and Otis[6]. The three triangles bottom left were obtained at extreme altitudes on Mount Everest[7]. Diagonal line shows respiratory exchange ratio of 0.85 for barometric pressure of 372 torr and predicts that the inhabitants at 5,950 m will have alveolar P_{O_2} and P_{CO_2} values of approximately 42 and 22 torr, respectively.

Although the 1935 expedition put the mine at 5,800 m, a 1972 large-scale contour map of the area (Institute of Military Geography, Santiago) puts it at 5,950 m. We measured the barometric pressure as 373 torr and a reading of 371 torr was made by R.B. Schoene in March 1986. The pressure–altitude relationship is latitude-dependent and the latitude of Aucanquilcha at 21° south is similar to that ot Mount Everest (28° north) where the relationship has been accurately measured[5]. This confirms an altitude of approximately 5,950 m.

Few physiological data are yet available on these men. The barometric pressure of 371–373 torr means that the P_{O_2} of moist inspired gas is only 68 torr. If their alveolar P_{O_2} and P_{CO_2} conform to the pattern previously described for acclimatized lowlanders and high altitude residents[6,7] they would have alveolar P_{O_2} and P_{CO_2} values of approximately 42 and 22 torr respectively (see figure). Arterial blood samples were taken from three of the men in March of this year when they were visiting Ollague (3,700 m P_B 490 torr) and these gave a mean haematocrit of 60.89 per cent which is similar to that of acclimatized lowlanders at a similar altitude[3].

Few people live permanently above 5,000 m even in the Peruvian Andes, or the Himalayan ranges of Nepal or Tibet. The caretakers of the Aucanquilcha mine apparently live at a far greater altitude than anyone else in the world.

I am indebted to R. Santolaya for making the arrangements to visit the mine, to R.M. Winslow for measuring the hematocrits and to R.B. Schoene for a measurement of barometric pressure.

Functions of leaf fall

SIR—Ford has suggested that leaf fall is the mechanism of excretion in vascular plants[1]. But to view the senescing leaf simply as an 'excretophore' may be to limit our vision. Some species may avoid accumulating high concentrations of heavy metals by removing them in senescent leaves[2]. The dead leaves of other species release allelopathic compounds which play an active part in interspecific competition[3]. And the maintenance — indeed the creation — of the plant's habitat, the A and B soil horizons, depends on leaf fall. The degree to which nutrient elements are withdrawn from leaves before they fall varies between ecological communities and correlates with the availability of nutrients in the soil[4]. Thus elimination of waste products of metabolism may not be leaf fall's only adaptive function.

A contrary view[5] is that higher plants have been able to derive a variety of selective advantages from their dead and dying parts, thanks to their 'modular' form of construction[6]. This allows parts of the organism to be shed without prejudicing the survival of the whole. The result is that as in life so in death and fall, leaves have been subject to many selection pressures and many functions are now achieved by the process.

The practical importance of all this is that it implies that leaf senescence is not simply an avoidable evil. The use of 'anti-senescence' genes or chemicals to increase leaf area duration and therefore yield in agricultural crops, may prove to be not quite as straightforward as has sometimes[7] been assumed.

Undirectional spin

SIR—When I wrote my paper on undirectional spin[1], which was recently referred to in *Nature*[2], I unhappily had not seen a paper[3] on this topic which preceded mine by a few years. This highly illuminating work, which overlaps mine hardly at all, is particularly to be recommended to your readers for its excellent simulations.

Detecting Earth-like planets

SIR—Angel *et al.*[1], while advocating the use of a 16 m diameter telescope optimized for infrared observations to search for Earth-like planets outside the Solar System, criticize my suggestion[2] of using an interferometric system, operating at optical wavelengths, for the same purpose. Their criticism supposes that the sidelobe levels would be objectionably high because of the optical imperfections in the interferometry elements but here we point out that there is a fundamental error in their analysis.

Sidelobe suppression is an important issue for both concepts. The interferometer that I discussed would consist of a number of telescopes of diameter D, deployed in an array with spacings larger than D, but not so large that a planetary disk would be resolved. The elements would be pointed away from, but still close by, the star in searching for planets, but photons from the star would cause a noise background because of the finite sidelobe response. The star could be used as a phase reference to stabilize the interferometer, thus allowing coherent integration, and the diffraction sidelobes would be minimized by apodizing the aperture illumination of the individual elements (which were 1.5 m telescopes in the example given). Still, there would be noise sidelobes introduced by surface irregularities in the optics and it is control of these sidelobes that was being questioned by Angel *et al.*

To summarize the causes of noise sidelobes, the usual definition of gain will be used; relative gain (sometimes called directivity) is the gain normalized to unity on the optical axis (this is the inverse of the definition given by Angel *et al.*). The gain contribution from the noise sidelobes at an angle (θ) off the optical axis will be denoted by $G_n(\theta)$. Intensity in the image plane will be the Fourier transform of the auto-correlation of the amplitude error in the aperture-plane phase front. The precise form of the sidelobes will depend upon the error distribution, but as a representative case let the errors have a random distribution, with an auto-correlation of the form

$$<y^2(\tau)> = <\delta^2> 1 - e^{-(2\tau/l)} \qquad (1)$$

for separation τ: ι is a correlation length and is the phase error. If the r.m.s. surface error is ε, then $<\delta^2> = (4\pi\varepsilon/\lambda)^2$. It then follows from the work of Ruze[3] that, for a uniformly illuminated aperture of diameter D with $\delta << \lambda$, the relative gain of the noise sidelobes will have the distribution

$$G_n(\theta)> = 8\pi^2(\iota/D)^2(\varepsilon/\lambda)^2 e^{-(\frac{1}{2}\pi l\theta/\lambda)^2} \qquad (2)$$

Physically, the gain distribution will be a speckle pattern extending over an angle $\approx (\lambda/l)$ with individual speckles of size $\approx (\lambda/D)$.

In their remark that "The speckles will look like a cluster of barely resolved stars of 21st magnitude, in which is hidden a 28th magnitude planet" Angel *et al.* misunderstand interferometry. The speckle pattern is derived from spatial frequencies less than (λ/D), whilst the interferometer fringes come from spatial frequencies much larger than (λ/D). Hence the interferometer fringe amplitude comes from the planet and not from the speckles, which only contribute the noise that was accounted for in the signal-to-noise calculation. Their assertion is, therefore, incorrect.

Angel *et al.*, in estimating noise sidelobes from their equation (1) for the quantity they call the gain, illuminate the fundamental issue. Equation (2) shows that the distribution of errors must be considered. The total power scattered from the main beam depends only upon ε, and if, for a given ε, l is small, the scattered power is distributed over a large angle, and the close-in sidelobe level will be low. That is why I chose l = 1 cm as the correlation length, giving a sidelobe suppression 1.6×10^3 greater than the example given by Angel *et al.*

On the other hand, if the only errors in the phase front were from large spatial frequencies, their objection would be well-taken. A beautifully polished surface, whose only errors in figure were on large scales, would be unsuitable for finding planets since all the noise sidelobes would be clustered close to the main beam. Thus, the example quoted by Angel *et al.*, who used l = 40 cm as the correlation length in their calculation, is concentrating on the wrong regime. Note that, in my discussion, a mirror diameter of 1.5 m was chosen for the receiving elements, because of the extensive industrial experience in making high-quality mirrors in this size range. Industrial suppliers, in informal inquiries, have indicated that achieving this precision of the element surfaces is an economic, not a technical, question.

In summary, it is far too early to choose between the optical interferometer and the monolithic infrared telescope for a planetary search, as both the optical and infrared approaches need more extensive study. The challenges are well-defined and there are no fundamental physical laws that forbid their solution.

B.F. BURKE

Department of Physics,
Massachusetts Institute of Technology,

1. Burke, B.F. *Nature* **322**, 340 – 341 (1986).
2. Angel, J.R.P., Cheng, A.Y.S. & Woolf, N.J. *Nature* **322**, 341 – 343 (1986).
3. Ruze, J. *Proc. Instit. elect. electron. Engng* **54**, 633–640 (1966).

ANGEL *et al.* reply—Burke has defined a mirror surface by equation (1) with l = 1 cm, showing that a relatively large r.m.s. error can be combined with very low sidelobes at 1/4 arc second radius. But this bears little relationship to the best optical surfaces currently made. In practice, errors are not confined to small scales of 'orange peel' and 'dog biscuit'. Zonal figuring, in particular, leaves circular waves on the crucial scale of 40 cm (λ/l = 1/4 arc s). For optical detection of a planet at this radius with apodized 1.5 m mirrors, sidelobes of 10–7 peak intensity need surface accuracy of about 1 Å r.m.s. on a scale of 40 cm, regardless of finer imperfections. By comparison, figuring errors on this scale are about 50 Å r.m.s. in the Hubble Space Telescope mirror. We would find the case for optical planetary detection more convincing if suggestions were given for dramatic breakthroughs in figuring, testing and support methods.

Does the use of an interferometer help, given an overwhelming need for high contrast rather than spatial resolution? For overcoming the photon noise of scattered light it offers at best no advantage over a single dish of the same area. The array gain cannot be better than the value of $D^2\theta^2/8\pi\delta^2$ given in our paper, where D is the diameter of the single dish that collects the same light. The character of the background is the same as the speckle-fringe convolution familiar to observers with ground-based optical interferometers[1], except at an appropriately reduced intensity level. As in the case for the single 8 m dish analysed in our paper, by morphology there is no way to distinguish a planet from the much brighter scattered starlight fringes. Only if the interferometer baseline is 40 m or more will a solar-type star at 4 pc be resolved and the scatterd light modulation be reduced. But an interferometer with so large a baseline, if arranged for good ultraviolet plane sampling, loses efficiency. Much of the planetary energy appears in parts of the diffraction pattern of low surface brightness[2], and the signal to noise ratio becomes much less than optimum.

We conclude that neither the optical spectrum nor interferometry are suited to this problem. The infrared telescope with filled aperture that we described has improved contrast and reduced scattered light for a given figuring precision, and can be accurately aligned by correcting for errors sensed at optical wavelengths.

Announcing a major, new publication from The British Mycological Society

Covering all aspects of fungi and their uses in science, industry and conservation this exciting new journal will be launched in January 1987. Written mainly for the professional mycologist, **The Mycologist** will appear quarterly and is published by Cambridge University Press. Regular features will include mycotechnology, photographing fungi, identification of fungi, book reviews, developments in mycology and news of international mycological associations. **The Mycologist** is available on subscription for £6.00 ($12.00) per annum.

NEW

THE SOFTWARE DIRECTORY FOR MOLECULAR BIOLOGISTS

Christopher Rawlings

This single volume brings together the scattered information on software available to molecular biologists.

The Software Directory compares and critically appraises specialized software for molecular biology, and also provides you with concise descriptions of commercial and business software applicable to laboratory work.

Each entry covers functional features, machine type, computer manufacturer, operating system, and author or company. The book also contains a thorough index of all the software listed, under seven different headings (the five above, plus package name and keyword)—so that you can always find the software that is right for your work, quickly and easily.

The all-new *Software Directory for Molecular Biologists* gives you accurate information on all known software in the field—commercial or non-commercial. You will save time and money with this invaluable guide.

"... the series should become a standard reference work."
Medical Laboratory Sciences

Monographs on Pathology of Laboratory Animals

Sponsored by the International Life Sciences Institute (ILSI)

Editor: **T. C. Jones,** Harvard Medical School

These monographs provide authoritative microscopic and ultrastructural descriptions of naturally occuring or experimentally induced neoplastic and nonneoplastic lesions in several species of laboratory animals. The identifying pathologic features are correlated with toxicologic, biologic and behavioral data as well as with data from other species including man.
The international editorial board critically reviews all manuscripts. The frequency of specific lesions in different geographic regions and laboratory environment are depicted graphically.
The volumes make use of an internationally accepted nomenclature to improve worldwide communication among scientists, industries and governmental agencies investigating the safety of foods, drugs and chemicals subject to animal tests.

Urinary System

Editors: T. C. Jones, U. Mohr, R. D. Hunt

1986. 36 figures, 44 tables. XVIII, 405 pages.
Hard cover DM 265,–. ISBN 3-540-16591-6

As in other volumes of this series, the structural aspects of natural and induced disease are used to identify specific lesions of the urinary system. The biologic significance of each lesion in then explored in detail for the rat, mouse and hamster. The effects of genetic and environmental background are evaluated whenever possible, and differences are described between species and strains of laboratory animals.

Digestive System

Editors: T. C. Jones, U. Mohr, R. D. Hunt

1985. 352 figures, 24 tables. XVIII, 386 pages.
Hard cover DM 292,–. ISBN 3-540-15815-4

Respiratory System

Editors: T. C. Jones, U. Mohr, R. D. Hunt

1985. 279 figures, 20 tables. XV, 240 pages.

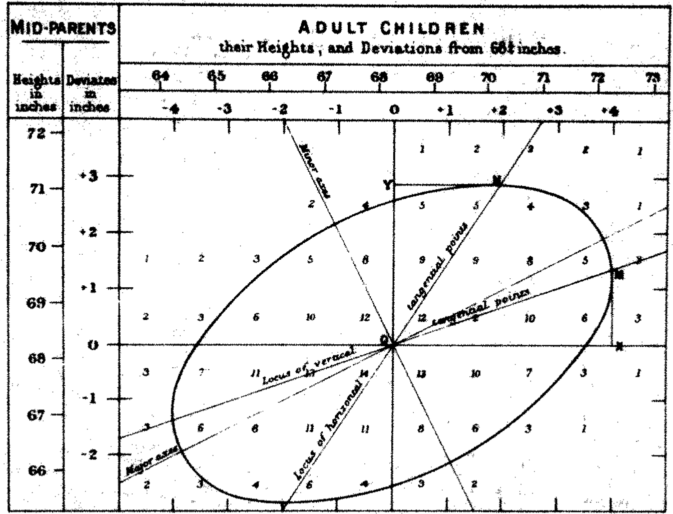
Meaning from numbers

Ian Stewart

The Rise of Statistical Thinking 1820 – 1900. By Theodore M. Porter.
Princeton University Press: 1986. Pp.333. $35, £23.40.
The History of Statistics: The Measurement of Uncertainty Before 1900.
By Stephen M. Stigler. *Harvard University Press: 1986. Pp.410. $25, £21.25.*

THERE are many histories of mathematics. Statistics, a younger science, has been comparatively neglected. But now we have the happy conjunction of not one, but two fascinating books that describe the origins and early development of what is arguably *the* mathematical tool of this century. Both are scholarly yet readable; both cover the same period; and both are published by Ivy League presses. There the resemblance ends, and the books largely complement one another, the main overlap being the underlying historical reality.



Work of stature — Galton's 1886 plot of children's height against the average height of their parents, suitably smoothed to show the "series of concentric and similar ellipses" which brought together his ideas about regression in a single elegant mathematical package. (Reproduced from The History of Statistics.*)*

The Rise of Statistical Thinking avoids technicalities and concentrates on the flow of ideas between the natural and social sciences. It emphasizes the philosophical issues raised by novel statistical methods, and how they affected the subject's development. If it has a flaw it is that the technicalities have been smoothed away a little too much, so that one forgets that the founders of the subject were grappling with difficult mathematical, as well as social and philosophical issues.

The History of Statistics is stronger on the mathematical developments involved, especially the early history of probability theory, and is organized a little more explicitly around a selection of key figures. Mathematical detail is especially evident in the first half, where Stigler describes the contributions to probability theory of mathematicians such as Legendre, Laplace, Bernoulli and Gauss. This tends to give the impression that mathematicians have no part in human affairs except by virtue of their mathematics, whereas Laplace, for example, took a great interest in the implications of his work.

The most striking feature of the story is that both the "hard" and "soft" sciences played decisive roles in the development of statistics, and that important ideas and methods were transferred between them — in both directions. To illustrate this in microcosm, consider the "error law" or normal distribution. The name "error law" originated in the work of eighteenth-century astronomers and mathematicians, who, in trying to calculate the orbits of celestial bodies, were forced to take account of the effects of observational error. The idea was transferred into social science by Adolphe Quetelet. He was impressed, for example, by Laplace's probabilistic analysis of whether atmospheric pressure was subject to a regular cause of diurnal variation, and applied such analysis to everything he could think of: measurements of the human body, crime, marriage, suicide. By the early 1870s the idea had moved back into the physical sciences, with the development of statistical mechanics. In his book, Porter points out that both James Clerk Maxwell and Ludwig Boltzmann emphasized the success of the error curve in social science to justify importing it into physics. For example, in 1872 Boltzmann wrote:

> . . . the molecules of a body are indeed so numerous, and their movements so rapid, that nothing ever becomes perceptible to us except average values. The regularity of these mean values may be compared to the astonishing constancy of the average numbers furnished by statistics . . .

Quetelet was quick to draw general conclusions from the supposed constancy of mean values of social and anthropometric variables, and was the originator of the tantalizing notion of the "average man". He was influenced by the philosophy of Victor Cousin, and the idea of the *juste milieu* which simultaneously emphasized the supremacy of the bourgeoisie and embodied ideals of political moderation. To Quetelet, the "average man" was not just a mathematical abstraction, but a moral ideal. Others disagreed, and the applicability of the error law became highly controversial.

For Francis Galton, like Maxwell and Boltzmann, the error law was a means, not an end. Galton's interest in it arose in a curiously incidental way. A friend of his, William Spottiswoode, wrote a rather dreadful paper applying it to the alignment of mountain ranges. This paper drew Galton's attention to Quetelet's work.

Galton strongly opposed the interpretation of the law that anything exceptional was a flaw. To astronomers, variations in observations were errors, and the aim of the error law was to eliminate them. To Quetelet, deviation from the mean was a sign of moral or physical imperfection. To Galton, however, the variations themselves were the interesting phenomena, and the last thing he wanted to do was eliminate them. Galton, indeed, was the founder of eugenics, and he laid the ground for the "nature–nurture" debate. Always a forceful figure, in 1877 he campaigned to have Section F of the British Association — Statistics and Economic Science — expelled, because it wasn't mathematical enough. He also used the methods of social statisticians to debunk conventional religion: the most notorious of his writings on the subject was *Statistical Inquiries into the Efficacy of Prayer* in which he observed that sovereigns, whose lives were the object of regular prayerful appeal by entire nations, lived no longer than other members of the upper classes. Clergymen had a similar lifespan to physicians or attorneys. Insurance companies charged the same premiums to missionary ships and slave vessels.

Galton's most important contribution, to which Stigler devotes the best part of a chapter, was the idea of regression. Galton could not understand why the degree of variation of a characteristic did not increase from one generation to the next. Surely Quetelet's error law, with its implications of underlying homogeneity, *denied* the possibility of inheritance of characteristics? He eventually realized that a normally distributed mixture of normal distributions would combine to give one overall normal distribution. Each characteristic could follow its own error law. He built a mechanical device, the quincunx, in which lead shot bounced off pins (effectively performing a random walk), to demonstrate the principle. ▶

Comparing the distribution of the heights of children to those of their parents, Galton smoothed the data and obtained a dramatic example of what would now be called a multivariate normal distribution. This led him to the idea of regression lines and gave rise to the analysis of variance.

These ideas were taken up by Francis Ysidro Edgeworth, Karl Pearson and George Udny Yule, who between them took statistics into the twentieth century. According to Stigler, "Even in the varied world of nineteenth-century statisticians . . . Edgeworth was an anomaly". He was a classicist with no higher mathematical training who, while studying law, also undertook a massive programme of self-instruction in mathematics. From the beginning he sought links between mathematical ideas and areas such as psychology, economics and ethics. Soon he began to enquire into the statistical significance of irregularities in observations. At the jubilee meeting of the (Royal) Statistical Society he presented a paper on significance testing for the mean, and went on to develop an even more important idea: the correlation coefficient. Edgeworth changed the focus of statistics. Originally it had been about errors in observations. Now it was about the analysis of structure in data.

The nineteenth-century statisticians placed so much emphasis on the normal distribution that one might be forgiven for assuming that they recognized no other distribution curve. This is not entirely true, but they did expect observations of a single, homogeneous phenomenon to conform to the normal curve. Pearson challenged that viewpoint, and in his first publication on statistics he outlined an extensive theory of skew, or asymmetric, distributions. The full version ran to over a hundred printed pages and led to his election to the Royal Society. Pearson, whom Porter describes as a buccaneering type, was forever trying to grab new territory for statistics; in one memoir he applied his theories of skew variation to 14 examples, including the sizes of crabs, the American divorce rate and the number of petals on buttercups.

Yule was a student of Pearson, and when he arrived at Pearson's laboratory in 1893 he was probably expecting to study applied mathematics. But by 1895, says Stigler, "he was a statistician", and one showing signs of growing independence. Yule applied Pearson's skew curves to data on the frequency of paupers per poor-law union (combination of parishes for administrative purposes). Soon after he applied correlation methods to show that, contrary to assertions of Charles Booth in *The Aged Poor*, there was a relation between (in modern terms) the ratio of direct welfare to work-relief, and the incidence of poverty. In Yule's hands, Galton's eugenic idea of regression became a universal (though still controversial) tool for the analysis of cause and effect.

Thus, by 1900, the main foundation stones of classical probability theory and statistics had been laid. Both authors sensibly stop there, rather than plunging into the technical intricacies of the twentieth century. These are two important and substantial books which, between them, give a great deal of insight into the creation of a fundamental branch of science. In particular it is instructive to witness the way in which general mathematical concepts evolved from a morass of special problems about an enormous variety of topics, at a time when the most difficult question was to find the right questions to ask. □

Northern waters

W.J. Gould & D.G. Masson

The Nordic Seas. Edited by Burton G. Hurdle. *Springer-Verlag: 1986. Pp.777. DM 198.*

"HAFVILLA" is a term used in the Norse sagas to denote getting totally lost at sea. In the scientific sense, *The Nordic Seas* might well provide us with a safeguard against such a fate.

The editor has collected together lengthy contributions from leading authorities in their respective fields, and has produced an impressive reference book on the oceanography (including studies of ice and climate), geology and geophysics of the seas lying between Norway and Greenland.

As is inevitable in such a compilation, there is a degree of duplication of material — for example between the chapters "Brief Overview of the Physical Oceanography" and "The Arctic Waters" — but this is a minor criticism. Over 200 pages are devoted to climatology, ice cover, oceanography (including sound speed) and tides, while the remaining 400 or so deal with geology and geophysics. A surprising omission is any mention of biology, because the subject is of interest to some physical oceanographers and the Nordic Seas are an area in which a great deal of work has been carried out on the relationships between physical and biological indicators and on the effect of physical parameters on fisheries.

The latter part of the volume deals with topography and geology. Much has been written on the geology of the area in recent years but this is the first truly comprehensive review, discussing everything from superficial sediments to sound velocity in the mantle. With its detailed subject index and comprehensive bibliography, it is an excellent "geological dictionary" and will be indispensable for those interested in the Nordic Seas and surrounding areas.

John S. Shelton

Outstanding feature — the 500-m high Ship Rock in New Mexico, a volcanic pipe which was exposed by erosion of its enclosing rock. The picture is taken from M.J. Selby's Earth's Changing Surface: An Introduction to Geomorphology, *published by Clarendon earlier this year. The book will be reviewed in* Nature's *annual textbook issue on 12 March 1987.*

The geological section has its disappointments, however. There appears to be little purpose in the straightforward description of bathymetry (Chaper 9), particularly because it is largely repeated and explained in terms of the underlying geology in the first part of the following chapter. Chapters 10 and 11 are simply too long; much of the considerable volume of data from areas peripheral to or analogous to the Nordic Seas could probably have been omitted without detriment to the overall content. Too much emphasis has also been placed on explanation of even the simplest geological terms — surely inappropriate in a work intended primarily for experts in the field. Finally, although it is otherwise well produced the book suffers from poor reproduction of many line drawings, to the extent that the chapter on bathymetry loses almost all of its impact because contour lines on the charts are invisible and only the annotation remains.

But the merits of the volume greatly outweigh the flaws. *The Nordic Seas* will find its way into the libraries of a wide range of scientific establishments and will be much referred to. It is as up to date as could possibly be expected and will remain as a key document for many years. □

W.J. Gould and D.G. Masson are at the Institute of Oceanographic Sciences, Brook Road, Wormley, Godalming, Surrey GU8 5UB, UK.

Parasitic puzzles

Sydney Cohen

Living Together: The Biology of Animal Parasitism. By William Trager. *Plenum: 1986. Pp.467. $71.40.*

William Trager has been a dedicated student of animal parasitism throughout his 50 years on the staff of the Rockefeller Institute in New York. During most of that time the subject was a relatively neglected one. The simpler prokaryote parasites and their host interactions are more amenable to study and received much greater attention. The recent surge of interest in animal parasitism reflects an increased awareness of the global impact of animal parasites as human pathogens, but stems also from several technological advances which have transformed the feasibility of carrying out experiments in the subject. Among such advances is Trager's own most notable scientific achievement, with Jensen in 1976, of cultivating for the first time the human malaria parasite, *Plasmodium falciparum*.

Animal parasites are extraordinarily complex and adaptable organisms. During successive life cycles in different host species, individual parasites may assume forms so disparate as to have been originally regarded as separate species. Alternating life cycles may also involve abrupt changes in metabolism, such as the switch from the glycerophosphate oxidase system of the bloodstream form of African trypanosomes to the cytochrome-mediated respiration of the insect form which is non-infective for its mammalian host. The study of animal parasitism is therefore basically an attempt to understand the sequential control of gene expression which generates alternative parasite forms adapted to recognition, penetration, growth and reproduction in hosts as different as (for example) the sandfly and man. In addition, the student of animal parasitism must attempt to delineate the complex reactions of the host to invasive challenge.

In confronting this daunting task, Trager deals first with a series of fundamental biological events. He starts with parasite recognition and entry into the host, and their attachment to and penetration of specific host tissues and cells. There follows a discussion of the interface between host and parasite and the molecular exchanges across these surfaces that are vital for parasite survival. Host reactions to parasite invasion are considered in relation to innate immunity, the important and often mysterious role of the spleen, acquired immunity and the pathogenesis of parasitic disease. In the latter part of the book, phenomena of parasitism are discussed in relation to a selection of specific protozoan and helminthic parasites of human beings and other vertebrates that are currently the centre of research work. The closing chapters deal briefly with symbiosis and with the methods traditionally used for the control of parasitic diseases, namely, chemotherapy and ecological methods such as vector control.

Throughout the text, Trager draws attention to the innumerable questions raised by the phenomena he describes. In a few instances these can be satisfactorily accounted for in molecular terms. For example, we at last have an answer to the long-standing puzzle of why West Africans and their descendants in the New World are totally refractory to infection with *Plasmodium vivax* and yet are susceptible to the other plasmodial species that infect mankind. Also, the means whereby the sickle-cell gene engenders resistance to infection by malignant tertian malaria is understood in detail. A great deal is also known about the structural and genetic basis of antigenic variation in African trypanosomes which mediates their evasion of potentially lethal immune attack by the mammalian host. For the most part, however, the biological phenomena described by Dr Trager with arresting simplicity provide a Pandora's box of puzzles which will stimulate and challenge future generations of molecular pathologists. The answers — when they come — will illuminate not only the mechanisms of animal parasitism but also our understanding of biological differentiation.

In his introduction to the book, Joshua Lederberg remarks that descriptions of the lives and adaptations of animal parasites are "a veritable Arabian nights of narrative, not of the human imagination, but of Nature's". The subject is indeed a fascinating one, and also is of great consequence in human health and welfare. This book, distilled from a lifetime's work, and set out in uncluttered style with abundant illustrations, will be read with profit and enjoyment by a wide audience including both aspiring and established molecular parasitologists. During the past decade many imaginative initiatives have transformed the study of animal parasitism by bringing together research workers from a variety of disciplines. Dr Trager's book will give further impetus to recruitment into this engrossing and important area of research. ☐

Sydney Cohen is Emeritus Professor of Chemical Pathology in the United Medical and Dental Schools of Guy's and St Thomas's Hospitals, London SE1 7EH, UK.

Unsure accuracy

Alan J. Charig

The Riddle of the Dinosaur. By John Noble Wilford. *Faber & Faber/Knopf: 1986. Pp.304. £14.95, $22.95.*

One might assume from the title that this is just another book on dinosaurs; after all, there are already so many on the market that thinking up a new title must always be a problem. But the exact wording hints strongly at the distinctive nature of this excellent volume. For it is not a descriptive work, listing the various genera of dinosaur and giving an account of the anatomy, physiology and habits of each, nor is it even concerned with their evolutionary history; rather does it deal with the history of dinosaur discovery, with dinosaur research and with the many controversies (both past and present) that bedevil the life of the dinosaurologist.

The text has been well researched and is factually correct. It is also stylishly written, and is *interesting*, even to the professional dinosaur worker. Most important of all, it reports on the controversies in a balanced, impartial manner, often coming to no positive conclusions but leaving the reader sitting on the fence — which, in our present state of knowledge, is in many cases the proper place to be.

The author has based much of his book on interviews and discussions with well-known scientists active in the dinosaur field. Since he himself is an American, a Pulitzer Prize-winning science correspondent for *The New York Times*, it is understandable that those people he chose to talk to were all from the United States; the book therefore gives the impression that dinosaurology today is an almost exclusively American subject. His historical perspective nevertheless embraces a fair amount of material from outside North America; it includes — as it must — the story of the first discovery of dinosaur remains, in England, and the initial perception, by Mantell and subsequently Cuvier, that reptiles of enormous size and (as originally conceived) herbivorous diet had existed in Mesozoic times.

My only complaints are to do with the illustrations, which are extremely few. One of them, the family tree on p. 189, is familiar; I recognize it from another volume, although its source is nowhere acknowledged. In the middle of the book are seven colour restorations by Douglas Henderson; his dinosaurs look wooden and his pictures as a whole have neither scientific nor aesthetic appeal. Moreover three of the seven are given the wrong date.

That notwithstanding, here is a book that no dinosaur addict — be he a professional or one of those innumerable keen amateurs — can afford to be without. ☐

Is the reductionist beyond belief?

William Paton

God and the New Biology. By Arthur Peacocke. *Dent: 1986. Pp.198. £10.95. To be published in the United States by Harper & Row.*

"THE brain secretes thought as the liver secretes bile; and you are all just bundles of conditioned reflexes". With this ending to his lectures on the alimentary tract, my physiology professor, the late John Mellanby, leant on his elbow on the lectern, and beamed at us. Although he seemed a pretty implausible reflex-bundle himself, that, 50 years ago, was my first introduction to reductionism. A.J. Ayer's *Language, Truth and Logic* was also giving logical positivism a brisk run. An advanced cleric of the day, L.W. Grensted, was said to believe that "There is no God, men are monkeys and there may be spooks". To the eye today, it was all good clean fun.

Faith, reductionism, the "enfant terrible" and the "advanced cleric" are still with us — but the antitheses are less sharp. The church has learnt to face the criticisms of rigorous scholarship, and science that the ethical problems it can create need ethical principle not of its making for their resolution. Leaders of science and religion are now less prone to pronounce at each other's expense.

THE MANAGEMENT OF AIDS PATIENTS

Edited by DAVID MILLER, JONATHAN WEBER and JOHN GREEN

The Management of AIDS Patients is the first comprehensive guide to the practical clinical management of patients with AIDS or HTLV III infections. The book avoids the sensational aspects of the disease, offering solid advice and information for all people involved in patient care.

The editors and many of the contributors come from St Mary's Hospital, London one of the foremost centres in Britain for the treatment of AIDS patients. The knowledge and experience of these experts has been combined to provide a much-needed book for doctors, nurses, dentists and indeed for health-care professionals everywhere.

M MACMILLAN PRESS

Dr Peacocke's book on biological reductionism is admirably consonant with this atmosphere. He is well-qualified; a physical biochemist and tutor in Oxford, who took orders, became a college chaplain in Cambridge and is now director of the Ian Ramsey Centre in Oxford, an institution recently founded for the study of ethical problems in science and medicine. The book pulls together his thinking over a number of years.

His conclusion is best given in his own words (though they are more precise than colourful):

> It *is* possible for higher level concepts and theories... to be non-reducible to lower level concepts and theories, that is, they can be autonomous. At the same time one has to recognise the applicability of the lower level concepts and theories (for example, those of physics and chemistry) to the component units of more complex entities and their validity when referred to that lower level. That is, with reference to biology, it is possible to be anti-reductionist without being a vitalist. Higher level concepts and theories often refer to genuine aspects of reality at their own level of operation and we have to eschew any assumptions that only the so-called fundamental particles of modern physics are "really real". To do so is indeed a kind of "fundamentalism" of a pseudo-scientific kind that is as much to be avoided in impartial enquiry as its religious namesake.

The book is a critical review of a rather extensive literature on and around the "reducing" implications of modern biology, molecular biology, genetics, evolution and sociobiology (but, deliberately, not neuroscience).

Dr Peacocke finds a genuine middle ground. The reductionist refuses to accept any "extra" (for example, entelechy or vital principle) beyond the laws of natural science in order to explain natural phenomena. The anti-reductionist finds it inconceivable that the full variety of biology and human life can be so explained without it. But molecular biology and genetics do bring one striking gift: the breadth of their explanatory power shows how, from simple elements, systems of astonishing complexity and richness can arise. Randomness presents itself not as some irrational intrusion, but as a source of creativity. And it seems that in these new systems, there is a kind of autonomy. Social behaviour, for instance, may indeed depend on the existence of intermolecular forces, but it is to be discussed and experimented on in terms of its own concepts rather than, say, that of the Van der Waals equation. So, too, the B Minor Mass is a "mere" assembly of diatonic tones — yet we have to understand and discuss it in musical, not acoustic language. If, still on the threshold of knowledge, we can already see that in the primary chemical elements there lies the potential for the synthesis of proteins and enzymes, and cell replication, cell-constituent assembly, speciation, learning and association, what may there not be still to be revealed?

Like other intermediate positions, it may not satisfy. Does it leave, for the Christian, room enough for a God with a loving personal relation to his creation? Does it provide, for the reductionist, too much room for self-deceiving religious aspirations to creep in? Perhaps it is not so much the possible existence and human awareness of some higher being that can most worry a scientist, but the idea of that being interfering with the natural course of events, with "natural law". Yet the question is not much different from the age-old one of whether our own day-to-day decisions (seemingly "free") actually modify events or not. If our belief in the one influence is valid and compatible with natural law, why not the other?

Dr Peacocke, though unequivocally Christian, is not, I think, pressing his views. His posture is like that of Bishop Butler in the *Analogy of Religion*, published almost exactly 250 years ago:

> It is come, I know not how, to be taken for granted, by many Persons, that Christianity is not so much as a Subject of Enquiry; but that it is, now at length, discovered to be fictitious. And accordingly they treat it, as if, in the present Age, this were an agreed Point, among all People of Discernment; and nothing remained, but to set it up as a principal Subject of Mirth and Ridicule, as it were, by way of Reprisals, for having so long interrupted the Pleasures of the World. On the contrary, thus much, at least, will be here found, not taken for granted, but proved, that any reasonable Man, who will thoroughly consider the Matter, may be as much assured, as he is of his own Being, that, however, it is not so clear a Case, that there is nothing in it.

For those who do not like to see people bludgeoned into belief, and who are also interested in the work of recent years by both a theologian and a scientist, Dr Peacocke's eirenic writing will be much welcomed. ☐

CONVENIENT·INFORMATIVE·TIMELY·PROVOCATIVE

FOUR DYNAMITE REASONS WHY YOU SHOULD SUBSCRIBE TO BIO/TECHNOLOGY NOW . . .

1. You'll save time. Because you don't have time to read every journal in the field, BIO/TECHNOLOGY is written and edited to give you all the information you need in ONE convenient source. BIO/TECHNOLOGY is the only journal to give you news. Features. Original research. Product evaluations. Industrial applications. Job openings. Book and product reviews. And more. If it's important to your work, you'll find it between the covers of BIO/TECHNOLOGY.

2. You'll learn new ways to improve your on-the-job skills and run a more successful operation. Each month BIO/TECHNOLOGY gives you the scoop on invaluable start-up information . . . the latest instrumentation . . . marketing breakthroughs . . . funding sources . . . new technologies . . . patents and licences. . . profiles on how others are avoiding the pitfalls and reaping the rewards. In fact, just one practical tip from BIO/TECHNOLOGY can be worth many times the cost of your subscription.

3. You'll be up-to-date on all major industry developments. With correspondents all over the world, BIO/TECHNOLOGY delivers the inside story on who's doing what, where. You'll get the latest word on changing government regulations and tax law, and how they affect your work.

Plus you'll read original research papers by bench scientists, engineers, and biologists that will help keep you in the forefront of every new discovery worth knowing about.

4. You'll get new ideas you can put to use immediately. BIO/TECHNOLOGY lets you rub elbows with eminent scientists, tour new facilities and learn how new processes work in every field from genetic engineering to molecular biology. Each month, BIO/TECHNOLOGY helps spark ideas for your own research, for new industrial applications and for getting along in the increasingly competitive financial arena.

If you're not already subscribing to BIO/TECHNOLOGY, don't delay the moment any longer - return the coupon below and we will send you twelve issues. You risk nothing. If for any reason BIO/TECHNOLOGY doesn't live up to your highest expectations, just let us know and you'll receive a full refund on all unmailed copies. Remember too, that your subscription may be tax deductible.

NATURE VOL. 324 11 DECEMBER 1986 COMMENTARY 523

The music of digital computers

Philip Campbell

More and more composers are relishing the unprecendented freedom provided by digital processors to manipulate both internal and external characteristics of sounds.

AMONG the most laughable events in the history of music—according to the cartoonists of the time at least (Fig. 1)— were the concerts of the Italian futurists during the first decades of this century. Depicted thus as sonic anarchists, contemporary photographs and manifestos nevertheless indicate the high seriousness with which, with the help of their 'noise-intoners' ('*intonarumori*'), the futurists fused the sounds of everyday machinery and mechanically synthesized noise into no-doubt outrageous cacophony. Though that artistic movement proved still-born, more recent figures, driven by a similar determination to escape what they see as the shackles of the past, have provided the composer with an instrument of more profound potential—the digital computer, capable of dissecting, transforming or synthesizing sounds according to a limitless variety of prescriptions.

The association of the computer with music goes back several decades. Composers such as Milton Babbit have used it since the 1940s to create ultra-rigorous twelve-tone music while, at another extreme, Iannis Xenakis has used it to inject a more statistical component into musical design[1]. Others have used computers for musical analysis and for modelling aspects of musical perception (see, for example, ref. 2).

But it is only now that the capacity of the digital computer is beginning to approach that required to make it a truly flexible tool for the creative musician—not a crutch by which deficient composers can save themselves work but a doorway to new paths of musical imagination, in particular those that encompass the microstructures of sounds.

In this article I shall concentrate on two particularly stimulating and poetic realisations of the computer's potential. Both, as it happens, were produced at what is currently the mecca of computer-assisted music, the Institut de Recherche et de Coordination Acoustic/Musique (IRCAM)—a subterranean establishment adjacent to the Pompidou Centre in Paris. The first, *Mortuos Plango, Vivos Voco* by the English composer Jonathan Harvey, is a composition on tape, about ten minutes long, which manipulates and intertwines only two sounds—a bell and a singing voice. The second, *Répons* by Pierre Boulez, is yet to be completed but, through several preliminary exposures, has already established itself as a benchmark in the use of computers to transform the sounds of musical instruments during a live performance.

Consider the scale of the problem. Beethoven's ninth symphony reaches our ears in the form of a complex pressure signal lasting about one hour. The frequency range of the best human ears extends upwards of 16 kHz; to satisfy them, a digital device wishing to reproduce the aural magic of, say, the Berlin Philharmonic must be able to synthesize or reproduce waveforms up to such frequencies—we can safely set the upper limit at 20 kHz. The principle of digital operation involves breaking up the continuous signal into a series of discrete samples and, because one has to have at least two samples per oscillation to reproduce a wave at a given frequency, we require a sampling rate of 40 kHz. Furthermore, the amplitude of the waveform as it varies from sample to sample must be resolved with good precision, otherwise noise ('quantization errors') will be introduced. Sixteen bits are usually considered as an adequate representation for each sample ($2^{16} = 65536$).

Thus simply to store Beethoven's ninth symphony in a digital memory requires about 14×10^9 bits; to synthesize it from scratch would represent a truly gargantuan feat of calculation (and perhaps a sterile one at that). For any instrument one might require a digital oscillator for each harmonic component of the waveform, each of a relative amplitude that, as it happens, varies according to the pitch and loudness of the note being played. Furthermore, to sound natural each harmonic component has to have the appropriate relative phase together with a small degree of random variability. Finally, the resulting tone has its own 'global' envelope determined by the composer's score, variable loudness as in a crescendo, for example, or perhaps a long sustained note of rapidly re-iterated attacks, a tremolando.

It is clear that to provide a flexible digital instrument for the composer requires truly formidable computer power. Necessarily, both of the pieces to be discussed here make do with considerably

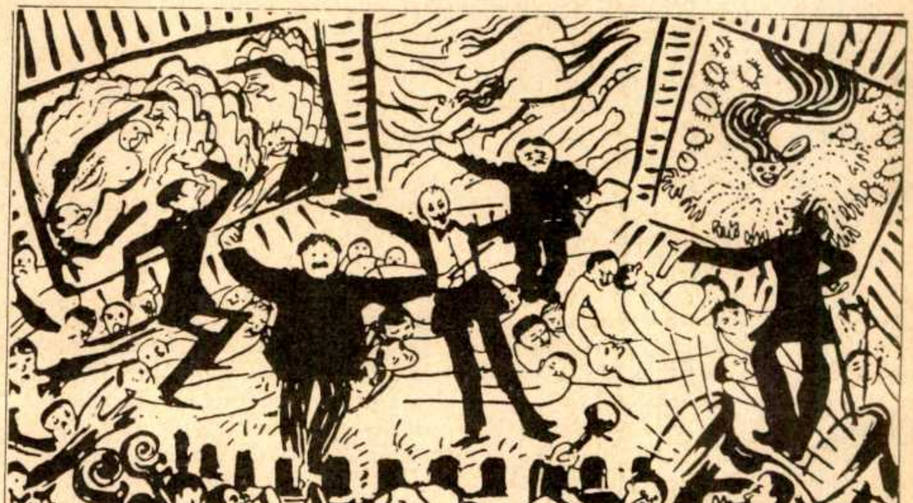

Fig. 1 A futuristic evening (Boccioni, 1911).

less than the full real-time synthesis described above. The tape of *Mortuos* was painstakingly accumulated over months of work in a studio (there is no musical score—to perform the piece one simply plays the tape). The live transformations of *Répons* primarily involve relatively simple arithmetic operations on incoming signals. Of course the musical power of such techniques springs not from their degree of sophistication but from the sureness of judgement with which they are married to strong ideas.

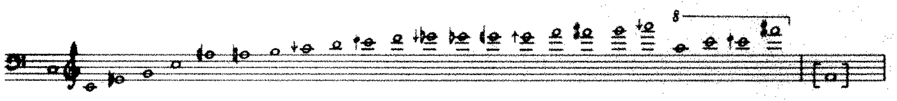

Fig. 2 Spectrum of the tenor C bell of Winchester cathedral in musical notation. The final F in parentheses is a fictitious harmonic, apparent only to the human ear deceived by upper harmonics[4]. Key: 𝄲 sharpened (raised) by a quartertone: ♯ sharpened by a semitone; 𝄳 flattened (lowered) by a quartertone; ♭ flattened by a semitone; ↑ adjusted by less than a quartertone.

The music of *Mortuos*

In the compact Norman tower of Winchester Cathedral can be found a set of seventeenth century bells, on the largest of which—the tenor C bell—are inscribed the words "*HORAS AVOLANTES NUMERO, MORTUOS PLANGO: VIVOS AD PRECES VOCO*" ("I enumerate the fleeing hours, I mourn the dead, I call the living to prayer"). Two sounds provide the basic elements from which *Mortuos* is constructed: the peal of this bell and the treble voice of the composer's son singing these words.

The publishers of *Nature* are, alas, insufficiently generous to provide the reader with a complimentary recording of *Mortuos*. Moreover the only commercial recording currently available[3] is unlikely to be found on the shelves of any but the most enlightened record stores (of which there appear to be none in London, for example). In the face of such obstacles, the following description of the music will have to suffice.

Any attentive reader of newspapers will have noticed the old trick by which his or her attention is sought—the classic first paragraph in which the essence of a story is presented with maximum impact. Harvey achieves precisely this, opening *Mortuos* with a vigorous carillon of bells which gradually declines in intensity until only two or three slowly pealing bells are left, over which the boy intones part of the inscription from which the title is drawn. Both bell and boy sounds, here and throughout the piece, are digitally synthesized or reproduced.

The significance of this carillon is greater than might be thought at a first hearing, when it is likely to appear as a random clustering of bell sounds. As it happens the composer is here representing in macroscopic terms the microstructure of the tones of the C bell. The harmonics produced following a bell stroke, which Harvey analysed (4) by a standard fast Fourier Transform, are shown in Fig. 2. During the reverberation these harmonics decay in descending order. This microprocess is writ large in the opening carillon in that each of the bells that simultaneously sound is repeatedly playing one of these harmonics; the higher the pitch of the bell, the more rapidly it repeats its stroke and the sooner it ceases, giving rise to the cumulative and compelling effect described.

Each of these 'bells' was synthesized with a spectrum identical, in relative terms, to that in Fig. 2, being simply a reproduction of the C bell transposed upwards in pitch. The reverberating tones of the C bell were digitally sampled and stored in a 'wave-table' within the computer memory which could itself be sampled at varying speeds, both backwards and forwards. This facility allowed Harvey not only to generate the opening carillon but also, later in the piece, to manipulate and overlay the pattern of decaying harmonics to yield subtle rhythmic effects or, by simply reversing the order of fading, to 'turn the bell inside out'[4].

Having caught his listener's attention with this declamatory exposure of his basic materials, Harvey proceeds to unfold the only element of the composition which might be called a 'theme': the slow succession of notes drawn from the C bell spectrum, shown in Fig. 3. Each note is played by bell tones 'faded' in and out so that successive notes overlap, their combined spectra providing a high frequency sheen above the notes. Such effects of timbre, together with harmonic juxtapositions such as that between an A♭ in the spectrum of the note F and the following A♮ of the "melody", all in the context of the quiet simplicity of the theme itself, combine to yield a memorable and beautiful statement.

This gesture opens the first of the eight principal sections of the piece, each of which begins with one of these thematic notes struck by a bell: within each section that note provides a basis for computer-aided musical development. Thus the entire piece adds up to an elaboration of the theme, all built with the materials presented at the outset.

In one sense the music is tonal (in contrast to the atonal style prevalent in music written over the last two or three decades), in that a pitch from which the material springs is fairly explicit at any point in the composition. The intervals within the primary bell spectrum, particularly the fourth, fifth and octave, pervade the piece—though a unique and essential flavour is added by those notes most removed from the well-tempered scale. But at no point is the writing harmonic in a progressive fashion (as in the classical style, where one chord leads to another via movement of the bass). In that sense the piece is static—a contemplation, if you like, of the inner life of certain sounds. Nevertheless, the flow of Harvey's invention creates a momentum of its own.

The techniques by which each of the thematic notes is elaborated within each section represent something of a showcase for the potential of the computer for sound sculpture. For instance the second section (based on G) leads to the third (F) by an unprecedentedly literal means of harmonic preparation: from a chord comprised of a combination of boy and bell tones, some of the notes suddenly slide upwards and/or downwards in pitch (an effect known as a glissando) to arrive at a new set of notes forming part of the spectrum of the F bell stroke which follows. Here it is the synthesized voices of the boy which execute the glissandi whereas, in the third section, it is the sine wave components of the bell that do the work in what turns out to be a study of glissando manipulation.

In the fifth section such simultaneous glissandi, executed in clusters of voices with added reverberation, provide a spectacular quasi-choral backcloth. Harvey organises and overlays the glissandi so as to generate a sense of chordal progression behind fragments of text sung solo in the foreground.

Each section of *Mortuos* exhibits at least one distinct facet of the digital computer's ability to render malleable the internal as well as the external characteristics of sounds, varying the juxtaposition of the harmonic components such that bell and boy at times merge imperceptibly into one another—with the bonus of spatial effects added by means of the eight tracks of the tape which can be independently routed to different speakers.

The eighth section provides a final example. Here the synthesized C bell peals with slow repetition while a choir of boys

Fig. 3 The eight primary pitches from the bell spectrum which define both the 'theme' and the principal sections of *Mortuos*.

periodically 'tolls' a dissonant note cluster derived from the C bell's spectrum. But the harmonics of the bell are differentiated by the manner in which their loudness is varied. Some are sustained over many strokes while the majority follow the pattern of impact and subsequent decay, but with added slow variation within the overall decay envelope. This simulates the effect of the swing of a bell—for a static listener, the perceived spectrum varies cyclically with the changing orientation. And in an inspired final gesture, Harvey removes the initial sounds of the impacts, maintaining the 'swinging' effect within the fading peals. It is as if the air itself were echoing the vanished bell.

Synthesis in *Mortuos*

The techniques used by Harvey (together with his technical assistant at IRCAM, Stanley Haynes) represent an appreciable proportion of those currently available for digital synthesis. (For an excellent overview see ref. 5 or refs. 6 and 7). Once the harmonic components of the C bell had been determined, its sound could be synthesized by combining sine tones of appropriate frequencies and relative amplitudes and phases—a technique known in the trade as additive synthesis. Another approach adopted, known as fixed waveform synthesis, was to store the digitally sampled sound in successive memory locations—the wave table technique already mentioned. Finally subtractive synthesis, in which a broad-frequency-band source is subjected to appropriate filtering, was used to reproduce the boy's voice.

Additive synthesis. The complexities of building up the highly varied sounds of musical instruments from their components have already been mentioned. Bell sounds, at least in their natural form, are somewhat simpler to reproduce. By means of the Music V software at IRCAM[8,9], Harvey was able to generate both the natural bell sounds and the control of individual harmonics described above. Additive synthesis also permitted interpolation between two tone qualities or timbres at a given pitch; thus by appropriate variation of the harmonics a bell sound could gradually be transformed into a treble voice or vice-versa. Furthermore, by sending different harmonics to different speakers the composer was able to conjure up the illusion of being inside the bell.

Fixed waveform synthesis. By storing sound in a wavetable, one loses the ability to manipulate its harmonic components but gains significantly in the ease with which the sound as a whole can be transformed. For example one can easily transpose the sound to a higher pitch by increasing the effective rate at which the waveform is sampled. For a given rate of access to the memory, one can double the frequency (transpose up an octave) by sampling every other location along the wavetable. Of course this procedure distorts the waveform, making its envelope less smooth and thereby introducing noise, but sampling rates are typically high enough for this not to matter. Another problem occurs if there are harmonic components present whose frequency is higher than half the effective sampling frequency. Such components will be insufficiently sampled and will lead to "aliasing"—the generation of spurious signals at lower frequencies.

Subtractive synthesis. One of the longstanding goals of sound synthesis is that of mimicking the human voice—the ultimate user-friendly computer will of course use speech synthesis at a level indistinguishable from that of humans. The approach adopted by most working in this area is that which our species has evolved: a sound source subsequently modified by a series of resonators that provide individual characteristics as well as common elements of language such as vowel sounds. These manifest themselves as distinctive features in the spectrum superimposed on the fundamental tone of the speaking or singing voice. The source in the human case is a double reed (the vocal chords) which modulates a stream of air travelling from the lungs through the trachea, a tube of continuously varying diameter which in turn feeds several cavities including the mouth and nose. The lips, tongue, palate and glottis can introduce turbulence or sudden perturbations into the flow to produce 'fricative' and 'plosive' sounds respectively. The aim of subtractive synthesis is to mimic this system with appropriate sound sources and filters.

To reproduce his son's voice for *Mortuos*, Harvey used the CHANT algorithm developed at IRCAM by Xavier Rodet and others[10]. This digital approach generates fricative and plosive sounds by means of a flat-spectrum source coupled to appropriate filters, generating a series of pulses spaced according to the desired fundamental frequency. This output is then fed through a more complex set of filters to reproduce the effects of the resonant trachea, larynx, mouth and other cavities. (At the time that *Mortuos* was written the CHANT algorithm could not simulate consonants, which were therefore digitized directly from the boy's voice).

The design of filters, whether analog or digital, is a vast subject in itself. Just as in a simple electronic circuit it is far from intuitive to decide what arrangement of capacitance, inductance and resistance will provide a specified frequency response, so the design of filters can require detailed calculation straying into the complex plane of imaginary numbers, for example.

Digital filters need not be complicated in practice, however. By simply taking a running average of pairs of successive samples, for instance, one smooths any sudden change in amplitude thereby effectively applying a low pass filter. More generally, by adding or subtracting appropriately weighted input and (previous) output samples one can apply a filter of almost any desired characteristics. Finding the right arithmetic combination is the problem. An alternative approach, adopted in the CHANT program[10], is to use each pulse of the signal from the sound source to generate, in parallel, the calculated impulse responses of the desired filters. These responses, which take the form of exponentially damped reverberations decaying over several sample periods, can simply be read from memory and appropriately summed for each output sample.

Perhaps the most striking feature in *Mortuos* is the apparent ease with which, with the help of these digital techniques, two totally different sources of sound (one inflexible and metallic, the other variable and human) are bonded together as complementary acoustic entities, exhibiting or merging their individual characteristics at the composer's will.

Computation in performance

Répons, the latest composition of Pierre Boulez, is something of a landmark, not least for the degree of technical and musical integration between computer and musicians. As is typical of a Boulez composition, the piece has driven music critics to extremes: "... spasmodic gasps and lurches ... no purpose ... at odd moments it was superficially stimulating as a cold shower can be..." (*New York Times*); "... a great blinding sun of a piece, commanding its satellites in majestic orbit ... the supreme exercise of the intellect becomes the supreme gratification of the senses ... reverberating like bell towers of a mighty celebration" (*Boston Globe*). As it happens, no-one (other than the composer, perhaps) has heard the work in its entirety. The musical score is complete, however, and many of the computer transformations have been written, and have been heard in a number of preliminary performances.

The title of the piece, derived from the words *réponse* (reply) and *réponsoire* (responsory), reflects the composer's focus on relationships between a soloist and a group. This idea applies both literally to the ensemble of performers—six soloists responding to a 24-strong group of instrumentalists, one computer responding to the soloists—but also figuratively to the music itself. The aural clarity of much of the writing and the sheer drama of many of the computer transformations combine to yield a formidable impact in the concert hall.

The physical layout of a performance

of *Répons* is itself unusual. Six soloists (two pianos, harp, vibraphone, glockenspiel and cymbalom) and six loudspeakers are distributed around the performing space while the intrumental ensemble (woodwind, brass and strings), electronic processors and conductor are placed centrally. Only the soloists, connected to the processors by acoustic and contact microphones, are electronically transformed although their natural sounds are, of course, also heard.

The soloists have certain sound characteristics in common. Each note, being produced by struck or plucked strings or a metal bar, consists of a sudden attack and resonant decay, such that every instrument can be subjected to the same type of computer transformation. The 13,000 or so lines of computer code already used in the piece produce a variety of transformations such as modulation of one instrumental tone by another, controlled retardations to produce rhythmic patterns, frequency shifting and selective amplification and mobile distribution of sounds around the speaker system. (Boulez specifies very precisely the effects that he wants. His instructions are then expressed in computer code by his assistant Andrew Gerzso.)

The technology of *Répons*

The signals from the six soloists feed via a standard mixer into a 'matrix'. This 16 × 16 network can be programmed to adopt particular configurations by which, for example, one of the input channels can be fed into several outputs or vice-versa; furthermore these analog channels can each be amplified or attenuated. The matrix, controlled by a 68000 VME computer, distributes processed signals around the speaker system, again according to preprogrammed patterns which are activated as the performance proceeds. The matrix is also responsible for feeding signals to and from the analog-to-digital (AD) and digital-to-analog (DA) converters which form the interface with the core of the system, the 4X sound processor which is itself also controlled by a 68000 computer.

Designed by ex-nuclear physicist Giuseppe di Giugno, the 4X is the most powerful sound processor currently available, the speed and scope of which stem from its eight separately programmable processor boards[11]. Each of these consists of a unit for arithmetic and logical operations (the latter manipulating the 24 individual bits that make up each binary word, the former using those words as standard binary numbers), a multiplier and three main memories: 64,000 words, each of 16 bits, for the wave-table, 1,024 words of 48 bits for program storage and 1,000 words of 24 bits for program variables. Also within the 4X there is a control board, including 256 programmable timers which can, for example, initiate exchanges of program segments or memory with the 68000 host computer at prearranged times.

For all its sophistication, the 4X has a number of shortcomings which the next generation of machine—the 5A, scheduled for completion in 1989—should overcome. As well as being physically more compact and portable as a result of its use of very large scale integrated circuits, the 5A will have better data width or resolution (32 as opposed to 16 bits), a higher sampling rate (40 rather than 16 kHz) and larger storage capacity.

A more subtle improvement will follow from the use of floating point rather than integer arithmetic. Calculations involving floating point representation are slower but the improvements in signal-to-noise ratio arising from increasing resolution (or decreasing quantization error) are more substantial. The extra data width will provide another benefit: although the resolution of the AD/DA converters may be 16 bits (which is entirely adequate for most purposes) a higher resolution is needed within the calculating units to minimise the effects of rounding errors which accumulate over successive arithmetic operations, potentially disastrously if only 16 bits are used.

For any particular section of the musical score of *Répons* there is a corresponding segment of computer program, keyed in at the appropriate moment of the performance by typing in a single stroke at the keyboard of the 68000 VME. Throughout that section of the piece, while the players and conductor perform the musical score in the usual fashion, any signal from a particular soloist will be transformed automatically by the respective 4X processing board, subject to independent routing or attenuation by the matrix. Boulez intends to develop more sophisticated and multipath programs for subsequent compositions.

The music of *Répons*

Of all the computer-assisted musical gestures used by Boulez, by far the most arresting and theatrical occurs at the point where the soloists and the 4X first enter the proceedings (score number 21 in ref. 12). This entry follows an extended introductory exposition in which Boulez presents musical metaphors for the title of the piece, including most noticeably sections where certain pitches attain particular prominence while chords and textures shift about them—a procedure equivalent to the 'pedal' in classical harmony. The subsequent music sets the instrumental ensemble and the soloists in a continual dialogue, the two groups performing contrasting musical materials.

This pedal device again assumes prominence at the soloists' entry, represented by a massive chord played by all six in arpeggiated fashion (that is, the notes contributed by each soloist are struck or plucked in rapid ascending order). Different soloists are amplified through different speaker combinations adding to the spatial impact of the gesture. As this chord decays, successive soloists each play an answering chord, the respective chords having top and bottom notes in common (see Fig. 4), adding a degree of aural focus to the electronic manipulation which is also applied at this point.

Two computer transformations operate here: time delays and frequency shifts. The delays are applied simply by storing every digital sample into a wavetable as it arrives and then retarding the "pointer" by an amount corresponding to the milliseconds of delay required. Each delayed signal can be individually attenuated.

A selection of these delayed signals are fed through a variety of digital frequency shifters. By appropriate manipulation of a group of successive samples these add or subtract a specified frequency to every harmonic component of the signal[9].

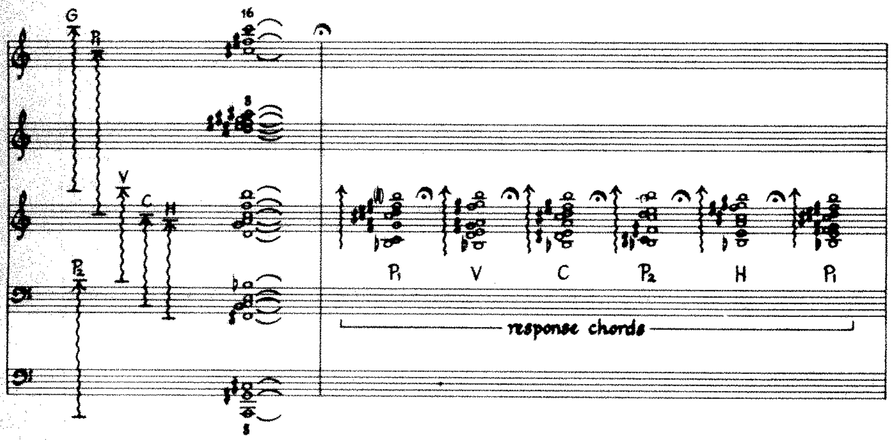

Fig. 4 Entry of soloists in *Répons*, reduced score. All chords are played as loudly as possible, each separated by several seconds. The arpeggiated contributions of each soloist to the initial chord are indicated: P1,2, pianos 1 and 2; H, harp; V, vibraphone; C, cymbalom; G, glockenspiel. Note that the part of the initial chord played on the vibraphone is of particular significance (see text). The six chords that follow are subjected to extended computer transformations.

Because the musical scale is logarithmic (for example, every octave step upwards in pitch represents a doubling of frequency), the linear transformation of frequency addition or subtraction will completely alter the harmonic relationships and hence the character or timbre of the sound. In many cases the result is reminiscent of tuned metal percussion instruments from the Far East—the Balinese *Bonang* or the Chinese *Yün-lo.* Despite the diminished "purity" of the spectrum, the fundamental pitch is usually clearly audible.

The manipulation of pitches, particularly within chords, is fundamental to the musical and electronic writing in *Répons.* One chord in particular appears to contain the roots of much which follows: that played by the vibraphone within the first entry chord (see Fig. 4). This appears in a prominent form at the very opening of the piece; moreover the surrounding components of the entry-chord, each of the answering chords played by the soloists and some of the frequency shifts are derived directly from it[13]. This 'primary' chord also appears prominently elsewhere.

An attempt to represent the combined effect of delays and frequency shifts, as specified by the *Répons* software for one of the soloist's response chords, is shown in Fig. 5.

These techniques are applied at several other points in the composition but the aural images that result vary considerably according to the musical context. For instance, at one point all the soloists are gathered together (in the bar preceding number 27 in ref. 12) to play the primary chord discussed above. This recapitulation of the chord is of some significance within the overall form of the piece and is certainly exhibited as such: it suddenly emerges at full volume from the ensemble of soloists, being sustained by tremolando with gradually decreasing loudness over several seconds—a significant duration in this context. The solo tremolandos are all fed through the same sound processor with several delays being applied, each delay with its respective frequency shift and each directed through a different speaker. Thus the scope of this already powerful moment is enhanced in pitch and space.

One technique not mentioned so far, and yet one which dominated earlier developments in analog music studios, is ring modulation. Here two signals are simply multiplied together. For two sine waves this results in the suppression of the two waves and the generation of two product waves or sidebands whose frequencies are the sum and the difference of the originals. For any instrumental sound one effectively multiplies every harmonic component by a modulating sine wave of specified frequency, which can result in very "thick" tones, packed with partials (spectral components which are not harmonically related to the fundamental) and bearing no resemblance to the original tone. The principal interest of ring modulation arises from the subtlety in the choice of the modulating frequency. If this frequency is harmonically linked to those of the instrumental tone, the resulting partials overlap to yield a 'cleaner' spectrum.

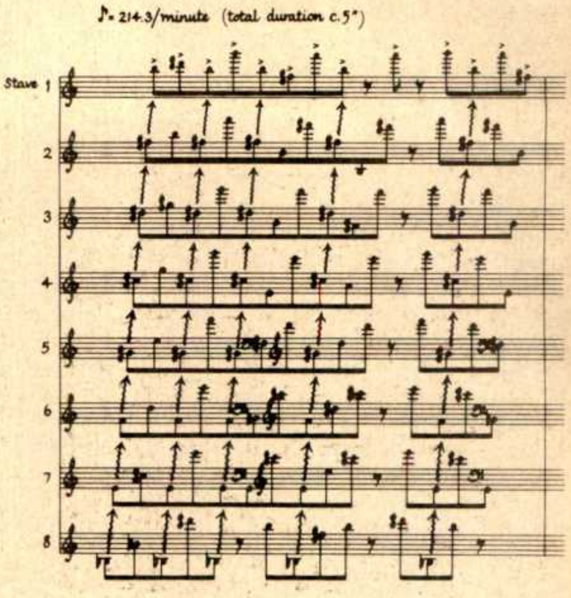

Fig. 5 Computer transformation generated following the final chord shown in Fig. 4. Each stave (from 1 to 8) contains the notes (or their nearest semitone approximations) that are generated by each of the eight notes in the chord. Thus the first note of each stave—linked from stave to stave by arrows—forms part of the arpeggiated chord played on the piano. Subsequent notes linked in similar fashion form the same chord delayed without frequency shift. All other notes are the products of delays and frequency shifts. The 14 delays applied are regularly spaced at 0.28 seconds. The uppermost initial note is emphasized by the pianist in performance, so that its transformations dominate the texture. The ear does not follow each line but resolves the texture into layers of rhythmic patterns at different registers (bass, treble and so on). This combined with the exotic timbres resulting from the frequency shift gives an overall effect of multiple echoes of the piano's chord in the midst of a rhythmic gamelan-like texture. This diagram was derived from the computer code of *Répons.*

One particularly complex example of this approach occurs in *Répons* (at score number 53, ref. 12). Here Boulez gives each soloist a different collection of seven pitches to be played in a variety of orders and rhythms. In designing the ring modulations for this passage, the composer treated these notes as eighth harmonics of respective fundamentals, choosing as modulating frequencies the *n*th harmonics where $n = 2$ for the first piano, 3 for the vibraphone and so on. The groups of modulating frequencies are injected on the respective processing boards of the 4X. Simultaneously, Boulez specifies several optional layers of transformations with differing combinations of delay and ring modulating frequencies. The options vary from instrument to instrument, the particular combination of layers being chosen in part by a random number generator, resulting in the most elaborate transformations in the entire piece.

Such complexity, which if excessively applied leads to tired ears however fascinating the detail, is preceded and contrasted by a simpler but still striking device, in which every soloist rapidly reiterates (albeit with ornamentation) a single note (B below middle C—see score number 52, ref. 12), thus providing an excellent opportunity to throw the computer's role into sharp definition. Here it acts as a ring-modulating 'light-house': a series of 'flip-flop' switches within the software scans around the soloists, applying time-varying modulation frequencies giving rise to rapidly varying spatial distributions and bands of transformed tones diverging upwards and downwards in pitch.

The final moments of this extensive piece refer back to the first entrance of the soloists discussed above, both in its musical elements and in the combination of frequency shifts and delays used by the computer. As was shown in Fig. 5, the use of arpeggio in the soloists' chordal responses gave rise to markedly rhythmic sequences of notes overlain out of phase. Here, in contrast, the transformed chords are played without arpeggio. The final gesture of all, for example, comes from the computer as it reflects—via a few delays and frequency shifts—a single quiet piano chord. The lack of arpeggio in the initial attack results in a well-defined (albeit brief) rhythmic series of transformed chords, a surprisingly simple and gentle end to a massive and complex composition, and all the more effective for that.

The past, the future

This essay may be considered by some to be something of an insult to the general discipline of computers and composition—no serious attempt has been made, after all, to set *Mortuos* and *Répons* within their historical and contemporary context. For example, the work of the Italian futurists pales into complete insignificance when compared with that of the equally radical pioneer of *musique concrete,* Edgard Varèse. He, at least, held a vision whose fulfilment may now be seen on the horizon. "I dream of instruments obedient to my thought" he wrote, "and which, with their contribution of a whole new world of unsuspected sounds will lend themselves to the exigencies of my inner rhythm". And for years such centres as Stanford, MIT, Bell Laboratories and institutes in Paris, Cologne and Milan have developed the hardware, the software and the music on which this fulfilment is being built.

For all that, it seems that such studies have reached a turning point within the general context of contemporary music. A substantial proportion of the most gifted young composers of the 1950s and 1960s were obsessed with musical language (and necessarily so), to the extent that uncompromising explorations alienated the bulk of the public audience traditionally associated with 'serious' or 'art' music. Only a few, the most notable being Karlheinz Stockhausen, found the world of electronics appropriate to their modes of communication (or, in too many cases, the lack of it). Thus the combinations of exploratory languages and techniques pushed composition with electronics into a ghetto within a ghetto.

In contrast, the powerful techniques becoming available for digital synthesis, and compositional achievements such as those of Harvey and Boulez at IRCAM, have recently stimulated a degree of interest among the wider community of composers that is unprecendented. Given the technical facilities and assistance that IRCAM is now providing to composers new to electronic techniques, and given that many of these composers are writing music that is less forbidding than much written only fifteen years ago, the time must rapidly be approaching when the widest musical public will be able to encounter the best of this work with ease.

This enhanced degree of interest from composers is likely to throw into relief all the more vividly the questions—both practical and theoretical—that are raised by the use of computers. For instance, what is their potential formal significance in live transformation? The devices used in *Répons*, for example, are purely passive in formal terms in that they produce reflections of composed material. These aural images add an indispensible component to the fabric of the piece but not to its essential form—they are the equivalent of a cathedral's windows rather than its weight-bearing walls and arches.

But the potential is there. As a move in that direction, Boulez intends to return to a previous composition, Explosante-Fix, which incorporated (unsatisfactorily in his view) live electronic manipulation. The piece will be revised so as to include reactive manipulation of the structures of chords as the performance progresses.

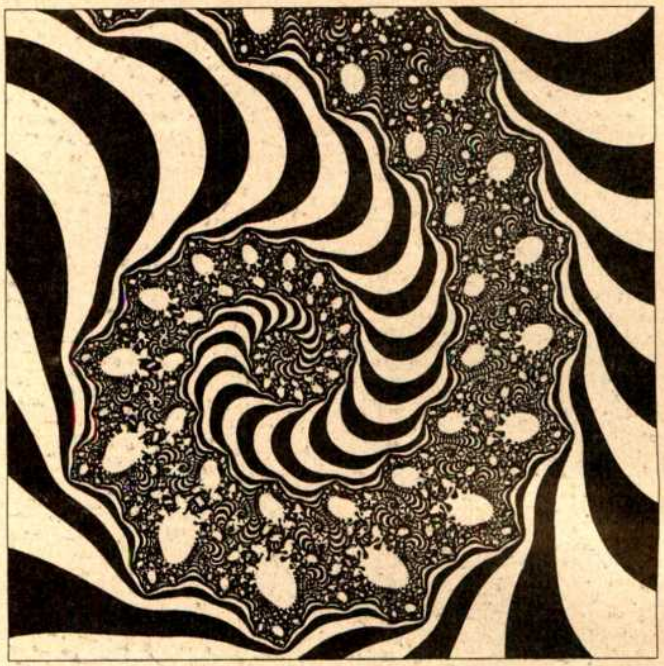

Fig. 6 A highly expanded view showing the border of the Mandelbrot set for the operation $x_{n+1} = f(x_n) = x_n^2 + c$, as mapped onto the complex c plane. The black and white areas demarcate values of c that lead the process $f(x)$ to different regions ('attractors') of the complex x plane[14].

And there are more extreme possibilities. One can imagine an abstract composition whose micro- and macro-structures derive entirely from mathematical formulae exploiting relationships between pitches, harmonics and rhythms for example. Before dismissing such a scheme as depressingly arid, the sceptical reader might examine pictorial representations derived from a mathematical entity known as the Mandelbrot set[14]. The nonlinear properties of the associated formulae, mapped onto the complex plane, produce an endless and stunning variety of spectacular images (for example see Fig. 6). A literal transcription from the two-dimensional pictorial frame to that defined by frequency and time would prove unsatisfactory. Nevertheless if there is an analogous "fractal" music waiting to be discovered then only digital techniques are likely to find it.

Other more fundamental questions have been touched upon recently by one of France's most experienced and influential computer-composers, Jean-Claude Risset[15]. For example, the access provided by digital systems to what one might call a multidimensional sonic continuum leads to a problem of aural hierarchy: to what extent does musical cognition depend on discrete structures such as scales or rhythms? And once such basic elements of language have been defined, further hierarchical problems arise, as many composers have realised following the musical revolutions that occurred in the early years of this century. Specifically, given completely new possibilities for the synthesis of sound, what are the self-consistent equivalents of the phrase, the counterpoint, the development section or the symphony that sprang naturally from diatonic and chromatic harmony in earlier times?

No doubt the strongest of musical instincts will continue to be required to solve such problems without sacrificing the degree of communication necessary to justify the effort. "It has often been said that music is as much a science as an art;" writes Boulez[16]. "How could these two entities be fired in the same crucible, except by the imagination, that queen of faculties!".

Thanks are due to Pierre Boulez for access to IRCAM, to Andrew Gerzso for introducing me to the workings of *Répons* and for supplying scores and software, to Gerzso and Jonathan Harvey for helpful comments on the article, and to Elaine Gould for her musical calligraphy. ☐

Cosmic microwave background anisotropy

Nick Kaiser* **& Joseph Silk**†

Current hypotheses for the origin of structure in the Universe lead to predictions of the amplitudes of anisotropies in the cosmic microwave background radiation. The dipole anisotropy is related to density fluctuations on large scales and to other determinations of our motion relative to distant galaxies. Observation and theory are coming tantalizingly close to measuring the elusive anisotropy, or to revealing that our ideas about the origin of galaxies and large-scale structures are in need of substantial revision.

STUDIES of the angular structure of the microwave background radiation play two distinct roles in cosmology. First, there are those anisotropies that are intrinsic to the microwave background. These provide an unsurpassed glimpse of the early Universe, propagating freely to us from an epoch when the Universe was much simpler than it is today. Galaxy clusters had not formed, nor, most probably, had galaxies themselves. Detection of anisotropies in the background radiation would provide a unique measure of the primordial density fluctuations from which the present large-scale structure of the Universe developed. Yet despite continuing and ever-improving measurements, no such anisotropies have been discovered. Here we describe some of the current hypotheses for the origin of structure in the Universe, and the calculations which have been made to predict the amplitude of the microwave anisotropy. A different test of cosmological theories is provided by the dipole anisotropy of the microwave background, which arises from our motion relative to a uniformly expanding 'cosmic frame' defined by the mean state of motion of matter at great distances. We describe this anisotropy as extrinsic, and infer a solar motion which can be used to constrain both the large-scale density fluctuations in which we are embedded and independent determinations of our motion relative to distant galaxies. In the latter part of this review we describe the present status of these studies.

Origin of structure

Large-scale structure originated, according to the primaeval hypothesis, from infinitesimal density fluctuations in the earliest instants of the Big Bang. Inflation[1] has provided a tentative answer to the question of the origin of these fluctuations[2-5]. Quantum fluctuations are amplified to large scales during the exponential expansion phase which characterizes the inflationary epoch. The inflation is driven by vacuum energy during a first-order phase transition which occurs as the energy of matter decays. The universe evolves from the symmetric state of false vacuum, when the fundamental forces are unified, to the asymmetric state of the true vacuum. During the inflationary phase, described by de Sitter space-time, there is no particle horizon. The fluctuations are boosted to a scale-invariant amplitude, up to scales comparable to the radius of the inflated space-time bubble, which greatly exceeds our present horizon, and models can be constructed that yield density fluctuations at horizon crossing of

$$(\delta\rho/\rho)_{\mathrm{H}} \approx 10^{-4} \qquad (1)$$

Values much larger ($(\delta\rho/\rho)_{\mathrm{H}} \approx 1$) would be disastrous for cosmology, producing black holes and large inhomogeneities, and much smaller values would not lead to any galaxy formation. It is remarkable that constraints on the precise value of $(\delta\rho/\rho)$ can be inferred from constraints on temperature fluctuations $\delta T/T$ in the cosmic microwave background. Indeed, all currently acceptable cosmological theories require large-scale structure to have originated from infinitesimal fluctuations at early phases of the Big Bang, and these inevitably leave a signature in the form of temperature fluctuations $\delta T/T$. Whether the amplitude (1) will emerge naturally from a quantum gravity model is not known. Because quantum gravity is poorly understood, most approaches to this problem begin when a classical description first becomes valid, well below the Planck energy of $\sim 10^{19}$ GeV. According to one school of thought, the inflationary potential can be designed to yield the correct $\delta\rho/\rho$, which can then be interpreted as an otherwise unknown particle physics parameter. This process results in a scale-invariant spectrum of gaussian density fluctuations. Another view is that the initial fields that describe the energy content of the Universe are chaotic and highly variable in space and time[6]. Beginning with this initial space-time foam, an anthropic argument is applied to infer that a very special region, with sufficiently regular fields, will inevitably exist and be able to inflate sufficiently to dominate space-time, producing a highly isotropic (and nearly homogeneous) universe. More than one epoch of inflation could have occurred[7], and a wide range of possible primordial fluctuation spectra can arise.

One intriguing consequence is that the primordial fluctuations might be formed exclusively on small scales, far smaller than those of galaxies or galaxy clusters. Galaxy formation can still occur, however, if nonlinear structures develop on stellar mass scales; an amplification process can then produce large-scale structure[8,9]. This happens as follows: massive stars form, explode as supernovae, and sweep up large shells of ambient matter which subsequently fragment on much larger scales, into pieces with the mass of star clusters. If sufficient energy is to be released by dying stars at this stage for the process to repeat, amplifying to larger and larger scales, then formation of structure on galactic mass scales can be achieved. Galactic binding energy, in such schemes, may be said to be of mediaeval, rather than primaeval, origin: it is secondary, having been induced by the explosions altering the distribution of matter.

In the primaeval picture, the excess binding energy of a cluster of galaxies can be traced back to a primordial excess of density in the same co-moving region at the inflationary epoch, whereas in the mediaeval picture this binding energy is imposed at a very late epoch, when the region is well inside the horizon. There is yet another hypothesis, the 'cosmic string' model[10,11], in which the binding energy fluctuations on a given scale are induced by the dynamics of the string network as that scale enters the horizon.

In each of these models there is a link between the very earliest instants of the Big Bang and the large-scale structure of the Universe today. The microwave background fluctuations result from the linear growth regime of the primordial fluctuations, and thus bypass much of the uncertainty associated with nonlinear evolution. Observations of the microwave background anisotropy provide a unique probe which may help to distinguish between the various models for the origin of galaxies.

Intrinsic anisotropy

Figure 1 shows what one may learn by studying the anisotropy of the cosmic microwave radiation. The microwave photons stream freely to the observer ('here and now') from the surface of last scattering, which in the standard model of the Big Bang occurs in the redshift range $z \approx 1{,}100$–$1{,}500$. The last scattering surface has a finite thickness Δz, which is due to the noninstantaneous recombination of the hydrogen and to the residual ionization level which freezes out. A transmission factor per unit redshift interval, $(d\tau/dz)\exp(-\tau)$, defines the effective profile of the last scattering surface, where $\tau = \int_0^z n_e \sigma_T \, c dt$ is the optical depth to redshift z, σ_T is the Thomson cross-section and n_e is the electron density. This function can be approximated by a gausian which peaks at $z = 1{,}065$, with a gaussian width $\Delta z = 80$ (ref. 12). The corresponding co-moving distance that describes the thickness of the last scattering surface is $\Delta L \approx 7h^{-1}\,\Omega^{-1/2}$ Mpc (where h is the Hubble constant divided by 100 km s^{-1} Mpc^{-1}).

The finite width of this shell smooths out fluctuations on angular scales $\Delta\theta \lesssim 8\,\Omega^{-1/2}$ arc min. Even larger-scale primordial fluctuations are not necessarily preserved: a source of energetic photons or heat could re-ionize the Universe or increase its ionization over the low post-recombination value ($n_e/n_H \lesssim 10^{-3}$) and thereby shift the last scattering surface towards lower redshift. As the thermal history of the Universe at the relevant epoch ($1{,}000 \gtrsim z \gtrsim 30$) is uncertain, there is considerable ambiguity in the interpretation of fine-scale anisotropy. This ambiguity is avoided if we search over angular scales exceeding that subtended by the particle horizon at the latest possible epoch of last scattering. No causal process could erase such structure. This angular scale is $\sim(\Omega/z)^{1/2}$ radians, where Ω is the cosmological density parameter. As the minimum redshift at which significant scattering could have occurred ($\tau \gtrsim 1$) is ~ 30 if the baryon density parameter $\Omega_b \lesssim 0.1$, we infer that an observational strategy aimed at fluctuations over angular scales of $\gtrsim 10°$ would involve the least number of assumptions about the early evolution of the Universe.

The corresponding co-moving linear scale is ~1,000 Mpc. At recombination, a linear scale of 100 Mpc subtends an angle of $\sim\Omega h$ degrees. Observations of the background radiation fluctuations therefore nicely complement studies of galaxy clustering, which provide firm evidence for structure only on scales of up to a few Mpc, in probing the large-scale structure of the Universe. Thus, the interpretation of large-angle anisotropy is independent of the uncertain ionization history, but is crucially dependent on the assumed extrapolation of density fluctuations to large scales by means of equation (1). For small-scale anisotropy the situation is reversed. Regardless of the angular scale considered, the radiation has streamed freely since the Universe was very homogeneous, at which time it was well described by linear fluctuation theory. Thus, in contrast with studies of galaxy formation and clustering[13-16], the complexities of nonlinear evolution are completely bypassed. The detection of anisotropy on any angular scale could provide a unique and direct measure of the primordial fluctuations from which large-scale structure evolved.

Predicting $\Delta T/T$. A variety of calculations predicting $\Delta T/T$ can be found in the recent literature; they differ mainly in the assumed material content of the Universe, the assumed initial fluctuations and the normalization to present-day structure. In order to make sense of the issues here, we first describe one set of calculations, which we refer to somewhat arbitrarily as the standard model, and then describe variations on this theme.

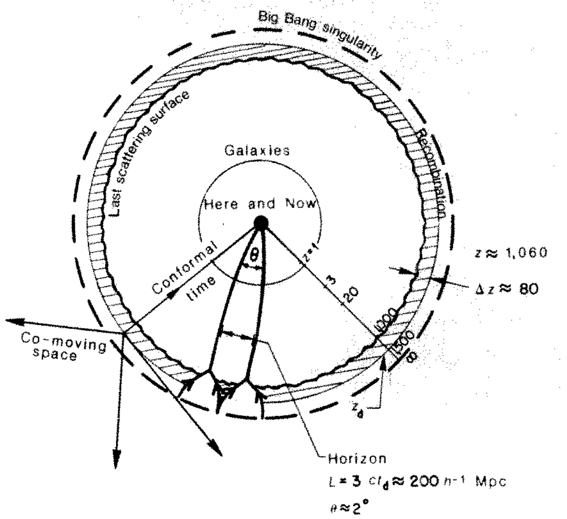

Fig. 1 A co-moving space/conformal time diagram of the Big Bang. The observer ('here and now') is at the centre; the Big Bang singularity is the outermost dashed circle, and the horizon scale is schematically indicated at last scattering.

The 'standard' model: cold dark matter with isentropic gaussian fluctuations. The fluctuations in this model have been studied in detail[17,18]. The Universe is assumed to have three components: a cold, collisionless fluid (this might represent axions, for example); the baryonic gas, initially hot and fully ionized; and the photons and neutrinos, described by a distribution function, with the former being coupled to the gas by electron scattering. The initial state is assumed to be isentropic, which means that, for any two types of particle A and B, the ratio of the number density of As to Bs, n_A/n_B, is a constant independent of position. This terminology arose in the context of a universe containing only radiation and plasma, for which the ratio of the number of photons to the number of baryons n_γ/n_B is a measure of the entropy (per baryon). Such perturbations are sometimes referred to as 'adiabatic' because they can be generated by compressing all of the particles in some region, producing a net density perturbation $\delta\rho(r) \equiv \rho(r) - \rho$. Strictly speaking, one must also specify the initial peculiar velocity field, but this is usually dispensed with by stipulating that the perturbation should contain only growing modes.

A 'gaussian' field is one which can be generated as a linear sum of spatial Fourier components with random phases. Such a field is specified by its power spectrum, which in this case is taken to be the Zel'dovich spectrum, $|\delta_k|^2 = |\delta\rho/\rho|_k^2 = Ak$ (where k is the wavenumber of a Fourier component and A is a constant to be specified by a normalization described below), which results in binding energy fluctuations that are scale-invariant.

With the initial conditions thus specified, the spatial Fourier modes can evolve independently until some time after recombination. This results in final linear fluctuations in the matter and radiation which are now decoupled. The angular dependence of the sky fluctuations is now completely specified. The amplitude, however, remains to be fixed. This 'normalization' is performed by requiring that the density fluctuations be of sufficient amplitude to generate the observed large-scale structure. This is conventionally measured by the integral of the galaxy–galaxy correlation function: $J_3(x) = 3/x^3 \int_0^x \xi_{\text{gal-gal}}(r) r^2\, dr$, where x is a measure of the separation between an arbitrarily selected pair of galaxies. Note that despite the fact that $\xi(r) \gg 1$ on small scales, this integral satisfies linear theory[19]. One evaluates this at a scale where the fluctuations are linear but large enough so that $\xi(r)$ is well known. For example, at $x = 10h^{-1}$ Mpc, the r.m.s. fluctuations are ~50%. This normalization assumes that the galaxies are 'fair tracers' of the density field. Although this is a fairly natural assumption, this need not necessarily be the case. If the Universe has closure density ($\Omega = 1$), then it seems that galaxies must be more strongly clustered than mass, at least in the dense clusters where virial analysis is applied to estimate mass to light ratios. In considering these models, some allowance must be made for this, somewhat reducing the amplitude of $\delta T/T$.

There are two final complications. Uncertainty in the Hubble constant H_0 leads to uncertainty in $\delta T/T$. Specifically, for cold dark matter, a decrease in H_0 leads to an increase in L_{eq} (the radius of the co-moving sphere encompassing the causal horizon at the epoch of equality of matter and radiation densities), and thus to an increase in $\delta T/T$. Similarly, if $\Omega < 1$, $\delta T/T$ is increased, approximately in proportion to Ω^{-1}. This is because the Universe becomes curvature-dominated at redshift $\sim 1/\Omega$, and fluctuation growth effectively ceases. One is now in a position where $\delta T/T$ can be predicted. The detailed coupling of matter and radiation must, of course, be followed. This involves solving the perturbed Boltzmann equation for the photon intensity today[20,21]. Rather than give any details here, we will simply indicate in a qualitative manner the magnitude of the various terms that contribute to $\delta T/T$.

On small scales, corresponding to a co-moving scale that subtends the thickness of the last scattering surface at ~ 10 Mpc, there are adiabatic temperature fluctuations. These were first predicted in 1967[22,23], and would be of order $(1/3)\delta\rho/\rho$ were recombination instantaneous and complete. Their angular scale is typically 5–10 arc min, and fluctuations of smaller angular scale do not survive recombination. The amplitude of these small-scale fluctuations is reduced, because of the finite thickness of the last scattering (LS) surface, to $\delta T/T \approx (\delta\rho/\rho)_{LS}/30$. On larger scales, the random motions of fluctuations induce Doppler shifts. These dominate $\delta T/T$ at co-moving scales $d \approx L_{rec}$ (the radius of the co-moving sphere encompassing the causal horizon at recombination) at $\sim$50–100 Mpc, corresponding to angular scales of 1–2°, and are of order $\delta T/T \approx (\delta\rho/\rho)_{LS}(d/ct)_{LS}$, where c is the speed of light and t is the time elapsed since the Big Bang. On the largest scales, the gravitational potential difference between last scattering and now generates gravitational redshifts, of order $\delta T/T = (\frac{1}{3})(\delta\rho/\rho)_0(d/ct)_0^2$. These fluctuations, also first predicted in 1967[24], are contributed by co-moving scales d of 10^3–10^4 Mpc, and dominate over angular scales greater than a few degrees[18].

The result of all this is a gaussian sky pattern (the gaussian nature of the fluctuations being preserved in linear theory), with roughly equal power in each logarithmic interval of angular wavenumber. The r.m.s. amplitude is a function of global cosmological parameters such as Ω, h and Ω_b, and constraints can be placed on these by comparison with the stringent small-scale anisotropy limits. High-density models are generally consistent with these limits, but low-density models can be excluded. There are two reasons for this: first, there is reduced growth of $\Delta\rho/\rho$ at late times if $\Omega \ll 1$, and second, the fluctuations appear at a more favourable angular scale. The results we have described were obtained numerically. The anisotropy on large scales, much greater than the horizon size at decoupling, for these isentropic fluctuations can be calculated analytically[24] (see ref. 25 for an application to cold dark matter). The effect is analogous to the usual gravitational redshift effect, with photons being redshifted (blueshifted) if they were last scattered in overdense (underdense) regions. The amplitude of $\Delta T/T$ is one third of the newtonian peculiar potential ϕ evaluated at the point of emission.

In these calculations it is assumed that the Universe is not re-ionized after recombination. There is some justification for this in that, for most reasonable choices of parameters, the spectrum of density fluctuations is such that very little matter forms nonlinear structure at a sufficiently early epoch to plausibly re-ionize the Universe[17,18]. We now describe some variations on this 'standard' model.

Hot dark matter. An interesting alternative is to replace the cold dark matter (axions, photinos, or the like) with hot dark matter such as massive neutrinos. The main effect of this is to erase post-recombination density fluctuations on scales smaller than that of superclusters (the angular dependence of $\Delta T/T$ being largely unaffected because the $\Delta T/T$ fluctuations on small scales are in any case smeared out)[17,26]. The normalization to J_3 (for galaxies) is now questionable, because galaxy formation is a secondary phenomenon in a neutrino-dominated universe, arising from pancake fragmentation[27]. An alternative normalization is to require that 'pancake' collapse should occur sufficiently early to form quasars and the most distant galaxies. For a neutrino mass of $\sim$30 eV, the predicted anisotropy is compatible with the current upper limits.

Isocurvature fluctuations. An alternative to the isentropic fluctuations discussed so far is the 'isocurvature' mode. These fluctuations are, in a sense, orthogonal to the isentropic modes because, while the latter have fluctuations in the total energy (and therefore in space curvature) but no variation in the relative abundances of the various particles, fluctuations can be realized by spatially varying the equation of state on some initial $t =$ constant hypersurface in a universe which was hitherto absolutely homogeneous. This process conserves energy locally, so any excess in one species is balanced by a deficit in the others. It is the constancy of the spatial curvature on this initial hypersurface which gives rise to the terminology employed here. These fluctuations are not, strictly speaking, isothermal, but are often referred to as 'entropy' or 'isothermal' fluctuations.

Isocurvature fluctuations in a universe dominated by cold dark matter have recently been investigated[28,29]. The small-scale anisotropy is very similar to that arising from isentropic fluctuations. The large-scale anisotropy, however, is about an order of magnitude larger. This increase is a consequence of two factors: the first is that the spectrum of density fluctuations is flatter than in the isentropic case, because no sub-horizon growth occurs in the radiation era. Thus, with the same normalization, the value of $\Delta\rho/\rho$ at large scales is about twice as large.

The origin of the other factor can be understood as follows. Imagine that, at some early time $z \gg z_{eq}$, we impose a positive perturbation to the axion density $\Delta\rho_A/\rho_A = \Delta n_A/n_A = \varepsilon$ in some large spherical region destined to enter the horizon at some time after z_{EQ}. We must also impose a smaller compensating negative perturbation in the radiation density, $\Delta\rho_\gamma/\rho_\gamma = -(\rho_A/\rho_\gamma)\varepsilon$, so that ρ_{TOTAL} is unperturbed. When this region enters the horizon, the density of the radiation will be negligible, having been redshifted, so we will have a positive perturbation to the proper mass enclosed: $(\Delta M/M)_{proper} = \Delta n_A/n_A = \varepsilon$. However, from considerations of causality, we know that the gravitational mass as registered by an external observer is unperturbed. There is no paradox here; the perturbed region must now be sitting in a potential well of depth $\phi = \varepsilon$ so that $M_{grav} = M_{proper}(1-\phi)$ is unchanged. If the perturbation were isentropic then we would see the Sachs–Wolfe term, $(\Delta T/T)_{SW} = -\phi/3 = -\varepsilon/3$. However, this perturbation is not isentropic: we initially increased the number of axions but the number of photons was almost unaltered. Thus, relative to an isentropic state, we have a negative entropy perturbation, $\Delta n_\gamma/n_\gamma = -\varepsilon$, which gives rise to a temperature fluctuation $(\Delta T/T)_{entropy} = 4(\Delta n_\gamma/n_\gamma)/3 = 4\varepsilon/3$. We see then that the usual Sachs–Wolfe term is augmented by an entropy perturbation of the same sign but four times larger, and the net result is to increase $(\Delta T/T)_{TOTAL}$ by a factor of $\sim$5. With the conventional normalization, the predicted anisotropy is incompatible with the limits of Fixen *et al.*[30].

The re-ionized Universe. If re-heating were to occur, the Universe would become transparent over approximately one expansion time at the mean redshift of last scattering. The photons we see would then arrive from a broad range of redshifts, $\Delta z \approx z_{ls}$. The temperature anistropy due to the large-scale structure in such a re-ionized universe is smaller than that predicted to arise in a un-ionized universe. This is because, along any line of sight through the cosmic photosphere, we will see fluctuations due to many regions adding incoherently and this results in statistical cancellation.

The dominant source of anisotropy in a re-ionized universe is the peculiar motion of the last scatterers. The calculation of the anisotropy is greatly simplified by two approximations which are expected to hold to high accuracy. First, at the epoch of last scattering, the density fluctuations that give rise to the currently observed large-scale structure were still in the linear regime, and second, the dynamical effect of the radiation on the matter was almost certainly negligible. Hence we need only calculate the effect of the matter on the radiation.

The statistical cancellation due to the projection of density fluctuations along the line of sight depends on the statistical nature of the density perturbation field $\delta(k)$. If this density field was gaussian (that is, if the Fourier components $\delta(k)$ had random phases), then the temperature fluctuations on the sky, $\Delta(\theta)$, will also be a gaussian field. The power spectrum of this field, Δ^2, is related to the power spectum of density fluctuations by $\Delta^2 \propto k^{-4}\delta^2(k)$, where the constant of proportionality depends on the ionization history of the Universe[31]. A consequence of the fact that the scale of the fluctuations is much smaller than the thickness of the photosphere is that the fluctuations $\Delta(k)$ at some angular wavenumber k are determined solely by the value of δ^2 at the corresponding spatial wavenumber.

A useful measure of the amplitude of the temperature fluctuations at angle θ is $(\delta T/T)_\theta \approx \sqrt{k^2\Delta^2(k)}$, where $k \approx 1/\theta$. Similarly, the amplitude of the density fluctuation on scale λ is $(\Delta\rho/\rho)_\lambda \approx [k^3\delta^2(k)]^{1/2}$. Thus, to order of magnitude, we have $(\Delta T/T) \approx (H\lambda)^{5/2}(\Delta\rho/\rho)$ (where H, λ and $\delta\rho/\rho$ are evaluated at z_{ls}). Equivalently, we can write $(\Delta T/T) \approx (1/\sqrt{N})\phi_\lambda$, where ϕ_λ is the gravitational potential fluctuation on scale λ and N is the number of regions of size $\sim\lambda$ seen along a line of sight. One can infer that the anisotropy due to fluctuations of a given scale λ is smaller for smaller z_{ls} (as N is then increased), and ϕ_λ is approximately equal to the square of the velocity dispersion of the final nonlinear structures produced. As this velocity dispersion appears to be a non-decreasing function of mass (and therefore of λ), the result tells us that the greatest anisotropy is generated by the largest structures we see today. If galaxies fairly trace the mass distribution, then the anticorrelation seen in the redshift survey suggests that the power spectrum falls rapidly for $k \leq 2\pi/60h^{-1}$ Mpc. These fluctuations would generate $\Delta T/T \approx (3\text{-}6)\times 10^{-6}$ on an angular scale of $\sim 1°$. (We have here assumed $\Omega \approx 0.2$ in accord with the assumption that galaxies trace the mass). In a high-density universe ($\Omega \approx 1$), the amplitude would be smaller by a factor of ~ 3 and the anisotropy would appear at an angular scale of ~ 10 arc min.

On larger scales, the amplitude of $\Delta T/T$ depends on the extrapolation of the power spectrum. If this is assumed to be a power law with $\delta_k^2 \propto k^n$, then $\Delta T/T \propto \theta^{(-n+2)/2}$ and would increase with angular scale if $n \leq 2$. The estimate we have given above is the minimal anisotropy implied by the structure observed today, and it does not require any extrapolation of the power spectrum to large scales. The predicted anisotropy is well below the current upper limits on the relevant scales.

So far we have not specified the source of energy which re-ionizes the Universe. An interesting possibility is that these pre-galactic sources of radiation may, if they are sufficiently inhomogeneous, generate the large-scale structure[32]. A constraint on such theories is that, in addition to the 'Doppler scattering' fluctuations we have discussed above, the radiation released would probably have been degraded to microwave frequencies and would appear anisotropic on a scale of a few degrees, this being the angular size subtended by the width of the photosphere.

This effect was investigated in ref. 33. The assumptions are that a population of sources turn on and burn at redshift z_*, that these sources are inhomogeneous on some scale λ_* and are uncorrelated on larger scales (note that there is no assumed initial density inhomogeneity), and that these sources produce a substantial fraction of the microwave background. The diffusion or streaming of this radiation away from the sources then generates density fluctuations by the pressure of the radiation of the gas. This process can transfer momentum, and generate density fluctuations, on scales up to the radiation Jeans length, which is comparable to the scale of the largest structures we see today. The redshift of burning was taken[33] to be $z_* \approx$ 200-500; if z_* is lower than this, then radiation drag becomes inefficient, and for higher z the luminosity of the sources must exceed the Eddington luminosity. This process could generate the observed large-scale structure if the initial scale of radiation inhomogeneity is of the order of a galactic mass scale. The transfer of radiation smooths out the initially inhomogeneous radiation on scales up to the horizon scale at last scattering. The final microwave background anistropy predicted (assuming thermalization of the radiation by dust) appears at an angular scale of a few degrees and is comparable to the present upper limits on this scale.

On larger scales the temperature anisotropy decreases as $\Delta T/T \propto \phi^{-1}$, and so any quadrupole anisotropy would be very small. This $\Delta T/T \propto \phi^{-1}$ behaviour at large angles is the hallmark of spontaneous theories of formation of structure. Most 'primordial' theories of large-scale structure invoke a Zel'dovich spectrum which would generate large-angle $\Delta T/T$ fluctuations which are scale-independent. Thus observation of large and comparable quadrupole, octopole and higher-order moments would rule out spontaneous generation theories. Unfortunately, our Galaxy gives rise to anisotropy, with significant low-order multipoles. It may then be that one would be able to detect the Zel'dovich anistropy only on intermediate angular scales, where one could test for a dependence of $\Delta T/T$ on galactic latitude.

Anisotropy from cosmic strings. All of the mechanisms we have discussed so far give rise to gaussian fluctuations, either by virtue of the assumed initial conditions or, as in the re-ionized universe, where we have many fluctuation regions adding incoherently, so that the central limit theorem should apply. An interesting alternative is supplied by the 'cosmic string' hypothesis[10,11] (for a review of this subject see ref. 34). The perturbations provided by cosmic strings are inherently non-gaussian and result in step-like discontinuities snaking across the microwave sky[35-37]. The pattern is like that arising from a Zel'dovich spectrum, scale-invariant on large scales. In this picture, one would naturally expect the Universe to be re-ionized, so the theory is relatively immune to the constraints from small-scale anisotropy. In order to detect the distinctive features predicted in this model, one would need to scan a region of sky at least $\sim 10°$ square with reasonably good resolution.

ΔT/T *in the explosive model.* Explosive amplification[8,9] begins with rare seeds, either massive objects ($\sim 10^6$ solar masses) or possibly galaxies themselves, and results in a foam-like distribution of galaxies: swept-out voids separate thin shells, sheets and ridges where shells intersect, and there most of the galaxies form. The typical void size can be up to ~ 5 Mpc in diameter if sufficient explosive energy is available. Although this falls short of the observed voids in the galaxy distribution, which are ~ 25 Mpc across[38], the qualitative resemblance of the bubble-like structure of the galaxy distribution to that predicted in explosive amplification is tantalizing, and this model is a serious contender for explaining galaxy formation.

In fact, the voids are not completely empty, but contain hot shocked gas at a temperature of $\geq 10^8$ K. In the pancake fragmentation model, the physics of galaxy formation is very similar to that in the Ostriker-Cowie-Ikeuchi model[8,9]. Pancakes collapse to form thin, dense sheets of gas which fragment into galaxies, leaving behind large regions of tenuous hot gas. This hot gas can result in observable fluctuations in the cosmic microwave background, by means of the Sunyaev-Zel'dovich effect[39]. Microwave photons Compton-scatter against the hot electrons and acquire a perturbation in temperature, in the Rayleigh-Jeans part of the spectrum, of $\Delta T/T \approx -(2kT/m_e c^2)\tau_{\mathrm{es}}$, where k is the Boltzmann constant, m_e is the electron mass and τ_{es} is the scattering optical depth. $\Delta T/T$ for an individual pancake is proportional to the pressure, which is constant in the shocked region and depends only on the co-moving wavelength of the pancake and the epoch of pancake collapse. Although the distortion from an individual pancake at $z \approx 1$ is small ($\Delta T/T \approx 10^{-7}$), the contribution from the many ($N > 100$) pancakes along a typical line of sight increases the variance of the temperature fluctuations by a factor of $N^{1/2}$ between different lines of sight. Hogan[40] performed a similar calculation for the explosive galaxy formation model. He found that if the observed large-scale structure as measured by the galaxy autocorrelation function is generated explosively, small-scale anisotropy comparable to the Uson-Wilkinson limit[41] is produced. Vishniac and Ostriker[42] generalized this argument further, by noting that if the binding energy of the gaseous components of newly bound structures is thermalized, regardless of its origin (whether explosive or gravitational), then temperature fluctuations of amplitude $\sim 10^{-5}$ result on sub-arc-minute scales. Primordial fluctuations are greatly diminished on these scales due to the smearing associated with the finite thickness of the last scattering surface, and such secondary fluctuations are expected to dominate.

Searches for intrinsic anisotropy. Since the discovery of the microwave background radiation[43], many attempts have been made to search for angular anisotropy. These searches have used a variety of techniques to probe a range of angular scales spanning more than three orders of magnitude. It is often convenient, in the discussion of temperature anisotropies, to decompose the sky temperature pattern into spherical harmonics; these provide a complete and orthogonal set of modes. As we have mentioned, the $l = 1$ mode is probably dominated by our locally generated peculiar velocity, which may also generate a small $l = 2$ component. Any other anisotropies must be intrinsic. Observations at different angular scales suffer from different problems and require different observing strategies; it is useful to distinguish between 'large' angular scales for which $l \leq 10$, 'intermediate' angular scales with $l \approx 10$–100, and 'small' angular scales with $l \geq 100$.

For large and intermediate angular scales it is necessary to raise the observing apparatus above the bulk of the atmosphere. Anisotropometers have been deployed from balloons[30,44–46], from U-2 aircraft[47] and from a satellite[48]. These observations have typically employed beam-widths of a few to ten degrees and have obtained coverage of a significant fraction of the whole sky. Initially there was much emphasis on the possibility of a quadrupole anisotropy, and observers obtained estimates of the quadrupole tensor components from their data. These observations also contain useful information about higher-angular-frequency fluctuations on scales down to the beam-width. Although there have been claims of positive detections of quadrupole anisotropy at levels significantly above that of the noise, none of these have withstood the test of time, and the current upper limit from the Soviet RELIC experiment on any $l = 2$ mode is $\Delta T/T \leq 3 \times 10^{-5}$ with 95% confidence. The limit on the $l = 4$ mode is 5×10^{-5} (95% confidence). These limits are much smaller than the dipole amplitude, and this fact gives some support to the belief that most, if not all, of the dipole anisotropy is extrinsic or local, since one would expect any intrinsic dipole anisotropy to be of similar amplitude to the other low-order moments.

On intermediate angular scales there has also been one claimed positive detection of anisotropy[44], although few details of the method of analysis were given and no confidence level was quoted. Other workers have quoted upper limits of $\Delta T/T \leq 3 \times 10^{-5}$. More recently, an upper limit[49] of $\Delta T/T \leq 5 \times 10^{-4}$ (95% confidence) has been set at a beam-width of 2°. An upper limit of 5×10^{-5} (95% confidence) has been set over ~6–12° in a recent dedicated experiment at 3 cm wavelength (R. D. Davies *et al.*, in preparation). At small angular scales the emission from the atmosphere is less of a problem, and searches for anisotropy on scales of a few arc min have been made using conventional ground-based radio telescopes. The comparison of the results from these various observations, and their relation to quantities which can easily be predicted from theoretical models, are hampered by the variety of observing strategies employed. In order to achieve the high sensitivity required, it is necessary to perform a differential measurement; many different choices of beam geometry have been used. One possibility would be to allow the beam to drift across the sky and measure the r.m.s. fluctuations in the receiver output. This would then tell us the r.m.s. fluctuation in the sky temperature after this has been convolved with the beam pattern. In practice, however, a more common strategy is to repeatedly switch between two or more patches of sky and subtract the signal. If only two patches are observed, the output is simply the autocorrelation function of the (convolved) sky brightness. If, as is usual, the beam throw is comparable to the beam-width, then the output is a useful measure of the fluctuations on this angular scale. Such an apparatus would also have some sensitivity to fluctuations on much larger angular scales, because the apparatus measures the gradient of long-wavelength fluctuations. The most stringent current upper limits to small-scale anisotropy are those obtained by Uson and Wilkinson[41], using a double beam subtraction technique. They quote an upper limit $\Delta T/T \leq 2 \times 10^{-5}$ at $\theta \approx 4.5$ arc min, again with 95% confidence. This type of measurement is even less sensitive to large angular fluctuations because the beam geometry measures the second derivative of the sky pattern at large angles. Finally, we mention some searches for anisotropy on 'very small' angular scales (a few arc s), using the Very Large Array[50]. The sensitivity is somewhat poorer than that obtained on larger angular scales, with upper limits of 10^{-3}, 8×10^{-4} and 5×10^{-4} (95% confidence) at angular scales of 18, 30 and 60 arc s, respectively. These results have now been superseded by new, deeper survey at 6 cm, which improves on these limits by factors of 4 and 8 at 18 and 60 arc s, respectively[51]. Similar results have been obtained independently by H. M. Martin and R. B. Partridge (in preparation).

We also expect the microwave sky to display some linear polarization. To date, polarimetry searches have been carried out only at large angular scales[52,53], these searches having been stimulated by the suggestion[54] of a quadrupole polarization pattern in an anisotropic universe. Re-ionization can enhance this effect[55]. Polarization with a much smaller coherence angle will also arise due to inhomogeneity. The amplitude of the polarization pattern is of the order of the temperature anisotropy on a scale corresponding to the width of the last scattering shell[56]. If temperature anisotropy is ever detected, then polarization studies will provide an important test of the interpretation of such a result. It may be that temperature anisotropy searches will eventually be limited by confusion from faint sources. If this is the case, then polarimetry may provide the best way to view the primordial fluctuations.

Confidence intervals

The figures quoted above for upper limits on sky temperature fluctuations are a highly reduced form of the initial data, which typically consist of a set of N temperature difference estimates D_i together with estimates σ_i of the experimental uncertainty associated with each D_i. Before we consider the implications of the quoted upper limits it is important to understand the limitations of these statistics. To this end we will briefly discuss the method by which these confidence limits are arrived at and highlight some of the associated problems.

We will consider, for illustrative purposes, the simplified, though not entirely unrealistic example in which the D_i are measured in widely separated fields, and so can be considered to be statistically independent, and in which the instrumental variances are all equal: $\sigma_i^2 = \sigma_0^2$. In this case, the commonly adopted procedure[57] is to calculate the statistic $\chi^2 \equiv \Sigma D_i^2/\sigma_o^2$, and to ask, first, if there is firm evidence for fluctuations in excess of that produced by the receiver. Assuming that there is not, we then ask what is the value of σ^2_{ul} such that, if the true sky r.m.s. temperature difference is $\sigma_{\mathrm{sky}} = \sigma_{\mathrm{ul}}$, a value of χ^2 as low as that observed will occur only a fraction $1-c$ of the time. The number of σ^2_{ul} is our upper limit on the sky variance at confidence level c.

One problem with this method is that it requires a rather precise estimate of the instrumental variance σ_0 (ref. 58). For reasonably large N, the central limit theorem tells us that χ^2 will have a gaussian distribution with mean $N(\sigma_0^2+\sigma^2_{\mathrm{skv}})/\sigma_0^2$ and variance $2N(\sigma_0^2+\sigma^2_{\mathrm{sky}})^2/\sigma_0^2$. The upper limit is then $\sigma^2_{\mathrm{ul}} = \sigma_0^2\{(\chi_0^2/N)/(1-\alpha\sqrt{2}/N)-1\}$, where χ_0^2 is the value actually observed and α is the number of standard deviations associated with the confidence level c (for example, $\alpha = 1.65$ for $c = 95\%$). χ^2/N will be close to unity, $\chi^2/N = (1+\mathrm{O}(N^{-1/2}))$, and so $\sigma^2_{\mathrm{ul}} \approx \sigma_0^2 N^{-1/2}$. But the statistic χ^2 is inversely proportional to the estimate of σ_0^2, so σ^2_{ul} to be reliable, any systematic functional errors in σ_0^2 must be much smaller than $N^{-1/2}$. If we 'generously' overestimate σ_0^2, we will obtain much too low a value for σ^2_{ul} and we will be in danger of excluding the true hypothesis.

Another problem is that, by our definition of σ^2_{ul}, we will reject the true hypothesis a fraction $1-c$ of the time. Thus, if 20 upper limits at 95% confidence are found in the literature than the 'best' upper limit is likely to lie below the true value. The actual situation will be worse than this if there is any selection pressure to favour the appearance of 'good' results. This might occur if there is any tendency, either of a voluntary or involuntary nature, not to publish results which are deemed to be uninteresting compared to other published results. Such selection effects cause the number of independent samples of event space to exceed the number of published results. The rate of sampling of event space can also be boosted by combining sets of data from different runs, or if the decision to extend or curtail the experiment is made after any data have been collected.

If for these or other reasons, the value of σ^2_{ul} obtained has any influence on the publication of results, then the value of these constraints for rational decision making is debased. Ultimately, the only practical way to ensure that results are free of such bias is for the decision to publish or not to be made before the experiment is performed (with a blank space in the manuscript for σ^2_{ul} to be inserted, of course). It is after all only rational that the criterion for acceptance of such a paper should be the sensitivity of the apparatus, rather than the random number σ^2_{ul} which results at the end of the day.

Unreasonably restrictive upper limits may then occur by chance, or they may even be selected for. However, one should not simply accept this as a painful fact of life. Our procedure is guaranteed to reject the true hypothesis 5% of the time (for 95% confidence limits), but in any particular instance the data may give some indication as to whether this is such a case. For example, if $\sigma^2_{\mathrm{sky}} = 0$, then negative upper limits will occur. In such a case, we can be certain that we have been 'lucky'. There are other cases in which a positive limit results on the variance but in which one would be reluctant to reject the hypothesis that $\sigma^2_{\mathrm{sky}} \geqslant \sigma^2_{\mathrm{ul}}$. These are those cases in which, while our statistic indicates that the result is unlikely under the hypothesis $\sigma^2_{\mathrm{sky}} > \sigma^2_{\mathrm{ul}}$, the result is not significantly more likely under any alternative hypothesis. The problems associated with various statistical procedures for treating null results will be discussed elsewhere (A. N. Lazenby and N.K. in preparation), but for the present we note that the hallmark of such a spurious result is an unusually low value of χ^2. Visual inspection of the data presented in ref. 41 suggests this may have been the case in this instance. This is unfortunate because, taken at face value, this result rules out some interesting hypotheses.

Implications

Intermediate and large scales. The most immediate implication of these negative results is that we inhabit a universe that is currently uniform to a high degree of precision, at least on scales greater than the horizon size at last scattering. This inference is particularly certain because considerations of causality assure us that there is no mechanism which can render the Universe isotropic on scales exceeding the horizon scale at last scattering. Although we can observe only that region of space which is inside our present horizon, we can invoke the copernican principle to exclude such possibilities as that we inhabit an inhomogeneous universe which just happens to be isotropic about the Earth. We can also infer that the Universe is very close to homogeneous on scales much larger than the present horizon size[59]. If our universe is nearly homogeneous today, then it must have been prepared in a state with an extremely small amount of 'growing-mode' inhomogeneity present at early times; this preparation may have involved an inflationary phase[1]. The process which prepared the Universe may also have imprinted small departures from perfect homogeneity which could later grow to produce galaxies and other structure in the Universe. If this is the case, then it is most natural that the fluctuations should have curvature (specific binding energy) fluctuations which are independent of scale. Were this not the case, then it would be necessary to impose a special scale (that of curvature nonlinearity) in the initial conditions and this scale would not be many orders of magnitude different from the scale of galaxies. It is hard to see how the microphysics of the early Universe could produce such a scale.

On large scales the spectrum maintains its initial form. We can estimate the level of anisotropy which should be observed on intermediate and large angular scales, because the temperature fluctuations should be at least as large, to order of magnitude, as the specific binding energies of the largest structures we see today. Clusters have internal velocity dispersions of $v \approx 1000\ \mathrm{km\ s^{-1}}$ and so have specific binding energy $\phi \approx (v/c)^2 \approx 10^{-5}$. The binding energies of superclusters are thought to have similar magnitude and so we predict $\Delta T/T \approx 10^{-5}$. This is not much smaller than the current upper limits on these angular scales and so it seems that, with a modest improvement in the observational situation, we have the hope of either ruling out this picture or confirming the presence of these scale-free temperature fluctuations.

To obtain a quantitative constraint on $\Delta\rho/\rho$ on these scales, one can use the relation of Sachs and Wolfe[24] for the temperature fluctuation induced by a plane-wave density ripple. A convenient parameter to specify the amplitude of the perturbation is ϕ, the newtonian specific binding energy. The result of Sachs and Wolfe is simply that $\Delta T/T = \phi/3$. We have plotted the constraint on $(\Delta\rho/\rho)_\lambda$ using this relation, and the observed upper limits are shown in Figure 2. This constraint assumed that the initial fluctuation spectrum was initially isentropic.

Small scale. Observations on intermediate and large angular scales provide the best constraint on the amplitude of very-long-wavelength density fluctuations. On these scales, however, there is very little direct evidence for clustering of matter. On scales of $\leqslant 10h^{-1}$ Mpc we see strong clustering, at least of luminous material. The importance of small scale anisotropy studies is that they probe those length scales on which we actually see clustering, and so they provide a more direct test of theories of galaxy formation. Unfortunately, however, the interpretation of smallscale anisotropy is model-dependent: in order to apply this test one must first choose the nature of the initial fluctuations (for example, 'isothermal' or 'adiabatic'), assume some spectrum (such as a power law) and then propagate these fluctuations from some sufficiently early time until after the epoch at which the matter and radiation decouple. This linear evolution depends on the properties of the major constituents of the Universe at the time, so the abundances and masses of these particles must be specified. Up to this point the amplitude of the initial fluctuations is arbitrary. The next, and most uncertain, step is to normalize the calculation by requiring that the density fluctuations should have grown to the presently observed amplitude by today. One can then compare the predicted anisotropy with observations and thereby constrain the initial parameter space.

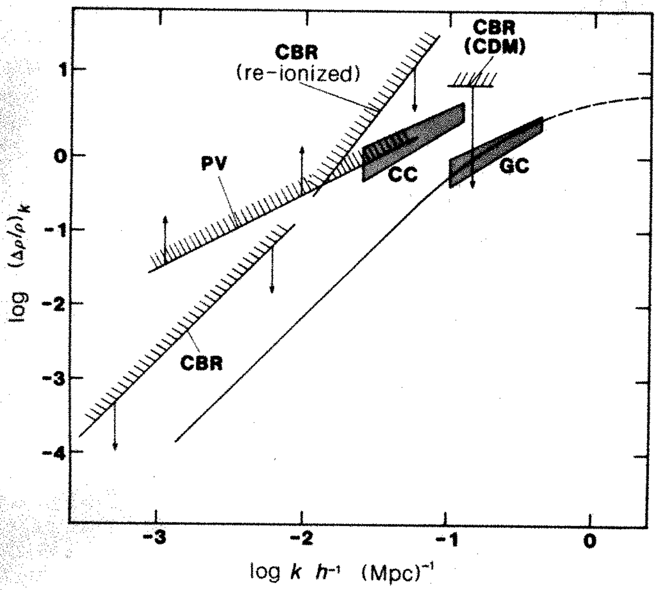

Fig. 2 Constraints on the power spectrum of density fluctuations in an Einstein–de Sitter ($\Omega = 1$) universe. $(\Delta\rho/\rho)_k \equiv k^{3/2}\delta_k/\sqrt{2}\pi$. The contribution to the r.m.s. density fluctuations per logarithmic interval of k, is plotted versus k, where $k(\text{Mpc}^{-1})$ is comoving wave number, $\delta_k = \int d^3k\, e^{ik.x}\,\Delta\rho(x)/\rho$, and x labels the spatial coordinates of an arbitrary point. Specifically, the mass fluctuation within a sphere of radius x is $\delta M/M = \int k^2\, dk|\delta_k|^2 W(kx)/\sqrt{2}\pi$, where the window function $W(kx) \approx 1$ for $kx \leqslant 1$ and $W(kx) \approx (kx)^{-4}$ for $kx \gg 1$. CBR, large- and intermediate-scale microwave anisotropy; we have taken $\Delta T/T \leqslant 3\times10^{-5}$ for $\theta \leqslant 10$ arc min and $\Delta T/T \leqslant 10^{-4}$ for $\theta \approx$ a few degrees. CBR(CDM), small-scale anisotropy limits in a universe dominated by cold dark matter. CBR(re-ionized), anisotropy limits if the intergalactic medium is re-ionized at large redshift and secondary fluctuations are generated as discussed in the text (see discussion of 'the re-ionized universe'). PV, constraint from peculiar velocity; power spectrum of galaxy clustering; CC, power spectrum of cluster clustering; CDM, theoretical preduction for density fluctuations in a cold dark matter model with $h = 0.5$. In a low-density universe ($\Omega = 0.2$), large- and intermediate-scale anisotropy limits are ~3 times lower; peculiar velocity limits are ~3 times higher; small-scale anisotropy limits are ~10 times lower.

In recent years, there have been interesting theoretical and observational developments concerning the small-scale anisotropy. On the theoretical side there has been a rise in popularity of models in which the bulk of the gravitating matter is in a form which is otherwise very weakly coupled to other forms of matter. These models generate a much smaller level of anisotropy than models in which the density is dominated by baryons. Meanwhile, the observational limits have improved, and now not only rule out baryon-dominated models (or at least those with 'adiabatic' fluctuations) but also place useful constraints on models involving weakly interacting 'dark' matter.

The normalization that has been used in these calculations is that the density contrast in spheres of radius $8h^{-1}$ Mpc should have unit variance today. This normalization is chosen because the fluctuations in galaxy counts in spheres of this size have unit variance and because it is thought that fluctuations on these scales should be described fairly accurately by linear theory, and so should be accessible to theoretical calculation. Ideally, it would be desirable to normalize on even larger scales where linear theory would be even more accurate, but unfortunately the estimates of fluctuations in galaxy counts on larger scales become very uncertain.

With this choice of normalization, the small-scale anisotropy limit allows one to exclude 'cold dark matter' models with $\Omega = 0.2$ (see the constraint labelled CBR (CDM) in Fig. 2). This conclusion is particularly interesting because this is the value for Ω implied if galaxies fairly trace the mass distribution. If the value of Ω is significantly greater than 0.2, then galaxies are, for some reason, more strongly clustered than the matter. If this is the case, then it is inconsistent to use the conventional normalization. Inclusion of this effect would lower the predicted $\Delta T/T$ still further in addition to the approximate Ω^{-1} scaling (by a factor of ~ 2)[60-62]; to detect such tiny fluctuations would require a great improvement over the current upper limits.

The possibility of ruling out a high-density Universe dominated by cold dark matter from small-angle anisotropy is therefore fairly remote. Large-angular-scale searches present a more hopeful prospect, although in this case the interpretation depends crucially on the assumed slope of the primordial spectrum of fluctuations. As we have mentioned, there are reasons to prefer the Zel'dovich, scale-free curvature spectrum. To rule out, or to confirm at the several-sigma level, the existence of the consequent scale-free temperature fluctuations would be a significant achievement.

Extrinsic anisotropy

The microwave sky has now been almost completely mapped at an angular resolution of a few degrees. The only convincing feature which has been observed to date is the 'dipole' anisotropy. Averaging together the two most precise of the recent measurements yields a dipole anisotropy with amplitude $\delta T/T = 1.2\times10^{-3}$. The usual interpretation of this anisotropy is that the Sun is moving at a velocity $v_{\text{solar}} \approx 380\ \text{km s}^{-1}$ towards an apex ~45° away from the Virgo cluster. The reason for this interpretation, rather than as a combination of extrinsic and intrinsic anisotropy, is that this dipole is at best an order of magnitude larger than the quadrupole or other low-order spherical harmonics on the microwave sky, and such an intrinsic pattern seems highly implausible. It may be possible to test this interpretation if the intrinsic quadrupole is really very small because, in addition to the dipole of amplitude v/c, our motion will also result[63] in an aligned quadrupole of amplitude v^2/c^2.

This measurement of the solar motion provides us with a constraint on large-scale density fluctuations because, if these induce an r.m.s. amplitude of $\gg 300\ \text{km s}^{-1}$, we must live in a very special position[64,65]. Unless there is some anthropic argument to favour the existence of observers in regions which seem to be special only in so far as they have an unusually low dipole anisotropy, we can exclude such hypotheses as unlikely. These hypothetical large-scale density fluctuations should be well described by linear theory, and we then have $v_{\text{rms}} \approx HL(\Delta\rho/\rho)_{\text{rms}}$, for fluctuations on length scale L. If we assume for the moment that the density fluctuations are a gaussian process, then the large-scale velocities will also be gaussian-distributed. We then have an upper limit at 95% confidence of $v_{\text{rms}} \leqslant 3v_{\text{solar}}$ as only ~5% of all observers have a velocity less than one third of the r.m.s. value. We have assumed a gaussian distribution, but this result is not very sensitive to the form of the tails of the actual distribution because we are calculating the probability of very small values of v/v_{rms}. The result would be misleading, however, if the probability $P(v) \neq v_{\text{rms}}^{-3}$ for $v \ll v_{\text{rms}}$, as would be the case if a small fraction of observers have $v \gg v_{\text{rms}}$ while most are nearly at rest. Note that we have ignored contributions to v_{solar} from small scales which are nonlinear ($\Delta\rho/\rho \gtrsim 1$). This is legitimate if we have no detailed knowledge of the form of these velocities, as the inclusion of small-scale $\Delta\rho/\rho$ will only broaden the distribution $P(v)$. But as we do have some knowledge of the Sun's motion in the Galaxy and the Galaxy's motion in the Local Group, we should incorporate this information. In doing so, we will be able to 'filter out' the nonlinear velocities and concentrate on those linear velocities of interest.

The first step in this process is to allow for the rotation of the Galaxy. This results in a larger velocity, $v_{\text{galaxy}} \approx 550\ \text{km s}^{-1}$, and therefore a weaker constraint than we would have if we had no knowledge of the galactic rotation. The reason for this is that the galactic rotation correction is almost parallel to the solar motion and is therefore unlikely (it means that we have one of the lowest dipole anisotropies of all observers in the Galaxy). However unlikely this state of affairs is *a priori*, it is hard to imagine that the galactic rotation estimate is wildly wrong, and so we must fully incorporate this information. The next step is to subtract the motion of the Galaxy with respect to other galaxies in the vicinity. Here, as we shall see, the situation is not so clear-cut. As before, the *a priori* expectation is that the velocity will decrease. However, as with the galactic rotation we should prepare ourselvles for possible surprises.

We determine the galactic motion with respect to a sample of galaxies around us by means of a 'Tully-Fisher' or 'Faber-Jackson' relation, or some analogous intrinsic correlation between a distance-dependent and a distance-independent quality. These 'L-σ' relations, or analogous relations, are established for a set of galaxies which we believe to be at the same distance from us (for example, in a cluster of galaxies). If we then assume that the correlation found is universal, this allows us to correct redshifts to true distances in a statistical manner by minimizing residuals. The validity of a velocity thereby obtained depends crucially on the assumed universality of the relation. If there are systematic differences in the zero-point of the relations from cluster to cluster, then these will be misinterpreted as peculiar velocities. An effect of this kind must be present at some level. In principle one can test for this by applying the method to clusters at a wide range of distances. Any spurious velocities will increase linearly with distance. These effects, if present at a significant level, do not however present any fundamental limit to the depth of sample for which one can determine the net velocity, as the number of clusters increases sufficiently quickly that the errors remain manageable.

The important question, for our purpose, is whether the source of our peculiar velocity has been localized within the sample. If so, we obviously get a stronger constraint on $\Delta\rho/\rho$ at large scales. It seemed, following the publication by Hart and Davies[66] that this was indeed the case. They studied a sample of galaxies with $v \leq 5{,}000\ \mathrm{km\ s^{-1}}$ using a radio variant of the Tully-Fisher (TF) technique, and found that the net motion of these galaxies with respect to the MBR was very small: $v_{\mathrm{HD}} = 130 \pm 70\ \mathrm{km\ s^{-1}}$. This result stands in contrast to the earlier result by Rubin *et al.*[67] for a sample of similar depth, although doubts about this result had already been expressed[68,69]. However, the Hart and Davies sample has now been reanalysed[70], and yields a much greater net motion of $\gtrsim 700\ \mathrm{km\ s^{-1}}$. An independent sample of similar depth was analysed by de Vaucouleurs and Peters[71], who found an intermediate value, $v_{\mathrm{dV}} \approx 300\ \mathrm{km\ s^{-1}}$. More recently, Collins *et al.*[72] and Burstein *et al.*[73,74] have found net streaming velocities of $\sim 700\ \mathrm{km\ s^{-1}}$ using slightly deeper samples, and are in approximate agreement with the original result of Rubin *et al.*[67]. However, these results had been preceded by those of Aaronson *et al.*[75], who used the infrared TF technique to analyse a sample of galaxies lying in the declination strip visible from Arecibo. They found a net motion of $\lesssim 200\ \mathrm{km\ s^{-1}}$, although the geometry of their sky coverage results in increased uncertainty for a velocity vector in the direction favoured by Burstein *et al.*[73,74] and by Collins *et al.*[72]. Another interesting result to emerge from the Aaronson *et al.*[75] sample is that the scatter of individual cluster velocities about the Hubble flow (or of any offsets in the TF relation interpreted as velocities) is very small. They obtained a limit of $\sim 200\ \mathrm{km\ s^{-1}}$ on the amplitude of such motions, roughly consistent with the individual cluster motions of $\sim 400\ \mathrm{km\ s^{-1}}$ (for a different sample) inferred by Burstein *et al.*[75], and suggesting that the infrared TF technique has very low intrinsic scatter.

The differences between the solutions found, both for net motion and for individual cluster motions, give some measure of the uncertainty associated with these methods. Certainly, the question of whether the source of the galactic motion has been localized remains in doubt. It is probably premature to try to use these data to constrain $\Delta\rho/\rho$ on very large scales. The most reliable datum we have is for the galactic motion of $\sim 550\ \mathrm{km\ s^{-1}}$ with respect to the microwave frame, and this results in the line labelled PV in Fig. 2. If a consistent picture for large streaming motions does emerge then this will imply, according to standard theory, sizeable density fluctuations ($\gtrsim 30\%$) on a scale of $\gtrsim 100h^{-1}$ Mpc. Such density fluctuations present a challenge to theorists: for instance, it appears that such fluctuations do not arise naturally in the cold dark matter model. A theory in which non-gaussian fluctuations emerge naturally, such as cosmic strings combined with hot dark matter, offers some prospect of simultaneously allowing large streaming motions and low $\delta T/T$. It should someday be possible to directly measure, or possibly exclude, such density fluctuations with large-scale redshift surveys.

Conclusions

The microwave background isotropy limits, as well as the measured dipole anisotropy and large-scale galaxy distribution, have already succeeded in severely constraining inflationary cosmological models. Indeed, the only survivors require an appeal to rather more contrived models than discussed here. One possibility requires a biasing scheme in which the observed galaxy distribution samples the gravitational effects of a universe with $\Omega = 0.1$, while the true Ω is unity[14,61]. Biasing schemes generally predict that $\sim 90\%$ of the Universe should contain 'failed galaxies', with the baryonic matter forming luminous galaxies only in the rare fluctuation peaks that sample $\sim 10\%$ of the Universe[76,77]. One alternative involves appeal to the vacuum energy density (or cosmological constant Λ): with $\Omega_{\mathrm{vac}} = 0.2$, where $\Lambda \equiv \Omega_{\mathrm{vac}}$, a combination of cosmological constant and cold dark matter can reduce both $\delta T/T$ and the large-scale peculiar velocity field to acceptable levels, while allowing light to be a good tracer of mass[78]. Another option is to let the cold dark matter (with $\Omega = 1$) decay into relativistic weakly interacting particles at a recent epoch (after galaxies have formed), thereby allowing astronomical measurements today to effectively sample a low-Ω universe[79,80]. This scheme apparently fails to produce flat galactic rotation curves[87] and generates an unacceptable feature in the galaxy correlation function[88], but it is consistent with $\delta T/T$ limits[81]. One could also revive hot dark matter in some non-baryonic guise such as the massive neutrino, with nonlinearity of the hot dark matter at a very recent ($z \approx 1$) epoch, as required by the various constraints such as $\xi(r)$ and the pairwise galaxy peculiar velocity distribution, but now seeding the Universe with large-amplitude small-scale fluctuations (cold dark matter, cosmic strings?) in order to allow some, if not all, galaxies to form at an earlier epoch[7,82,83]. Finally, the wakes produced by cosmic strings could themselves generate large sheet-like structures which might dominate the large-scale galaxy distribution[84–86]. String models naturally yield low (but ultimately observable) $\delta T/T$.

It is of course conceivable that we are completely on the wrong track. Perhaps the primordial fluctuation spectrum was not described by a scale-invariant power law, nor was it gaussian, nor even adiabatic. One might then resort to explosive amplification of primordial seeds to explain galaxy formation and leave little trace of the primordial initial conditions. This still poses the problem, however, of the origin of the large-scale clustering of the galaxies. We do observe large-scale correlations (superclusters and voids): surely these trace initial conditions. If our interpretation of the CBR in the standard Big Bang model is correct, and there is no real alternative, then we inevitably expect to see some residue of these initial conditions in the background radiation anisotropy. It would be too perverse of Nature to have thrown down an impenetrable screen which renders such fluctuations invisible. Eventual detection of $\delta T/T$ on some angular scale is inevitable, and it will surely elucidate one of the most challenging mysteries of the Big Bang theory, namely the origin and the formation of large-scale structure.
